
FARROW'S
MILITARY ENCYCLOPEDIA

A DICTIONARY OF MILITARY KNOWLEDGE

ILLUSTRATED

WITH MAPS AND ABOUT THREE THOUSAND WOOD ENGRAVINGS

BY

EDWARD S. FARROW, U. S. ARMY,

LATE ASSISTANT INSTRUCTOR OF TACTICS AT THE UNITED STATES MILITARY ACADEMY,
WEST POINT, NEW YORK

"What is obvious is not always known, and what is known is not always present."—JOHNSON.

COMPLETE IN THREE VOLUMES. VOLUME I.

NEW YORK:
PUBLISHED BY THE AUTHOR,
240 BROADWAY.
1885.

DEDICATED

TO THE

NATIONAL GUARDS OF AMERICA

In Appreciation of their Enterprise and Valor

AND AS A TRIBUTE OF HOMAGE

TO

GALLANT SOLDIERS.

PREFATORY NOTICE.

The design of this work is that of a Library of Military Knowledge for the People—not a mere collection of elaborate treatises in alphabetical order, but a work to be readily consulted as a Dictionary on every military subject on which people generally require some distinct information—no article being longer than is absolutely necessary. The several topics are not handled with a view to the technical instruction of those who have to make a special study of particular branches of military knowledge or art. The information given may be characterized in many instances as *non-professional*, embracing those points of the several subjects which every intelligent man or woman may have occasion to speak or think about. At the same time every effort is made that the statements, so far as they go, shall be precise and scientifically accurate.

Although about 30,000 subjects have been compiled from the various publications and records of the War Department, Foreign War Offices, and Military Works of reference, more than 5000 original articles have been prepared by specialists in America and abroad. While the Tactics, Ordnance, Gun Machinery, Implements, and Equipments of all ages and of all military powers have been fully described and illustrated under appropriate headings, a complete system of cross-references enables the military student to quickly locate several hundred articles pertaining to the general subject under investigation. Thus, under the article Magazine Gun will be found the following references: *Boch*, *Buffington*, *Bullard*, *Burgess*, *Burton*, *Chaffee-Reece*, *Clemmons*, *Colt*, *Dean*, *Elliott*, *Franklin*, *Hunt*, *Lee*, *Lewis-Rice*, *Miller*, *Remington*, *Russell*, *Spencer-Lee*, *Springfield-Jones*, *Tiesing*, *Trabue*, *Whitney*, and *Winchester Magazine Guns*. Under each of these articles are references to articles describing and illustrating all other arms of the respective classes. The Compiler has made special effort to set forth in detail the numerous decisions, rendered by the War Department and Tactical Department at West Point, on the tactical points raised and submitted from time to time by the Officers of the Army and National Guard. The descriptions and illustrations of more than 500 varieties of Gun Machinery, Steam Hammers, Cranes, etc., constitute a novel feature of the work to be appreciated by those wishing to investigate the subjects of construction, testing, etc.

The original plan has been strictly adhered to throughout; and if, as the work proceeded, there has been any change in the method or quality of the execution, it may at least be affirmed that the change has not been for the worse. After some experience, it became easier to find the person specially qualified to write a particular kind of article, and thus the circle of contributors became widened, and the distribution of the work more specialized. It was also seen to be desirable, in regard to certain classes of subjects, to admit a rather ampler selection of heads. This has been effected without increasing the scale of the work, not so much by less full treatment of the subjects, as by increased care in condensing the statements and omitting everything superfluous. A great quantity of matter pertaining to Foreign Armies has been introduced in this work, so as to enable the military student to compare the organization, arms, etc., of all armies with those of his own service. The Encyclopedia contains also descriptions of ancient armor, and of arms, lately in use, which have become obsolete, as it may be of some interest to follow the changes which have taken place in the mode and means of fighting from the earliest period down to the present time. The insertion of veterinary terms and of remedies for the common complaints of horses will be found useful under conditions where a Veterinary Surgeon is not available, as is often the case in detached parties of Cavalry. A description of all tools and machines found commonly in workshops may prove acceptable to Departmental Officers on their first joining Government Manufacturing Establishments.

Of the Sciences, the least adapted to encyclopedic treatment is Mathematics. All terms of common occurrence in Gunnery, Reconnoissance, etc., however, have been introduced, and a brief exposition of the subjects given, as far as could be done in an elementary way. Natural Philosophy has received ample attention, and all the leading doctrines and facts of general interest will be found under their appropriate heads, treated in a popular way, and divested as far as possible of the technicalities of mathematics. Chemistry, some knowledge of which is becoming daily more indispensable in all departments of military life, receives a comparatively large space. Prominence has been given to those points of the subject that have either a direct practical military bearing or a special scientific interest. During the progress of the work, several changes in the nomenclature and notation of the Science have come into general use; these have been duly noted under the appropriate headings. The new and far-reaching doctrines of the Corrèlation of Forces and the Conservation of Energy have produced vast changes in the nomenclature and classification of the various sections of Military Physics; while the more complete investigations into the phenomena and laws of light, heat, motion, and electricity have created virtually new sections, which must find a place in any adequate survey of scientific progress. Mechanical invention has, indeed, so kept pace with the progress of Military Science and the Art of War, that in almost every department of Physics improved machines and processes have to be described, as well as new discoveries and altered points of view. The manufacture of gunpowder and high explosives is a signal instance of the extent to which in our day scientific discovery is indebted to appropriate machinery and instruments of observation and analysis. These extensive changes in Physics involve corresponding changes in the method of their exposition. The scientific department of the work is consequently treated in all its branches in the most effulgent manner, and over 1000 very fine engravings are used for the purpose of illustration.

True to its projected plan as a LIBRARY OF MILITARY KNOWLEDGE FOR THE PEOPLE, this Encyclopedia will be found to be especially rich in notices of miscellaneous military matters. Some of the subjects introduced might perhaps be considered beneath the dignity of a book aspiring to a more severely scientific character; but all of them are, if not instructive, at least curious or entertaining, and likely to occur in the course of reading or conversation. During the progress of the work, the Compiler has received numerous assurances from parents as to how highly it was prized, even though only partly issued, by their sons at Military Schools, as a repertory of the kind of things they are constantly in search of and often puzzling their elders about. This use of the Encyclopedia has been steadily kept in view; and it is gratifying to learn that it is found efficiently to serve the purpose intended.

In conclusion, the Compiler asks the indulgence of Military Critics wherever errors or discrepancies have crept into this work, and begs to acknowledge the valuable help obtained from the works of many authors, both military and scientific, through the courtesy of Messrs. John Wiley & Sons and Mr. D. Van Nostrand, publishers, and the assistance he has received from various friends. To General Stephen V. Benét, Chief of Ordnance, United States Army, he is especially indebted for courteous assistance in the preparation of the work. To economize in space and to avoid crowding up the text, the name of the author from whom information has been derived has not been inserted after each quotation; but a list of all works which have been consulted, and from which extractions have been made, will be found at the commencement of each volume.

It is intended, with the view of meeting the changes which are constantly taking place in the *matériel* of armies, new processes, military inventions, etc., to issue a Supplement at suitable intervals, containing all alterations and additions.

ABBREVIATIONS OF MODERN TERMS, PHRASES AND TITLES EMPLOYED IN FARROW'S MILITARY ENCYCLOPEDIA.

A.A.S. (*Academiæ Americanæ Socius.*) Member of the American Academy.
A.B. (*Artium Baccalaureus.*) Bachelor of Arts.
A.B.C.F.M. American Board of Commissioners for Foreign Missions.
Abp. Archbishop.
A.C. (*Ante Christum.*) Before Christ.
A. D. (*Anno Domini.*) In the year of our Lord.
Æt. (*Ætatis.*) Of age; aged.
Al. Alabama.
A.M. (*Artium Magister.*) Master of Arts; (*Ante Meridiem*) Before noon; (*Anno Mundi*) In the year of the world.
An. (*Anno.*) In the year.
Apr. April.
A.R. (*Anno Regni.*) In the year of the reign.
Ark. Arkansas.
A.U.C. (*Anno Urbis Conditæ.*) In the year from the foundation of the city.
Aug. August.
Avoir. Avoirdupois.
B. Book; (*b.*) Born.
B.A. Bachelor of Arts.
Bal. Balance.
Bart. Baronet.
Bbl. Barrel.
B.C. Before Christ.
B.C.L. Bachelor of Civil Law.
B.D. Bachelor of Divinity.
Bd. Bound.
Bds. Bound in boards.
Benj. Benjamin.
Bk. Book.
B.L. Bachelor of Laws; Breech-loading.
B.L.R. Breech-loading rifled.
Bp. Bishop.
Brig.-Gen. Brigadier-General.
C., or *Cap.* (*Caput.*) Chapter.
Cal. California.
Cam., or *Camb.* Cambridge.
Caps. Capitals.
Capt. Captain.
C.B. Companion of the Bath.
C.C.P. Court of Common Pleas.
C.E. Civil Engineer.
Cent. (*Centum.*) A hundred.
C.J. Chief Justice.
C.O. Commanding officer.
Co. Company.
Col. Colonel; Colorado.
Com. Commodore.
Conn., or *Ct.* Connecticut.
Cor. Corinthian.
Cor. Sec. Corresponding Secretary.
Crim. Con. Criminal Conversation; Adultery.
Ct. Cent.
Cts. Cents.
Cwt. Hundredweight.
D., or *d.* Penny, *or* pence.
Dan. Daniel.
D.A.Q.M.G. Deputy Assistant Quartermaster-General.
D.C. District of Columbia.
D.C.L. Doctor of Civil Law.
D.D. (*Divinitatis Doctor.*) Doctor of Divinity.
Dea. Deacon.
Dec. December.
Del. Delaware.
Dep. Deputy.
Dept. Department.
Deut. Deuteronomy.
Deft., or *dft.* Defendant.
Dist. District.
Dist. Atty. District Attorney.
ditto, or *do.* The same.
D.M. Doctor of Music.
Dols. ($) Dollars.
Doz. Dozen.
Dr. Doctor; Debtor; Dram.
D.V. (*Deo Volente.*) God willing.
Dwt. Pennyweight.
E. East.
Ed. Edition; Editor.
Edw. Edward.
E.g., or *e.g.* (*exempli gratia.*) For example.
Eliz. Elizabeth.
E.N.E. East-North-East.
Eph. Ephesians.
Esq. Esquire.
et. al. (*et alii.*) And others.
etc., or *&c.* (*et cætera.*) And so forth.
et seq. (*et sequentia.*) And what follows.
Exod. Exodus.
Expl. Explanation.
Ez. Ezra.
Ezek. Ezekiel.
Fahr. Fahrenheit.
Feb. February.
F.G. Fine grain; Field-gun.
Fl., or *Flor.* Florida.
Fred. Frederic.
F.R.S. Fellow of the Royal Society.
F.S. Field-service.
Ft. Foot, *or* feet.
Fur. Furlong.
Ga. Georgia.
G.B. Great Britain.
G.C. Good conduct.
G.C.B. Grand Cross of the Bath.
Gen. General; Genesis.
Geo. George; Georgia.
Gov. Governor.
Gov.-Gen. Governor-General.
G.S. General service.
G.S.W. General service wagon.
H., or *h.* Hour.
Hab. Habakkuk.
H.B.M. His, or Her, Britannic Majesty.
H.C. House of Commons.
Heb. Hebrews.
Hhd. Hogshead.
H.L. House of Lords.
H.M. His, *or* Her, Majesty.
H.M.S. His, *or* Her, Majesty's Ship, *or* Service.
Hon. Honorable.
Hos. Hosea.
H.R. House of Representatives.
H.R.H. His, *or* Her, Royal Highness.
Hund. Hundred.
I., or *Isl.* Island.
Ib., *Ibid.* (*Ibidem.*) In the same place.
Id. (*Idem.*) The same.
i.e. (*id est.*) That is.
I.H.S. (*Jesus Hominum Salvator.*) Jesus the Saviour of men.
Ill. Illinois.
In. Inches.
Incog. (*Incognito.*) Unknown.
Ind. Indiana.
I.N.R.I. (*Jesus Nazarenus, Rex Judæorum.*) Jesus of Nazareth, King of the Jews.
Inst. Instant (the current month).
Io. Iowa.
i.q. (*idem quod.*) The same as.
Is. Isaiah.
It. Italics

Vis inertiæ. (L.) The force of inactivity.
Vis viva. (L.) Living force.
Vivâ voce. (L.) By the living voice.
Vive la bagatelle. (Fr.) Success to trifles.
Vive la Reine. (Fr.) Long live the Queen.
Vive l'Empereur. (Fr.) Long live the Emperor.
Vive le Roi. (Fr.) Long live the King.
Voilà. (Fr.) See there; behold.
Vox, et præterea nihil. (L.) A voice, and nothing more.
Vox populi, vox Dei. (L.) The voice of the people is the voice of God.

INDEX OF MATTERS NOT HAVING SPECIAL ARTICLES.

At the close of Volume III. will be found an Index of Subjects not having Special Articles. It has not been thought necessary to repeat in this Index the titles of the many thousand articles composing the body of the work. A person consulting the Encyclopedia is supposed, in the first instance, to look for the subject he is in quest of in its proper alphabetical place. If it is not to be found there, or by a *cross-reference*, by turning to the Index he is likely to get a reference to it under another name, or as coming in for notice in connection with some other subject. It frequently happens that subjects, having articles of their own, are further noticed under other heads; and where it seemed of importance, a reference is given in the Index to this additional information. The title of the article referred to is printed in *italics;* and when the article is of considerable length, the page is given in which the information is to be found.

CONTINUED REVISION.

The process of revising Farrow's Military Encyclopedia is constantly carried on, thus keeping up the information to the latest possible date. These revisions and additions will be supplied every few years in the shape of Supplements. A few blank pages are inserted at the close of each volume for the purpose of noting the reference to the various articles in the Supplements, which would naturally find alphabetical arrangement in the respective volumes.

LIST OF MAPS AND FULL-PAGE ILLUSTRATIONS IN VOLUME I.

ABACA.—The fibre of a species of plantain or banana, *Musa Troglodytarum*, a native of the Philippine Isles, where it is extensively cultivated. The leaf-stalks are split into long stripes, and the fibrous part is then separated from the fleshy pulp. A laborer can in this way produce daily 50 lbs. of hemp. Before 1825 the quantity produced was insignificant, but now it amounts to nearly 31,000 tons annually. In Manilla there is a steam rope-work for making ropes of it for naval and military purposes. They are durable, but not very flexible. The fibre of a number of species of *Musa* is used in tropical countries.

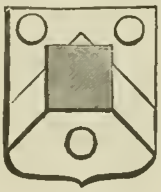
ABAISSE.—A term used in Heraldry. When the fesse or any other armorial figure is depressed, or situated below the centre of the shield, it is said to be *abaissé*. *Adossé* (back to back), *affronté* or *confronté* (facing or fronting one another), *aiguissé* (sharpened at the point), *ailé* (winged), are other heraldic terms borrowed, like *abaissé*, from the French, and used by English heralds in senses not differing essentially from their ordinary significations in that language. See *Heraldry*.

ABAMURUS.—A buttress, or second wall, built to strengthen another. These are frequently employed in fortifications.

ABANDON.—This term in a military sense signifies to retire suddenly from a place, fortified or otherwise, thus leaving it and the inhabitants to the mercy of the enemy. Abandoning any fort, post, guard, arms, ammunition, or colors without good cause is punishable as provided in the 42d Article of War. The term abandon is also used in the relinquishment of a military post, district, or station, or the breaking up of a military establishment.

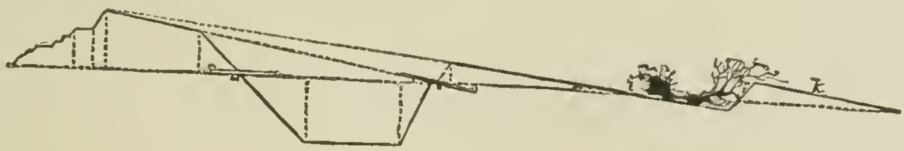
ABASE.—An old word signifying to lower a flag. *Abaisser* is in use in the French Marine, and both are probably derived from the still older *abeigh*, to cast down, to humble. In Heraldry, *abased* is used of certain armorial bearings, when turned downward toward the point of the shield. See *Heraldry*.

ABATEMENT.—In Heraldry, a mark placed over a portion of the paternal coat-of-arms of a family, significative of some base or ungentleman-like act on the part of the bearer. The coat is then said to be abated, or lowered in dignity. Guillim gives nine such marks, all of which are of either one or the other of the two disgraceful colors, tenné (tawny) and sanguine. Such are the delf tenné, assigned to him who revokes his challenge; the escutcheon reversed sanguine, proper to him who offends the chastity of virgin, wife, or widow, or flies from his Sovereign's banner; the point-dexter tenné, due to him who overmuch boasteth himself of his martial acts; and the like. Marks of abatement are generally repudiated by the best heraldic authorities. Menestrier calls them *sottises anglaises*, and Montagu is of opinion that we shall seek in vain for a more appropriate designation. Abatements are carefully to be distinguished from such subtractive alterations in coats-of-arms as signify juniority of birth, or removal from the principal house or senior branch of the family. These are commonly called marks of cadency, distinctions, differences, or brisures. The latter term is generally applied to marks of bastardy, which might with less impropriety be classed with abatements. See *Heraldry*.



Abatement.

ABATIS—ABATTIS.—An accessory means of defence formed by cutting off the smaller branches of trees felled in the direction from which the enemy may be expected. It is readily seen in the drawing how an abatis placed at *i*, will impede the approach of the enemy advancing over the glacis slope *k*, and expose his front to a galling fire from the principal guns of the work. The ends of the larger branches are sharpened, and the butts of the limbs or trees fastened by crochet-picket, or by imbedding in the earth, so that they cannot be easily removed. In redoubts or intrenchments they are usually fixed in an upright position against the counterscarp, or at the foot of the glacis, the plane of which is broken so as



Abatis.

to conceal the abatis from the view of the enemy, and to guard against obstructing the musketry-fire from the parapet in their rear. Abatis are also an excellent means of blocking up a road, when trees grow on either side. If branches are properly placed, and intertwined one within another, their disengagement is extremely difficult. An abatis will always be found a very useful and effective auxiliary to the defence of houses or isolated posts, if judiciously placed within range of musketry. When close in front of the windows on the ground-floor, or used as a cover to the entrance-door, it will be extremely difficult for the enemy to force his way into the building. It is very readily seen how a profile may be much strengthened by planting a row of palisades in the ditch, or even by driving stakes into it, and sharpening them, or making a perpendicular abatis, by planting brushwood upright in the bottom, with the ends sharpened. An expeditious way also of adding to the difficulties of an assault is seen where common hurdles or gates, rails or brushwood, laid on the ground soon after commencing the work, with their extremities buried under the parapet, may be made use of; the earth underneath them, not shown in the figure, should be cut away when the ditch has been sunk to its full depth. See *Accessory Means of Defence*.

ABDUCTION.—The diminishing the front of a line or column by breaking off a division, sub-division, or files, in order to avoid some obstacle.

ABET.—To encourage by aid or countenance; formerly used in a good, but now chiefly in a bad sense. It is a grave crime to aid or abet in mutiny or sedition, or excite resistance against lawful orders. Any officer or soldier who, being present at any mutiny or sedition, does not use his utmost endeavor to suppress the same, or, having knowledge of any intended mutiny or sedition, does not, without delay, give information thereof to his commanding officer, shall suffer death, or such other punishment as a Court-Martial may direct.

ABLE-BODIED.—A term, in a military sense, applying to one who is physically competent as a soldier for all duty.

ABLECTI.—An ancient military term applied to a select body of men taken from the *Extraordinarii* of the Roman army to serve as a body-guard to the Commanding General or the Consul. The guard consisted of forty mounted and one hundred and sixty dismounted men.

ABOLLA.—A military robe of thick woollen stuff (lined or doubled) worn by the ancient Greeks and Romans.

ABOMINATION OF DESOLATION.—The Roman standard which was set up in the Temple of Jerusalem, to which the soldiery offered sacrifices as to an idol.

ABOUT.—A technical word to express the movement by which a body of troops or artillery-carriages changes front.

ABRADANT.—A material, generally in powder, used in the armory for grinding. The term includes emery, sand, glass, and many other materials. Laps, glazers, rifles, paper, etc., are armed with abradants.

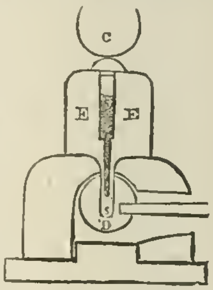
ABRI.—A French term signifying shelter, cover, concealment; arm-sheds in a camp secure from rain, dust, etc.; place of security from the effect of shot, shells, or attack.

ABSENCE.—Every officer commanding a regiment or an independent troop, battery, or company, not in the field, may, when actually quartered with such command, grant furloughs to the enlisted men, in such numbers and for such time as he shall deem consistent with the good of the service. Every officer commanding a regiment, or an independent troop, battery, or company, in the field, may grant furloughs not exceeding thirty days at one time, to five per centum of the enlisted men, for good conduct in the line of duty, but subject to the approval of the commander of the forces of which said enlisted men form a part. Every company officer of a regiment, commanding any troop, battery, or company not in the field, or commanding in any garrison, fort, post, or barrack, may, in the absence of his field-officer, grant furloughs to the enlisted men, for a time not exceeding twenty days in six months, and not to more than two persons to be absent at the same time.

Any soldier who absents himself from his troop, battery, company, or detachment, without leave from his commanding officer, shall be punished as a Court-Martial may direct.

Any officer or soldier who fails, except when prevented by sickness or other necessity, to repair, at the fixed time, to the place of parade, exercise, or other rendezvous appointed by his commanding officer, or goes from the same, without leave from his commanding officer, before he is dismissed or relieved, shall be punished as a Court-Martial may direct.

ABSOLUTE FORCE OF GUNPOWDER.—The absolute force of gunpowder is measured by the pressure which it exerts when it exactly fills the space in which it is fired. Various experiments have been made to determine mechanically the absolute expansive force of fired gunpowder, but with widely different results. Robins estimated it at 1000 atmospheres, Hutton at 1800, D'Antoni from 1400 to 1900, and Rumford carried it as high as 100,000 atmospheres. These discrepancies arise, in a great measure, from the very great difference which exists between the expansive force of the gases in the different moments of combustion, and from a want of coincidence in the observations.



The apparatus used by Rumford to determine this point consisted, essentially, of a small eprouvette, E, capable of holding exactly 25 grains of powder. The orifice was closed with a heavy weight, and the powder was fired by heating the stem of the eprouvette, S, with a red-hot cannon-ball, B. For the first trial he filled the eprouvette with 25 grains of the best quality of dry powder, and rested upon the cover the knob, C, of a 24-pdr. gun, whose weight was 8081 lbs. Notwithstanding its great strength, the eprouvette was burst at the first fire into two pieces, and the 24-pdr. was raised. Rumford endeavored to show from the weight thus raised that the pressure of the gases on the sides of the eprouvette was greater than 10,000 atmospheres. He further attempted to show, that as the tenacity of good iron is equal to 4231 times the pressure of the atmosphere on the same surface, and as the surface of rupture was 13 times that of the bore, the force necessary to produce the rupture of the eprouvette must have been 13 × 4231, or 55,003 atmospheres.

There are circumstances attending this experiment which should be taken into account, and which will very materially diminish this result. They are, the diminution of the tenacity of the iron, due to heating the eprouvette to produce explosion, and the incorrect method by which Rumford estimated the strength of a hollow cylinder subjected to a strain of expansion.

Experiments were continued with a similar apparatus to determine the relation between the density and the expansive force of fired gunpowder. The capacity of the eprouvette was nearly 25 grains. It was fired with various charges from 1 up to 18 grains; and the expansive force of each discharge was determined by the smallest weight necessary to close the orifice against the escape of the gas. With the results of 85 trials a table was formed, from which a curve was constructed which expresses the relation between the density and expansive force of fired gunpowder, from 1 to 15 grains. By analogy and calculation, this curve was continued up to a charge of 24 grains; and for the density corresponding to this charge the pressure was found to be 29,178 atmospheres.

This pressure is much greater than that developed in the explosion of projectiles and mines, owing to the low temperature of the surrounding surfaces and the large amount of heat which they absorb. It is the same with cannon, for the most rapid firing does not raise the temperature of the bore above 210° Fahr., which is much below that of the eprouvette. Besides, the powder does not completely fill the space in rear of the ball; and, as powder burns progressively, this space is enlarged before the gases are completely developed, and consequently their density is diminished. There is also a loss of force by the escape of the gases through the windage and vent.

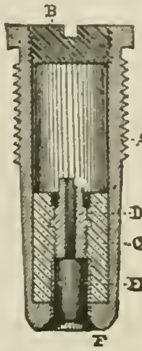
The following equation expresses the relation found to exist between the density and expansive force of charges of gunpowder, from 1 to 15 grains, fired in an eprouvette the capacity of which was 25 grains—or in other words, for charges in which the densities vary from .04 to .6: $p = 1.841(905d)^{1-0.362d}$; in which p represents the pressure in atmospheres, and d the density of the inflamed products. It will be seen from this equation that the pressure increases more rapidly than the density, since the exponent of the density is greater than unity. The density of the gases is equal to the weight of the powder burned divided by the space occupied by the gases. By substituting this in the equation, we can determine the pressure exerted at any given instant of the combustion. Although this relation is deduced for a particular kind of powder, it may be used for all service-powders and service-charges without serious error, since the actual amount of gaseous products is nearly the same for all, and the densities of the highest service-charges never exceed 0.6.

The accuracy of Rumford's formula has been lately verified by a series of experiments made by Captain Rodman. The apparatus used by this officer consisted of a very thick cast-iron shell, to which was attached an indenting piston for determining the pressure on the inner surface, or powder-cavity of the shell. The following table shows the pressures calculated by the formula and the pressures obtained by the experiments, for three different densities:

Density.	Pressure by Rumford's Formula.	Pressure by Rodman's Experiments.
$d = \frac{1}{20}$	1,290 lbs.	1,066 lbs.
$d = \frac{1}{10}$	2,900 "	2,525 "
$d = \frac{1}{2}$	3,700 "	3,220 "

The lesser pressure obtained by Rodman's experiments may be in a great measure explained by the facts that the shell was not heated, but fired with a friction-tube, and that the gas was allowed to escape through the vent. Further experiments were made which show that so long as the volume of the charge bears the same proportion to the space in which it is fired, the pressure on the unit of surface remains the same, no matter what may be the amount of the charge. This follows also from Rumford's formula, since the value of p is not affected so long as d remains the same. See *Explosion* and *Gunpowder*.

ABSTERDAM PERCUSSION-FUSE.—This fuse consists of a metal fuse-stock, A, closed at the front end by a screw-cap, B; a movable plunger, C, cast around a cone-piece, D; and a hollow tin cylinder, E. The tin cylinder, E, at the base of the plunger is cut longitudinally, so that when opened out into the recess, F, at the base of the fuse-stock, the plunger is held in place securely until the impact of the shell. The shock of discharge straightens out the tin, freeing the plunger, which moves forward to the cap, B, exploding the musket-cap on the cone-piece that ignites the bursting-charge. See *Fuse*.



ABSTERDAM PROJECTILE.—A projectile cast in a single piece and having an expanding ring of brass which projects three-eighths of an inch beyond the base of the projectile. See *Projectile*.

ABSTRACT.—A sheet of a prescribed form to accompany Returns, so prepared as to consolidate the contents of numerous Vouchers. The following is one form used by Quartermasters:

Abstract of Transfers of Funds made to officers on account of the Quartermaster's Department by ——— ———, ——— Quartermaster ———, U. S. Army, during the month of ———, 188—.

Date of Transfer.	No. of voucher.	To whom transferred.	Regular supplies.		Incidental expenses.				Barracks and quarters.		Transportation of the Army.		Clothing and equipage.								Total.	
			Dolls.	Cts.	Dolls.	Cts.	Dolls.	Cts.	Dolls.	Cts.	Dolls.	Cts.	Dolls.	Cts.	Dolls.	Cts.	Dolls.	Cts.	Dolls.	Cts.	Dolls.	Cts.
		Total..																				

I certify that the above abstract is correct.

——— *Quartermaster* ———

(Signed in duplicate.)

One copy of an Abstract is retained by the officer who makes the transfers, and the other is sent to the Chief of the Bureau with the Account-Current. See *Accounts-Current*.

ABUSES AND DISORDERS.—Every Commanding Officer is required to keep good order, and, to the utmost of his power, redress all abuses and disorders which may be committed by any officer or soldier of his command. If, upon complaint made to him of officers or soldiers beating, or otherwise ill-treating, any person, of disturbing fairs or markets, or of committing any kinds of riots, to the disquieting of the citizens of the United States, etc., the said Commander shall refuse or omit to see justice done to the offender or offenders, and reparation made to the party or parties injured, as far as part of the offender's pay shall enable him or them, he shall, upon proof thereof, be cashiered, or otherwise punished, as a General Court-Martial shall direct.

ABUTMENT.—The block at the rear of the barrel of a fire-arm (especially a breech-loader), which receives the rearward force of the charge in firing. It has the function of the *breech-plug* or *breech-pin* in the muzzle-loading fire-arm. A similar term is applied to the corresponding portion in breech-loading cannon. The variations in the arrangement are numerous, and the different devices form the subjects of many patents in the United States and foreign countries.

ACADEMIC BOARD.—The Academic Staff of the United States Military Academy. By law, the Academic Board consist of the Superintendent and the

Heads of the several departments of instruction. A majority of the Board constitutes a quorum. Dissenting members of the Board may present their views in a report which is entered on the record and transmitted to the War Department. The Board recommend for the approval of the War Department the text-books best suited for each department of instruction; examine Cadets, and decide on their merits, grant diplomas, and recommend for promotion; and report to the War Department on the system of studies and instruction, proposing any improvements therein that experience may have suggested. The deliberations and discussions of the Board are confidential, and no member nor the Secretary shall disclose the decision of the Board before the same shall be announced by proper authority, nor shall any member nor the Secretary discover or disclose the vote or opinion of any member. At the annual examination in June, the Academic Board examine, arrange in order of merit, and determine the proficiency of the Cadets of the First Class in all the studies prescribed for that class. For the purpose of examining the Cadets of the other classes, the Superintendent may, at his discretion, divide the Academic Board into Committees, each to consist of not less than three members of the Board, each Committee to examine, arrange in order of merit, and determine the proficiency of the Cadets in such branches of study as the Superintendent shall direct. The Superintendent may, at his discretion, be a member of either Committee, and preside therein; otherwise, the senior member of the Academic Board present shall preside. Each member of the Academic Board keeps careful notes of the examination, to enable him to give full and ample information, when required, of the performance of every one examined. To insure accurate classification and the ascertainment of cases of deficiency, every Instructor in charge of a section, just before its examination, carefully prepares and submits to the Examining Committee a list of such section, arranged in the order of merit as suggested by the marks during the term, and the impression which the daily recitations have left upon his mind, noting every case of doubtful proficiency. The Committees report to the Academic Board the results of their examinations of the several classes, upon which report the Board take such action as they may think proper. The senior Assistant in the branch of study under examination is a member of the Academic Board, or of the Committee, for all the purposes above mentioned; and the Instructor of the section under examination is a member of the Academic Board, or of the Committee, as the case may be, for the purpose of examining and arranging it in order of merit. The record of each Committee is kept by an officer detailed for that purpose, and is delivered by him, after the approval of the presiding officer, to the Secretary of the Academic Board,. for preservation among the records of the Academy; and no member of a Committee, nor its Secretary, shall disclose the decision of the Committee before the same shall be announced by proper authority. The Academic Board decide the question of proficiency of a Cadet by vote taken by ayes and nays (*viva voce* or by ballot, as the Board may decide). At the close of each examination the Academic Board report to the War Department the names of all Cadets who are deficient in studies or discipline, to be discharged, unless otherwise recommended by the Academic Board. The Superintendent may, at any other time, bring any Cadet before the Board to be examined, and reported in like manner, if found hopelessly deficient. No Cadet is promoted until he has completed the entire course of studies at the Academy and received a diploma from the Academic Board. In the promotion of Cadets the rank of each corresponds with his standing on the roll of general merit established by the Academic Board. No Cadet resigning his warrant, or otherwise separated from the Academy before the completion of his studies, shall receive an appointment in the Army until after the promotion of the class to which he belonged, unless on the recommendation of the Academic Board; nor then, if such appointment interferes with the rank of any Cadet of that class. The Medical Officers, convened annually at West Point, in the month of June, to examine into the physical qualifications of the candidates for admission into the Military Academy, are associated with the Superintendent of the Academy and the Commandant of Cadets; and these Officers constitute a Board for the purpose of examining into the physical qualifications of the members of the graduating class, and no member of that class can be commissioned in the Army, or attached as a supernumerary thereto, who, in the opinion of the Board, does not possess the requisite physical ability to serve his country in the arduous and laborious station of a Military Officer. See *United States Military Academy.*

ACANZI.—In military history, the name of the Turkish light-horse who formed the vanguard of the Sultan's army.

ACCELERATED MOTION.—Motion in which the velocity is continually increasing. When the increments of velocity are equal in equal times, the motion is said to be *uniformly* accelerated. The best example of such a motion is that of a falling body. It is found that near the earth's surface a body descending from a state of rest falls $16\frac{1}{12}$ ft. in the first second. Now a little consideration will show that at the end of the first second it is moving at the rate of $32\frac{1}{6}$ ft. per second. For since the velocity was nothing at first and increased uniformly, $16\frac{1}{12}$ ft. must have been the *mean* velocity—i.e., the velocity at the middle of the time; and therefore the velocity at the end must be double, or $32\frac{1}{6}$ ft.: $32\frac{1}{6}$ ft. is thus the measure of the accelerative force of gravity. At the end of the second and third seconds the velocity is found to be doubled, trebled, etc., or $64\frac{1}{3}$, $96\frac{1}{2}$ ft. See *Falling Bodies.*

ACCELERATING FORCE.—Force considered only with reference to velocity generated and not with reference to the mass moved. Accelerating force, if uniform, is measured by the velocity generated in a unit of time; if variable, by the velocity which would be generated in a unit of time if the force were continued constant during that unit. The best example of such uniform motion is that of a falling body.

ACCELERATING GUN.—A gun having additional charge-chambers and a muzzle covering, with the necessary means of exhausting the air, whereby the atmospheric resistance is removed from the front of the projectile while passing along the bore. As soon as the gun has been fired and the ball has passed the chamber, the fire in the bore ignites the charges in the additional charge-chambers, thereby giving the ball additional force. The average penetration with this gun in laminated armor composed of $\frac{1}{4}$-in. boiler-plates is $4\frac{7}{16}$ in.; and $4\frac{1}{4}$ in. in solid iron, using a $6\frac{1}{4}$-oz. steel bolt 8 in. long and $\frac{1}{2}$ in. diameter, with a charge of $4\frac{1}{8}$ oz. powder. See *Multi-charge Gun.*

ACCELEROGRAPHS.—The principle has long since been made known on which the apparatus called "accelerographs" are constructed, which the Marine Artillery Service has adopted, according to the invention of Mr. Marcel Deprez, and which are designed for measuring the succession of pressures developed in a given point of a powder-chamber by the combustion of a charge of powder either enclosed in a vessel or placed in the bore of a gun and acting on the projectile. The first apparatus which were established on this principle were experimented on in 1873, in the workshops of Mr. Bianchi, of Paris, for the study of combustion in a closed vessel; afterwards, in 1874, on the proving-ground of the Nevers foundry, for the study of combustion in guns. Since that time various improvements have been successively made in the mode of construction and in the manner of employment of these apparatus.

The accelerographs thus modified were employed several years ago, in numerous experiments, both at the laboratory of the central depot for powder and saltpetre, courteously placed at the disposal of the marine by the engineers of that service, and at the proving-ground of the Sevran-Livry powder-works with the double advantage of proving the material and the powder fabricated on the account of the department of the marine. In these trials these apparatus proved convenient for handling and of practical employment, and they furnished some valuable observations on the law of combustion of powder-charges, and on that of the development of the pressures resulting therefrom both in close vessels and in guns of various calibres. Also, by a slight modification of the accelerograph, employed for measuring the pressures developed in the firing of guns, this apparatus can be utilized for determining simultaneously the law of the pressure developed in the bore and the

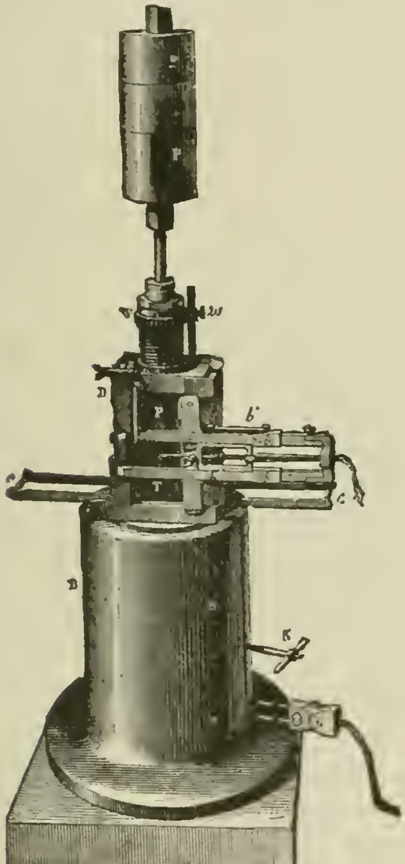


Fig. 1.

law of the recoil of the gun. The accelerographs in question were of the types called slide-accelerographs, in which the law of the movement of the piston, subjected to the action of the powder-gases, is deduced from that of the known movement of a style-bearing slide displacing itself in a direction normal to that of the piston. More recently there has been a return to the employment of accelerographs, in which the movement of the piston is deduced from the tracing of the vibrating fork. We will describe briefly the arrangements peculiar to these different apparatus. Finally, from the commencement of the experiments on accelerographs, trial was made conjointly of apparatus called accelerometers, based on the same principle, but which indicated, at each experiment, only one isolated value of the pressure developed by the powder, corresponding to an arbitrary subdivision of the duration of combustion of the charge. These apparatus, which require the repetition of identical experiments for determining perfectly the law of the development of the pressures produced by the combustion of a charge of powder placed in certain definite conditions, have been applied to the study of the combustion of powder in a closed vessel, as well as to the study of the pressure developed in the bore of guns. But they have been more especially employed in this latter case by placing them in front of the initial site of the projectile for measuring the pressure existing against the "sabot" of this latter at the same moment when it attains a definite point of its passage in the bore, because one single experiment with this apparatus suffices, in this particular case, to show the value sought. Accelerometers should present different arrangements, according as they are intended to be mounted on fixed receptacles for the study of the combustion of powder in a closed vessel, or as it is proposed to mount them on guns; two principal types have therefore been established, the one denominated weight-accelerometers, and the other spring-accelerometers. Fork-accelerometers have also been employed for increasing the precision obtained. We will describe briefly these different types, as well as the apparatus which it was necessary to create for obtaining the "tarage."

Slide-accelerograph, used for studying the combustion of powder in a closed vessel.—It is known that the accelerograph is arranged in such a manner as to indicate the law of the movement of a piston, of known section and weight, bedded in a groove cut normally in the sides of the powder-chamber and subjected freely, on its base, to the action of the gases produced by the combustion of the charge. The apparatus registers the spaces passed by the piston each instant during the combustion, and consequently these passages can be exactly measured for very small and regularly divided intervals of time. The curve of the spaces traversed by the piston is thus determined by points in the function of times, and by a known process, which will be referred to hereafter, the law of the velocities acquired and the law of the accelerating forces to which the piston has been subjected can be deduced. According to these remarks, each chronograph apparatus should be composed of a piston of definite weight and section, moving in a suitable groove, of a table supported by the piston and designed to receive the registerings, and of a chronographic organ designed to produce these registering tracings. To these pieces must be added for the apparatus designed for studying the combustion of powder in a closed vessel, the chambers or eprouvettes designed to contain the powder and the preceding organs. Finally, all the apparatus are completed by the special instruments for the "tarage" and the readings. Fig. 1 represents an accelerograph arranged for the study of combustion in a closed vessel, and mounted for that purpose on apparatus which has received the name of eprouvette. This eprouvette is composed of a removable chamber of steel, with very thick sides, in which the powder subjected to trial is exploded. As a precautionary measure, this chamber is introduced in a bronze envelope, B, furnished with a lid. On this envelope is mounted the frame of the accelerograph proper, D. The steel chamber is closed by two screw-stoppers, arranged so as to form obturators to prevent the escape of gas. This obturation is obtained by these stoppers terminating in perfectly adjusted parts and hollowed in the form of basins, whose bevelled edges can sustain a certain expansion from the pressure of the gases, and the higher the pressure on the sides of the cylindrical passage which they should stop the more exactly do they fit. The gases are collected for analysis by means of a screw-cock, K. The lower stopper is traversed by a truncated plug of steel, perfectly adjusted, prolonged by a cylindrical bar and electrically insulated from the body of the stopper by the interposition of a leaf of gold-beater's skin glued with gum-lac. This plug supports in the interior of the chamber, by means of a prolongation in the form of a terminal, the extremity of a very fine platinum wire, whose other end is fixed on a similar terminal communicating with the body of the apparatus. This wire, raised to a red heat under the action of an electric current brought by the conductors, ignites the charge of powder with which it is placed in contact.

The upper stopper is traversed by an orifice in which is adjusted, with care, the piston whose movement is to be registered. This piston extends through the lid of the bronze envelope, and is screwed at its upper extremity into a cubic piece, T, which slides in the rectangular frame which is sustained by the lid. The piston and the cube that surmounts it form thus a movable body of known weight, susceptible of being freely displaced under the action of the force developed by the powder-gases, but only within the limit of the stroke which the height of the frame that serves as guide permits. In the upper face of the cube is fitted an India-rubber plug, which abuts against a screw of large diameter, W, which holds the frame at its upper part; the shock which results from the arrest of the movement is thus deadened. The screw may be let down more or less, thereby diminishing at will the that of the slide, which are affected in rectangular directions, have a strictly common origin. According to this arrangement, if we suppose that the piston alone is displaced while the slide remains stationary, the stylus will trace, on the left side of the table, a vertical line, following the same law of movement which it is the question to determine. If, on the contrary, we suppose that the piston is immovable and the slide liberated, the stylus will trace on the upper part of the table a horizontal line, following a law of a known movement. If the two movements are produced simultaneously, their combination will produce a tracing in the form of a regular curve in the direction of the angle formed by the two preceding right lines, which will serve as co-ordinate axes; and if we measure with precision the abscissas and the ordinates of the different points of this curve, the horizontal abscissas giving the durations of the trajectory of the stylus, since we know the law of its movement, we shall have the vertical strokes of the piston which correspond to these known durations, and consequently we can ascertain by points the curve of the spaces passed by the piston in the function of the times. The readings, according to the two co-ordinate rectangular axes, are made by means

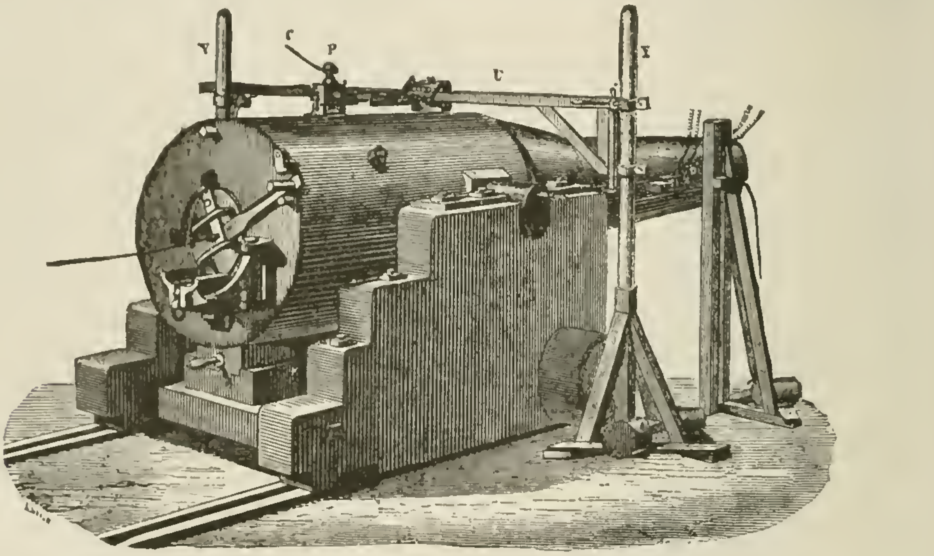

Fig. 2.

stroke from its extreme value, which is about 0.05 metres (1.968 inches). It is the law of the movement of the piston, or rather of the cube that surmounts it, which is the object to be registered. For this purpose a small square table of steel, or even of thick glass, covered with lamp-black, is fixed on one of the faces of this cube. In front of this table is arranged a small slide which has a stylus formed of a needle pressed by a small spiral spring, or, better, of a small flexible and finely cut steel pin. The slide slides between two parallel rails arranged horizontally, and in this movement its stylus traces a horizontal path on the table, on its upper part, if we suppose it to be immovable in its initial position. The slide is set in motion by the action of a trigger-spring, very rapid, which, in the apparatus represented by the figure, is nothing else than a strongly extended thong of India-rubber. The exact law of the movement which it takes under the influence of this spring is also known, as will be shown further on. It is kept, at the commencement of each experiment, at the extremity of its course by an organ arranged in such a manner as to liberate it at the precise moment when the piston is set in motion under the action of the powder-gases, so that the two movements, that of the piston and of a microscope, with crossed hairs, borne on a slide which can be displaced conformably to two rectangular axes, and which is set in motion in each of these directions by means of a micrometric screw. We can thus easily make the readings to the hundredth of a millimetre.

Slide accelerograph, employed for studying the combustion of powder in guns.—When the accelerograph is designed for measuring the pressures developed in guns, the piston is lodged in a steel bushing like those that are designed for the apparatus called crushers employed also for estimating the pressures produced by the combustion of powder. This bushing is screwed into a hole pierced in the sides of the gun, normal to the bore, at a point chosen for the purpose, and it terminates, on the outside, in a threaded head on which is screwed the frame which serves as guide for the cube designed to receive the table and as a support for the stylus-bearing slide. This frame and these organs may also be absolutely the same as in the powder-mill accelerograph, and the bushing which holds the apparatus may be placed in any position whatever, either in the vertical plane passing through the axis of the gun, or in any meridian plane inclined to the vertical. Fig. 2 represents an accelerograph installed on a 14-centimetre (5.51-inch) gun, model 1870, and placed in a vertical position. The slide represented by these figures differs from that described above, in that the apparatus is here arranged for registering the law of the recoil of the gun, as will be shown hereafter.

Fig. 3.

The only difference in signalling with the powder-mill apparatus, except this detail, is the arrangement placing the additional weight above the piston, when there is room, in order to increase, as occasion requires, the duration of the unobstructed stroke of the piston and to prolong it so as to continue the movement during an interval equal to that of the passage of the projectile in the bore. This weight, as it cannot, on account of the recoil movement of the gun, be guided by a stationary rod placed in the prolongation of the axis of the piston, as in the powder-mill apparatus, is here left free, and at the moment of the initial movement of the shot it is forced in the direction of the axis of the apparatus. If we suppose this latter to be vertical, as the figures show, the weight is forced vertically, but in consequence of the composition of the ascensional movement and that of recoil, it describes really a parabola, and it might fall on the gun if the precaution is not taken to attach it to the extremity of an elastic cord, of proper length, whose other end is secured at a fixed point. The tension of this cord, making it deviate from its plane curve, diverts it from the gun so that it strikes the ground at a distance from the carriage and the gun, which are thus preserved from the shock. This contrivance is not necessary if the lodgment of the piston of the accelerograph is placed in an inclined position in regard to the vertical; it is then only necessary for it to have, on the side, a sufficient space free to permit the projection of the weight. The necessity for employing a weight of this kind, if it is desirable that the apparatus should not reach the extremity of its path before the projectile has passed the whole length of the bore, is easy to demonstrate, and we can readily perceive that this weight ought to augment with the calibre of the gun, if we suppose the section of the piston to be constant and the free stroke allowed to the apparatus also invariable. We know, in fact, that if two movable bodies are subjected simultaneously to two forces which remain always equal to one another at each instant, but which, however, may be varied in some manner, the spaces traversed by these two movable bodies, under the influence of these forces, are constantly in inverse ratio of their mass. If, then, we suppose that the pressures developed in the chamber of the gun are exerted equally, at each instant, on all the elements of the interior of this chamber and, consequently, on the base of the piston of the accelerograph just as on the bottom of the projectile, we must admit, neglecting, however, the resistance opposed to the projectile by the forcing and the rifle-grooves, that the spaces passed at each instant by the projectile in the bore and by the piston of the accelerograph in its cylinder will be constantly in inverse ratio of the masses set in motion in each case, these masses being proportioned to the unit of surface. Now, in guns, the mass of the projectile referred to the unit of section increases with the calibre and also proportionally with this calibre, since if we suppose that the projectiles are similar, which is actually the case, their masses increase as the cube of the calibre, while the sections increase only as the square, so that the proportion of these two quantities increases as the first power of the calibre. If, then, for a given calibre, the dimensions of the accelerograph have been calculated so that the duration of the passage of the free stroke, the greatest that can be allowed it, is precisely equal to the duration of the passage of the projectile in the bore, it will be necessary in passing to a greater calibre to augment proportionally to the calibre the total mass of pieces set in motion, in order to continue to satisfy the same condition, and supposing that neither the stroke nor the section of the piston of the apparatus is changed. In the apparatus constructed, when a piston of half a centimetre square in section is employed, to which a free stroke is allowed of 5 centimetres (1.968 inches), the weight of the cube alone, which is about 4 kilogrammes (8.818 pounds) without additional masses, secures for the 14-centimetre (5.512-inch) gun, a registering duration nearly equal to that of the passage of the projectile in the bore; it is then only on departing from this calibre that it is necessary to employ additional masses to make the two durations correspond. By not making use of these masses we accelerate the movement of the piston and obtain in consequence greater precision in the tracing of the curve of the passage, but this tracing then applies only to a limited fraction of the duration of combustion of

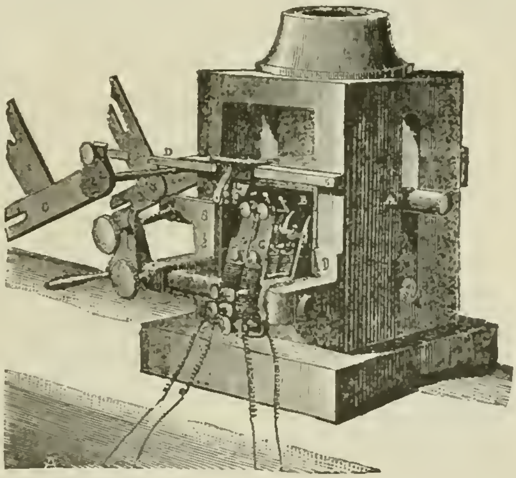

Fig. 4.

the charge. We can, moreover, without at all touching the other organs of the apparatus, vary at will the proportion of this duration of registering to the duration of combustion of the charge by changing the section of the piston; for this purpose the apparatus can be furnished with bushings and pistons of different dimensions.

Slide-accelerograph, employed for determining the law of the recoil of the gun.—In what precedes there was no notice taken of the influence exerted by the recoil movement of the gun on the movement of the accelerograph-slide, which serves to give the measure of the times. Now, it is easy to perceive that this influence is far from being unimportant and that it ought to be taken into account. If we suppose the plane of the accelerograph table to be adjusted parallel to the plane of fire, it is evident that the point of attachment of the extremity of the spring which operates the slide, which point is sustained directly by the frame of the apparatus in the simple accelerograph previously described, will be influenced in the recoil movement of the gun, while the style-bearing slide will be displaced in space. The displacement of the gun while the projectile is passing through the bore is, in fact, far from being unimportant, as has been admitted for some time, and it will be found that for a 24-centimetre (9.45-inch) gun, for example, it is nearly 30 millimetres (1.1811 inches). The tension of the India-rubber which causes the movement of the slide will then be diminished, in consequence of the inertia of this slide and of the spring also, if the point of attachment is turned towards the muzzle of the gun, so that the recoil is produced in a direction the inverse of the movement of the slide. On the contrary, it will be augmented if the apparatus is turned inversely; that is to say, if the point of attachment of the spring is placed towards the breech, so that the movement of the slide and the recoil movement are both directed the same way. It would be too difficult to take into account this disturbing effect whose causes are complicated, and it is more natural to seek to eliminate it altogether by giving to the apparatus a suitable position. The idea naturally occurs to the mind to adjust the apparatus in such a manner that the plane of the table may be normal to the plane of fire; under these conditions the slide is influenced in the recoil movement by its bearing on the guides, and its inertia cannot make it modify directly the tension of the spring which influences it. It was under these conditions that the experiments of Nevers were made in 1874, and it was also in this manner that the tracings reproduced above were obtained. But on applying the calculation to the results obtained by these tracings, it was easily seen that the recoil movement, in spite of the precaution taken in adjusting the table, still disturbed the work-

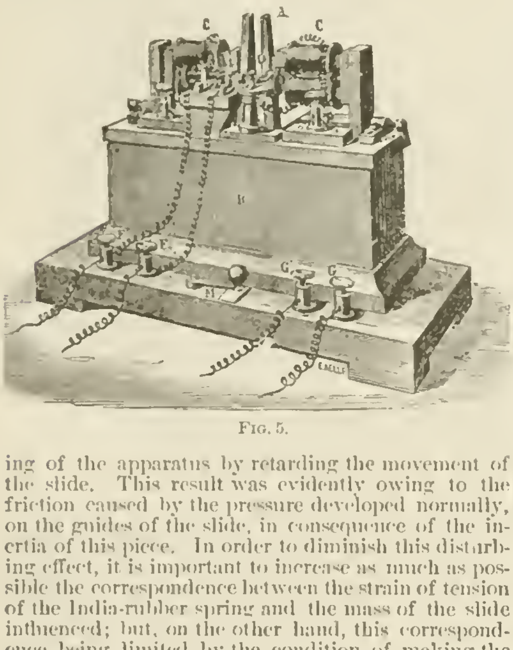

FIG. 5.

ing of the apparatus by retarding the movement of the slide. This result was evidently owing to the friction caused by the pressure developed normally, on the guides of the slide, in consequence of the inertia of this piece. In order to diminish this disturbing effect, it is important to increase as much as possible the correspondence between the strain of tension of the India-rubber spring and the mass of the slide influenced; but, on the other hand, this correspondence being limited by the condition of making the stylus pass over the width of the table in a time nearly equal to that required by the table in moving vertically over the extent of the free path of the apparatus, we are not at liberty to dispose of this element at pleasure. The inertia of the India-rubber spring, which, notwithstanding its small bulk, inclines to take a certain curvature through the effect of the recoil, presents also a disturbing element which it is utterly out of the question to take into account. It therefore is preferable to seek a different arrangement of the apparatus which eliminates all these causes of error. Now, if we suppose the table to be placed parallel to the plane of fire, and if we make stationary the point of attachment of the spring which sets the slide in motion, by fixing, for example, this point of attachment on a support independent of the slide, and placed near the gun, we see that the movement of the slide will be no longer altered through the effect of inertia; but, on the other hand, the table being drawn in the recoil movement, while the slide is displaced in space as if there was no recoil, the tracing given by the stylus will no longer be the same as that which was obtained before; the horizontal abscissas of the curve traced on the table will be, in fact, each instant, the sum of the passages of the stylus and the displacements of the gun in its recoil movement, if we suppose the point of attachment of the spring placed on the side of the muzzle of the piece, or the difference of these same quantities if we suppose this point placed on the side of the breech. It would therefore be necessary to know at each instant the displacement due to the recoil of the gun, in order to deduce from the curve traced the curve that would have been obtained if there had been no recoil. Now, it is easy to obtain, on the same apparatus, placed in this position, a curve that would show for each of the positions of the piston in its vertical displacement the quantity that the gun recoiled at the corresponding instant. It suffices, in fact, to fit on the table a stylus absolutely stationary in the space, that is to say, sustained by a support independent of the gun and the slide, in order that the table which becomes displaced before this stylus, by virtue of its two combined movements, may receive a new curve the ordinates of which will be the passages of the piston and the abscissas the passages of the gun. But as the gun in recoiling is subject to tremulous movements which might not always permit the stylus to rest in contact with the table, and which might also change the form of the curve, it is necessary to describe a right line on the table in its relative movement with the stationary stylus; and for this purpose it is mounted on a small slide which slides between two rails supported by the frame of the accelerograph. In order to keep it stationary between these rails it must be secured by a rod to a horizontal wooden cross-piece, supported by two stationary guide-posts, and passing over the gun.

Practically, in order that the same table may not be crowded with tracings, two similar tables are installed on the opposite faces of the cube pushed by the piston; and the stationary stylus, as well as the rails which hold it, are placed on one of the faces of the accelerograph-frame, while the rails guiding the movable slide are fixed on the other face. Fig. 2 represents an accelerograph apparatus mounted in this fashion on a 14-centimetre (5.51-inch) gun, model 1870. This apparatus is surmounted by an additional weight, retained by a cord; and in Y we see the uprights which sustain the cross-piece, U, to which are fixed on one side the point of attachment of the spring of the movable slide, and on the other side the steel plate the extremity of which bears the stationary stylus. The movable slide presents, besides, a very complicated arrangement, and it remains to show the object of it. If we retained the movable slide arranged as formerly, that is to say, attached directly to the India-rubber tension-spring, and although we have no more fear of the disturbing effects owing to the inertia of the slide and the spring, in consequence of the precaution that we have taken to fix the point of attachment of this spring to the stationary cross-piece, it might still happen that, under the influence of the concussion imparted to the gun at firing, and which makes the guide-bars which guide the slide vibrate, these guide-bars might pinch the slide between them and release it alternately, thus preventing it from taking the regularly accelerated movement which the India-rubber is calculated to impart. This is, indeed, what happened in the first trials, and a regular movement of the slide was obtained at first only for a very short time, which corresponded probably with the time employed by the powder in developing all its power and forcing the projectile in the bore, until the moment when, by the effect of the expansion, owing to the notable displacement of the projectile, the reaction of the sides of the piece causes the first vibrations of the metal. The curve traced on the table, after a very faint regular bend, presented all at once a distinct protuberance, denoting a sudden retardation of the slide. In order to obviate this inconvenience, we have formed the slide of two pieces, the one very light, bearing the stylus and running in very solid guides fixed on the frame; the other, much heavier, running in the guides supported by the wooden cross-piece and consequently fixed in space. The two slides are secured by a steel wire, flexible in every sense, but inextensible, so that the small slide may receive, in the direction of the guides, a movement identical with that of the large, notwithstanding the concussions of the gun, and it is on the heaviest slide that the tension-spring is fixed which produces the movement. We apprehend that, in this manner, we can give sufficient resistance to the guides of the small slide for them to yield a little under the effect of the vibrations, and sufficient solidity to the large motor slide so that the movement of this slide cannot be sensibly changed by the feeble relative resistance which the small "style-bearing" slide can oppose to it. We have said that the apparatus thus arranged furnishes two curves on the tables borne by the opposite faces of the cube pushed by the movable piston. One of these curves, that given by the slide drawn by the India-rubber spring, has its abscissas or horizontal co-ordinates, which are, at each instant, the sum of the displacements of the slide in the space and the horizontal displacements of the gun in its recoil movement; the other has its abscissas equal, simply, to these latter displacements. If we put on the successive abscissas of the first, the values equal to the abscissas of the second, we obtain, by the difference, the curve that would have been traced if the gun had not recoiled during the vertical displacement of the piston of the apparatus; that is to say, the curve by which the law of the movement of the piston is made known, in the function of the known law of the movement of the slide working separately, and consequently in the function of the times. By this known law is deduced, from the second curve, the law of recoil of the gun in the function of the times. Although the accelerograph just described is not furnished with organs for registering the moment of the departure of the projectile from the bore, we can, by the aid of the curves which it gives, estimate with a degree of precision the duration of the passage in the bore and deduce therefrom the quantity which the gun has recoiled while the projectile was passing through the bore. We know, in fact, that if we neglect the effect of the mass of the powder-gases, which, it is true, introduces a certain cause of error, we may admit that the projectile and the gun, including its carriage, must be displaced in an inverse direction, each instant in quantities inversely proportional to their respective masses. We may then, knowing the displacements of the gun, deduce therefrom the corresponding displacements of the projectile and, consequently, obtain the displacement of the gun corresponding to the passage of the projectile through the bore.

Electric register-accelerograph maintained by vibration.—The reading of the results obtained by means of the slide-accelerographs is long and difficult. As we have said, it is necessary at first to measure, by means of the microscope with double micrometric screw, the ordinates of the curve of "tarage" which correspond to the abscissas passed in the times increasing by equal fractions (for example, by thousandths of a second), which abscissas are ascertained by calculation. It is necessary afterwards, by means of the microscope, to trace on the curve of firing the ordinates thus obtained, and to read the corresponding co-ordinates, according to the conjugate perpendicular axis. These readings must all be made to the hundredth of a millimetre, and we understand how the successive operations so delicate may cause accidental errors; in every case it reduces the final precision; it would then be advantageous to find a means of measuring the durations more convenient and more precise in its employment. The solution of this problem seemed to require the employment of vibrating plates, inscribing directly, on the accelerograph-table, the spaces passed during intervals of time, each equal to the period of vibration of the plate, and thus we were induced, from the first, as we said before, to place a vibrating plate on one side of the movable slide (Fig. 1). This vibrating plate, furnished with a pen which rested on the blackened table, was, before firing, diverted from its position of equilibrium by means of a screw mounted on a projection of the movable cube, and which barely touched on the extremity of the plate, so as to detach it abruptly, as soon as the cube received the least displacement. The plate gave besides a great number of vibrations, usually a thousand a second, and it was carefully "tared" beforehand by means of the drop-chronograph, by a process easily understood by examining Fig. 3. A is the vibrating plate fixed on one of the guide-posts of the chronograph; the small turn-button B serves to keep it in the state of initial tension; it is encountered by the falling movable weight and suddenly turned away by a projection, C, on this weight. On this is fixed a small blackened table, D, so placed as to be encountered in its passage by the vibrating pen which traces the undulations whose spacing measures the duration in the function of the velocity of the drop-weight. This

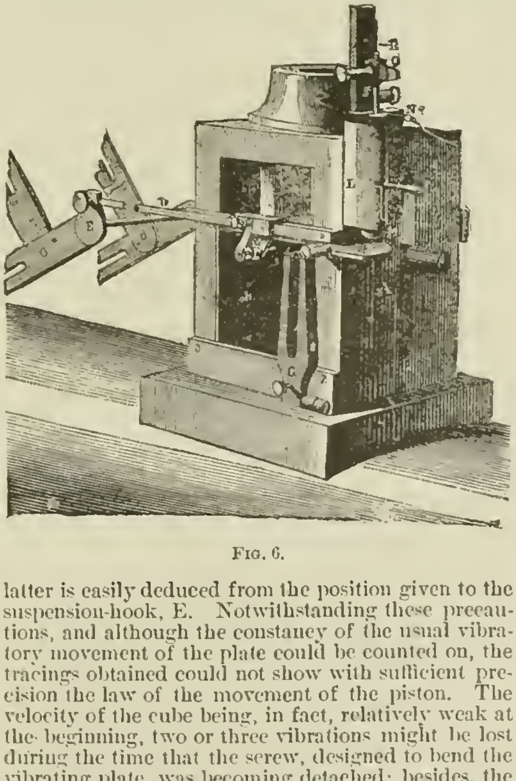

Fig. 6.

latter is easily deduced from the position given to the suspension-hook, E. Notwithstanding these precautions, and although the constancy of the usual vibratory movement of the plate could be counted on, the tracings obtained could not show with sufficient precision the law of the movement of the piston. The velocity of the cube being, in fact, relatively weak at the beginning, two or three vibrations might be lost during the time that the screw, designed to bend the vibrating plate, was becoming detached; besides, the regularity of the first vibrations of the plate was changed in consequence of the fact that the initial flexion, which was imparted to it by the pressure of the screw on its extremity, did not give it the same form that it takes in vibrating freely to the limit of its undulations, so that the first vibrations were employed by it to recover its natural state of molecular equilibrium, which, however, is very rapidly effected; it was necessary then to set aside these first defective vibrations, and it is precisely the movement registered by these first vibrations which it is important to know. On these two accounts it was proposed at first, as has been said already, to use the tracing of the vibrating plate only as a counter-register for testing if the accelerograph-slide had worked properly; a material disagreement between the total durations registered by the two apparatus must, in fact, indicate if the slide had sustained an unusual impediment, which, in certain cases, may be produced, either by the presence of grains of sand in the grooves which guide it, or even by the vibratory effect of those grooves under the influence of the firing, when the adjustage is too carefully made, or when the rails are too weak or too weakly supported on the apparatus. In order to lessen the inconveniences pointed out, trial was made of a new mode of disconnecting the vibrating plate, by producing the flexion of it by means of a jointed lever, its extremity acting on it while a projection on the movable cube was applied under the lever, near its point of articulation; thus the displacements of the piston were amplified and the disconnection accelerated, but no remedy was presented for the disturbing effect of the first vibrations. In order to obtain more precise results and to suppress entirely the style-bearing slide moved by a spring, it was purposed to utilize the properties of the small electro-magnetic registers constructed by Mr. Marcel-Deprez, the motion of which is sufficiently rapid to permit their following the vibratory movements of a tuning-fork electrically sustained, and giving as many as 1000 vibrations per second.

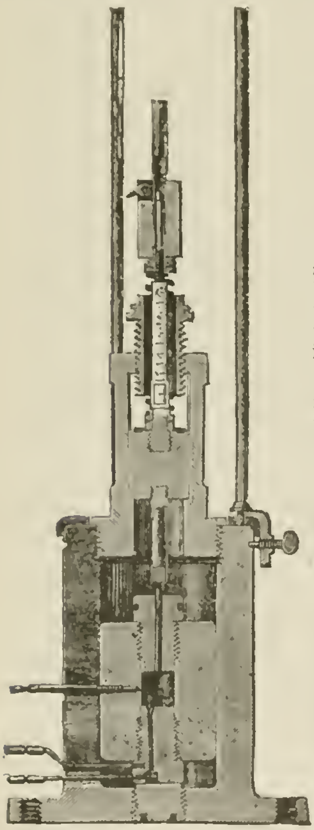
Fig. 4 represents the arrangement given to the apparatus in order to adapt it for registering the law of recoil of the gun, and also for measuring directly the duration of the trajectory of the projectile in the bore. The usual accelerograph-frame was retained, and for registering the rear face of the cube, B, was arranged to receive a second table, in front of which ran the stylus, secured by an inextensible wire, D, at a stationary point in space. In front of this face of the cube was mounted a cylindrical shaft, F, on which two small Marcel-Deprez registers, GG, were put; one of these registers was placed in a circuit passing through an interrupter fixed at the muzzle of the piece; the other was placed in a circuit passing through an interrupter-plate mounted on a fork electrically sustained and placed at a distance from the gun. When the fork was set in motion the current, passing through the electro-magnet, sustained at each period a rupture and a closure, so that the pen of the register, constantly resting on the table, took an oscillatory movement directed by that of the fork and strictly equal to it. The tracings of the pen were superposed as long as the table remained stationary; but as soon as the table was displaced, successive tracings were obtained, whose spacings indicated the displacements effected during each period. The fork was set in motion a little before firing the gun; on the shot leaving, there was found on the table a tracing left by the register directed by the fork and which gives the law of the movement of the piston, a signal given by the second register and which marks the space passed by the piston at the moment the projectile passes from the muzzle of the piece, and lastly a curve left by the stationary stylus and which shows the recoil of the gun each instant, in the function of the displacements of the piston. Fig. 5 represents the arrangement of the fork electrically sustained and designed to direct the movements of the vibrating register. On the examination of this figure we perceive that this fork, A, mounted on a cast-iron base, B, is sustained by means of two electro-magnets, CC, traversed by a special current and a flexible plate oscillating between two supporting screws, one a conductor, the other an insulator, arranged as has been previously shown. This plate, D, is fixed on one of the branches of the fork; the other branch bears symmetrically a similar insulated plate, E, supported, when the fork is at rest, against a metallic screw, and separating from this screw for an instant at each vibration of the fork. The plate is connected by a very fine flexible wire with a terminal, F, placed in the special circuit of the accelerograph-register; the supporting screw, communicating with the second terminal, F, is also placed in this circuit which is thus established by the contact of the plate and the screw, and interrupted on the cessation of this contact. By turning the screw slowly, the duration of the contact can be regulated at each period. The terminals, GG, serve to establish the current which sustains the movement of the fork, and the circuit passes through the handle, M, by which it may be interrupted at will. In the trials that were made, the fork and the batteries were placed a short distance from the gun, so as to have circuits only of small resistance; it was necessary to sustain the vibrating fork by means of these small model Delaurier elements, and four similar elements for each of the registers.

Electric fork-accelerograph.—This apparatus, which has been described, presented the inconvenience of not giving subdivisions of time sufficiently small to furnish with precision the value of the accelerating forces of the piston. Experience showed, in fact, that in order to calculate with sufficient precision the accelerations obtained during such a short space which corresponds with the development of the maximum pressure in the bore of guns, even those of large calibre, where this time is longest, it was necessary to descend, in measuring the times, below the thousandths of a second, and perhaps even to reach as far as five thousandths at the least. Now, it was practically impossible to make use of an electric fork directing a register and giving more than one thousand periods a second. A fork giving 1500 periods might, indeed, be electrically sustained, though not without difficulties; but the amplitude of these vibrations being very small, it was impossible to assure the regular movement of the interrupter-plate, and this sometimes missed its connection, which introduced irregularities in the movements of the register. As to this latter, the improvements effected by Mr. Deprez would have enabled it to give, in case of need, a greater number of signals per second than the limit sought, and there was no obstacle there. A new trial was made by employing an electric fork mounted directly on the accelerograph. The case and the piston of the accelerograph, as well as the table sustained by the latter, retained the same arrangements as before; but the shaft which contained the register directed by an exterior fork received directly a small diapason electrically sustained by the aid of an arrangement similar to that which has been already described; this arrangement is here fixed entirely on a metal frame, which contains the fork and which is movable with it on the support-axis, so as to permit the pen of the table to be brought nearer or separated at will, without prejudice to the vibratory movement. As long as the table is stationary, the tracings of the pen in motion are superposed and form only one mark; these tracings are separated and give a sinusoidal curve as soon as the table is set in motion under the action of the piston. A second stationary pen, on the support-frame, traces at the same time the median path, whose successive intersections with the sinusoid will give the spaces passed by the table during the corresponding periods. The results obtained with the fork-accelerograph, although superior to those given by the registering apparatus supplied by vibration, were not sufficient, however, and showed that it was necessary to seek to estimate still smaller intervals of time. The electric supply of a fork giving 2000 periods per second was, besides, very delicate. Its initial movement was tedious to obtain before each experiment, and it was rare that the apparatus could be kept without derangement in a working state during the whole continuance of a series. After having sought without success to solve the difficulty by the employment of a contrivance which would have given the means of subdividing, into a certain number of equal parts, the duration of each period of the fork, which might have admitted of preserving the last arrangement adopted, but by making use of forks giving only 1000 periods, and consequently easy to supply electrically, it was decided to try again the employment of the fork set in vibration mechanically.

Mechanical fork-accelerograph.—We have seen that in order to utilize a fork, vibrating mechanically at the moment of firing, for registering the displacements of the accelerograph-piston, it was sufficient to procure the initial movement of this fork a very little time before the projectile leaves the bore, so that, the vibrations having had time to regulate themselves when the piston sustained its first displacement, the origin and commencement of the movement could be registered without error. It is necessary, besides, that the discharge of the gun should follow very closely the initial movement of the fork, because if forks are used giving 2000 to 3000 vibrations, as those which are acknowledged to be necessary, these forks, set in vibration by an energetic shock, preserve only for a very short time, scarcely the tenth of a second, an amplitude sufficient to give proper tracings for the readings. Fire communicated by electricity gives, evidently, the solution of the problem, for we conceive that the mechanism whose release will produce the vibration might, in working, establish the current which will determine the inflammation, leaving, between these two operations, the interval strictly necessary to permit the vibrations of the fork to regulate themselves, without losing too much of their amplitude. Fig. 6 represents the application of this idea to an accelerograph which is arranged, with the exception of the organ for registering times, like those which have been previously described, and which consequently permits of measuring also the law of the recoil of the gun. A vibrating fork, G, is simply fixed in front of the table, whose branches are each furnished with a pen, in order the more surely to obtain a proper tracing. A wedge, H, on the extremity of a small, horizontal-jointed lever, can be forced between the branches of the fork and keeps them apart; it suffices to strike sharply on the other branch, K, of the lever in order to disengage it and make the fork vibrate; this latter then gives an acute sound which is perceptible only for a very short time. This shock may be produced in the apparatus by the extension of a spiral spring lodged in a small cylindrical box, L, fixed on the side of the case, and which suddenly pushes a percussion-lock, M, guided vertically through this box. The apparatus is cocked by raising the percussion-lock by means of a small handle, P, which passes through a vertical groove; this bends in the form of a knee to form a safety-notch. A pin, N, is then entered into a hole normally made in the spindle, which is an extension of the percussion-lock, and this latter is held only by the point of this pin, when the handle is moved back in the groove. By drawing away this pin, by the traction of a cord which is fixed to it, the working of the apparatus is produced. The precise moment of inflammation may vary within certain limits; in order to communicate the fire, the upper part of the spindle of the percussion-lock, which extends beyond the spring-box, is furnished with a metallic rubber, R, which may be fixed at a variable height by means of a pressure-screw, Q, and which rests upon an insulating rod terminated by a conductor, S, at its lower part. The metallic rubber of one part and the conductor of the other are put in communication with a firing-battery connecting with the electric percussion-tube of the gun, or with a platinum wire sunk in the charge, if the trial is made with a closed vessel. In consequence of this arrangement the circuit is closed only when the percussion-lock, pressed by the spring, brings the rubber in contact with the conductor-plate, and this contact is established at a moment which may vary, within certain limits, depending on the moment when the shock on the end of the lever produces the disconnection of the fork. The closing of the circuit may be made to precede the shock if the retardation of inflammation of the charge is relatively considerable, or, on the contrary, to follow it if the inflammation must be very prompt.

ACCELEROMETERS.—Accelerometers show, by direct registry, the law of the movement in the function of time of a piston subjected to the action of powder-gases. It has been seen in studying the accelerographs that an additional weight placed on this piston in such a manner that it may be thrown vertically without obstacle, when this latter is suddenly stopped, can show, by a single observation, the velocity acquired by the piston up to the end of its stroke. In fact, this weight, thrown freely and preserving the velocity which it had in common with the piston, will be raised to a height, h, given by the relation $v^2=2gh$, so that the observation of the height of the vertical stroke h will show the velocity v. If it is admitted that the phenomena of the combustion of the powder are reproduced identically in the like conditions, and if a series of detonations are effected with a constant charge, but varying the free stroke each time, which will be obtained, for instance, by lowering successively the stop-screw W, in Fig. 1, in the article ACCELEROGRAPHS, it is evident that the observation of the corresponding heights of throw of the additional weight supported by the piston would show the successive velocities acquired by this piston according to the gradually diminishing paths. We could then determine, by this simple process, and without a special chronometric organ, but on condition of repeating the experiments, the law of movement imparted to the piston. Mr. Marcel-Deprez, from the first, proposed the employment of apparatus of this kind, which appeared more easy to realize than accelerographs, and he gave them the name of accelerometers. In principle, these apparatus are composed of a piston of a certain weight, subjected freely to the action of the powder-gases, and for which a variable stroke may be allowed, exactly regulated each time; this piston must be provided, moreover, with arrangements for measuring the velocity acquired at the end of the stroke. For stationary apparatus, susceptible of being placed vertically, like those which may be installed on eprouvettes, the measure of the final velocity can be obtained simply by the observation of the height of the throw of an additional weight, as has been already explained. For apparatus designed to be placed on a gun, and which must consequently be subjected to the violent effects of recoil, an arrangement of this kind could not be employed, and Mr. Marcel-Deprez was obliged, in view of this particular case, to seek another means of measuring the velocity. By employing always an additional mass borne by the piston and thrown by it with the velocity which it is sought to determine, he pointed out two different processes, both very simple, for obtaining this measure. In one of the systems, the weight thrown, guided by a rod which passed through its axis, must meet with a constant resistance which could be regulated at will; in this case, the passage of the weight on the rod must be theoretically proportional to the square of the velocity, or if a constant antagonistic resistance could not be absolutely counted on, it would be necessary, by a previous "tarage," to determine the relation existing between the observed paths of the weight on the rod and the corresponding initial velocities.

In the second system proposed by Mr. Marcel-Duprez, we must oppose to the weight freely thrown, and always guided by a central rod, a variable resistance, but one known at each instant, as, for example, that which the compression of a spring develops; in this case, however, we may, for a spring and a given weight, determine, by a previous "tarage," the relation which connects the initial velocities with the paths necessary in order to attain them. We can also, by choosing springs susceptible of causing a variable resistance according to a simple law, ascertain that a law equally simple connects the velocities with the paths. If, for example, we suppose that the energy exerted by the antagonistic spring varies proportionally to the passages of the weight, measured on its leaving a fixed point situated on the trajectory of this latter, we can observe that the paths producing the stopping of the weight are rendered directly proportional to the initial velocities. The trials undertaken with the object of realizing the first system did not succeed; a slide has not yet been constructed running on a metallic rod on which a definite and strictly constant friction could be exerted over the whole length of its course. If that construction had been realized, we could, by letting the rod, furnished with its slide, fall vertically and from increasing heights, on an unchangeable obstacle, have obtained the paths of the slide proportional to the heights of fall, under the influence of the shock caused by the sudden stopping, since the velocities acquired in the fall of bodies are themselves proportional to the square roots of the heights of fall. But this result was far from being attained, and notwithstanding all the care taken in dressing and polishing the surfaces in contact, it was settled that the friction depended on causes too numerous and on influences too difficult to estimate for it to be possible to obtain results sufficiently regular; we found, in fact, that the adhesion at the departure being, in all cases, greater than during the movement, the slide, after having passed over a small space, with a very small velocity, afterwards took a velocity sensibly greater and a much longer path than was reasonably expected and without even giving regular values. Under these conditions we must depend upon the employment of the spring to weaken the velocity of the additional weight, when, by the arrangement of the apparatus, this detached weight is not left to the action of gravity alone, where we must operate on masses in motion, as in the firing of guns, or where the locality does not permit the installation of proper guides for measuring the vertical height of the weight. More recently use has been made of vibrating forks leaving on the additional mass thrown traces sufficient in number to determine the value of its initial velocity. The accelerometers which have been constructed may be distinguished as weight-accelerometers, spring-accelerometers, and fork-accelerometers; the two latter only can be mounted on guns. Simple accelerometers may also be distinguished, that is, those which contain only the organs designed for measuring the final velocity of the piston, and the accelerometers combined with accelerograph-organs, like those of which we have already spoken above. In these latter the accelerometer arrangement is usually employed only as a counter-register of the course of the accelerograph, and a few complemental details will suffice to explain the function of the organs represented by the figures which we have already appropriated to these apparatus. We will give these explanations directly and afterwards describe, more in detail, the arrangement of the simple accelerographs by referring to the mode of their employment.



The first powder-mill accelerographs constructed were arranged in such a manner that they could be used as weight-accelerometers by making use, in order to limit the stroke of the movable piston, of a screw by which this stroke could be reduced to a very small value and graduated at will. The registering of the height of the "cast" is obtained by arranging in the axis of the apparatus a vertical rod guiding the additional mass thrown; this rod is provided with a light slide of leather or felt, impelled with a very slight friction by this mass in its ascensional movement. The drawing represents, in section, an apparatus on which are placed simultaneously two different arrangements for measuring the final velocity of the weight; one of these arrangements is, like the preceding, a vertical rod guiding a slide impelled by the additional weight, which is provided with a Dobo ratchet-catch to prevent its falling violently on the piston; the other is a spring apparatus consisting of a spiral spring put on a rod which makes part of the piston and participates in all its movements. The upper part of this spring is fixed to the rod; its lower part is terminated by a mass of certain weight which rests freely on the head of the piston and is thus cast upward, when this latter stops, with the velocity which is to be determined. Thus this mass compresses the spring until its velocity is terminated, then the spring in recoiling pushes it back in its place. We apprehend that for a given spring and mass we might by a preliminary tarage determine the quantity of the compression of the spring for the successively increasing velocities, so that it may be easy afterwards to deduce from an observed compression the value of the velocity which produced it. We shall see further on how this tarage may be effected. In the apparatus represented in the drawing, in section, in order to determine the quantity of the compression of the spring in each experiment, there is placed on the mass which terminates the lower part of the spring a small slide forming a vernier, which slides with a slight friction on the central rod, which is divided into millimetres. This slide is pushed by the mass in its ascensional movement and abandoned by it when it redescends after having lost its velocity. The mass of the slide is so small that it could not sustain a throw which would push it beyond the position which the mass itself has reached, so that the division at which it stops may give the exact measure of the compression of the spring. If the place at our disposition does not admit of placing above the eprouvette a vertical rod to guide the weight thrown, the spring-system may suffice, which requires only a small height, by suppressing entirely the additional weight with ratchet mechanism; we may also, in this way, use a lighter piston and obtain greater velocities for smaller distances. If, on the contrary, we adopt the double system, we have the advantage of obtaining, for the measure of the final velocity of the piston, two values which must correspond. The spring arrangement may also be applied to accelerographs mounted on a gun, and give also in this case a check measurement for the final velocity of the piston. See *Accelerographs*.

ACCESSIBLE.—Easy of access or approach. A place or fort is said to be *accessible* when it can be approached with a hostile force by land or sea.

ACCESSORY MEANS OF DEFENCE.—The means employed as *accessory* usually consist of artificial obstacles, so arranged as to detain the enemy in a position where he will be greatly cut up by the fire of the work. Anything may be regarded as an obstacle to the enemy by which his attention is diverted from the assailed to his own situation; but no obstacle will be of much service to the assailed which is not within good striking distance of his weapons. The proper disposition, therefore, of obstacles is in advance of the ditch within short musket-range. Here they delay the assailant under fire, and give the assailed a feeling of more security as the assailant is kept further off. Marshes, water-courses, wet ditches, precipices, etc., may be regarded as obstacles, if they are sufficient in themselves to stop the enemy's progress. But, however strong, they are not solely to be relied on; as the strongest natural position may be carried if not vigilantly guarded.

In placing the ground around a work in a defensive attitude, every means should be taken to reduce to the smallest possible number the points by which the enemy may approach, so that, by accumulating the troops on the weak points, a more vigorous defence may be made. In making this arrangement, equal care should be given to everything that, affording a shelter to the enemy, would enable him to approach the work unexposed to its fires. To prevent this, all hollow roads, or dry ditches, which are not enfiladed by the principal works, should be filled up, or else be watched by a detachment, covered by an advance-work. All trees, underwood, hedges, enclosures, and houses, within cannon-range, should be cut down and levelled, and no stumps be allowed higher than two feet. Trees beyond cannon-range should not be felled; or if felled, they should be burnt, to prevent the enemy's movements being concealed. If there are approaches such as permanent bridges, fords, and roads, which may be equally serviceable to the assailed and to the enemy, they should be guarded with peculiar care, and be exposed to the enfilading fire of a work especially erected for their defence. See *Abatis*, *Chevaux-de-frise*, *Crow's-feet*, *Entanglements*, *Fraises*, *Inundations*, *Mines*, *Palisades*, *Small Pickets*, *Stockades*, and *Trous-de-loup*.

ACCIDENTAL LINE OF OPERATIONS.—Lines of operations are sometimes employed, different from those proposed in the original plan of campaign. To these lines the term *accidental* is applied. It does not follow that their adoption is a matter of accident, as might be inferred from their name. They are frequently the result of a change in the original plan, which probable change was foreseen and provided for.

ACCIDENTAL OBJECTIVE. — Accidental objectives are dependent upon the military operations which have for their object the destruction or disintegration of the enemy's forces. The position of the enemy determines their location. Thus, if the enemy's forces are greatly scattered, or his front much extended, the central point of his position would be a good objective point, since the possession of it would divide the enemy's forces, and allow his detachments to be attacked separately. Or, if the enemy has his forces well supported, a good objective would be on that flank the possession of which would allow his communications with his base to be threatened. It is well to remark that the term "point" generally used in this connection is not to be considered merely in its geometrical sense, but is used to apply to the *object* which the army desires to attain, whether it be a position, a place, a line, or even a section of country.

ACCIDENTAL STRATEGICAL POINT. — A point whose possession will give an advantage over the enemy, causing him to fight at a disadvantage, or retreat, is an "accidental strategical point," since it is frequently dependent upon the positions of the contending forces at a particular time. It is generally a "decisive point," for its possession insures success for the military operation with which it was connected.

ACCINTUS.—A word in ancient times signifying the complete accoutrements of a soldier.

ACCOLADE.—The term applied to the ceremony with which a knight was admitted into the Order of Chivalry. The Grand-Master, in receiving the neophyte, embraced him by folding the arms round the neck (*ad collum*).—In music, the accolade is the couplet uniting several staves, as in part-music.

ACCORD.—The conditions under which a fortress or command of troops is surrendered.

ACCOUNTANT-GENERAL OF THE ARMY.—An officer in the English service who has the control of military finance. He includes in his office that of Chief Auditor, an amalgamation with that of Accountant-General, which took place by order of the Secretary of State for War in 1870.

ACCOUNTS.—The systematic record of public expenditures. In the United States service, all officers, agents, or other persons who are charged with the safe-keeping, transfer, or disbursement of the public moneys keep an accurate entry of each sum received, and of each payment or transfer; and render distinct Accounts of the application thereof, according to the appropriation under which the moneys may have been advanced to them. Every officer or agent who, having received public money which he is not authorized to retain as salary, pay, or emolument, fails to render his Accounts for the same is deemed guilty of embezzlement, and is fined in a sum equal to the amount of the money embezzled, and is imprisoned not less than six months or more than ten years.

The following rules for computation of time are observed, when preparing Accounts for settlement:

1. For any full calendar month's service at a stipulated monthly rate of compensation (or yearly rate, if paid in regular monthly or bimonthly installments), payments are made at such stipulated rate, without regard to the number of days in that month.

2. When service *commences* on an intermediate day of the month, 30 days is assumed as the length of the month, whether the calendar length be 28, 29, 30, or 31 days, and pay allowed accordingly.

3. When the service *terminates* on an intermediate day of the month, the actual number of days during which service was rendered in that calendar month is allowed in payments.

4. When the service embraces two or more months, or parts of months, but one fraction is made. Thus, from September 21 to November 25, inclusive, is calculated September 21 to October 20, inclusive, one month; from October 21 to November 20, inclusive, one month; from November 21 to 25, inclusive, five days—making the time allowed two months and five days.

5. When two fractions of months occur, both together less than a whole month, as from August 21 to September 10, the time is determined thus: August 21 to 30, inclusive (ignoring 31st), ten days; from September 1 to 10, inclusive, ten days—making the time allowed twenty days.

6. Service commencing in February is calculated as though the month contained 30 days, thus: From February 21 to 28 (or 29), inclusive, ten days; but when the service commences on the last day of February, only one day is allowed in that month.

7. For commutation of subsistence, and for services of persons employed at a per-diem rate, payment is made for the actual number of days.

8. When service is rendered from one given date to another, the Account must state clearly whether both dates are included.

The Accounts of disbursing officers of the Army are kept in the offices of the Auditors of the Treasury by fiscal years; therefore no Account Current should contain mixed accounts, and no item should be entered thereon unless it pertains to the fiscal year to which the funds are chargeable, and *all accounts current, abstracts, and vouchers, including transfers and refundments,* should have noted in red ink on the face, as well as indorsed in the brief on the back, the fiscal year to which the funds pertain.

ACCOUNTS-CURRENT.—Running or continued accounts between Disbursing Officers and the Government Accountant Officers. In the United States service, the law requires that a separate account be kept with each appropriation disbursed. The forms of Account-Current and abstracts prepared for this purpose and approved by the Second Comptroller of the Treasury are used by disbursing officers. The Account-Current is made in duplicate; one copy, accompanied by abstracts and vouchers complete, is forwarded to the chief of Bureau within ten days after the end of the month; the other copy, also accompanied by abstracts and vouchers, is retained by the officer. Funds received from overpayments previously made are entered on the Account-Current in the proper column. The entries should show by whom and to whom the overpayments were made, on what account, and refer to the voucher and abstract. Funds received on account of overpayments made from appropriations not now controlled by the chief of their Bureau, except as hereinafter provided, may be entered under any head of appropriation on the Account-Current. All funds received from sales, refundments, or miscellaneous sources, are at once deposited in the nearest United States depository to the credit of the Treasurer of the United States on account of the appropriation to which it belongs, if any, and receipts taken therefor; the original receipt is forwarded to the chief of the Bureau, accompanied, if possible, by information showing to what particular appropriation the money belongs, and for what year. For funds thus deposited, officers take credit on their Accounts-Current. Accounts-Current should, when practicable, cover monthly periods only. They may, however, if necessary, be stated at intermediate dates when rendered to close accounts on renewal of bond, change of station, or taking advantage of leave of absence of more than ten days. In these cases the officer must make an actual *bona fide* transfer of his entire balance of public funds. The Account-Current must exhibit the receipts and expenditures for the period embraced, and must state the place or places where the balance due the United States is deposited. The amounts received and disbursed and the balance on hand under the several appropriations of each fiscal year must be exhibited. In crediting drafts on the Account-Current the *number of the requisition*, as indicated on each draft, is carefully noted in the credit entry.

The following is a form of Account-Current used in the Subsistence Department:

and plate, cartridge-box belt and plate, waist-belt and plate, gun-sling, bayonet-scabbard, and cap-pouch; to which, on a march, are added the knapsack, canteen, and haversack. Two loops are attached to the back of the cartridge-box for the passage of the belt, which passes diagonally across the body in front and rear from the left shoulder to the right side, where it passes beneath the waist-belt, and is secured to the cartridge-box by two buckles. For ornament a round brass plate (in the United States stamped with an eagle) is attached to this belt, so as to fall about the centre of the chest of the wearer. More frequently the plate bears the number of the regiment or the letter of the company. The waist-belt, as its name implies, passes around the waist, and carries the bayonet-scabbard and cap-pouch; it also serves to keep the cartridge-box and belt in place close to the body; it is fastened by a brass plate. The bayonet-scabbard is made of black bridle-leather; it has a shape to fit the bayonet, and is provided with a brass ferrule at its bottom for ornament and protection; a leather loop, or *frog*, is attached to the upper part of the scabbard for inserting the waist-belt. The cap-pouch is also made of black bridle-leather, and has a flap and inner cover, the flap being fastened by a brass button. The pouch is lined with sheepskin with the wool on, to prevent the caps from being jarred out and lost when the flap is not buttoned. The gun-sling is of russet bag-leather, 1¼ inches wide and 46 inches long; it has a standing loop at one end and a brass hook at the other, with a sliding loop between. All belts in the United States land service are black, and are made either of leather or of a strong species of felting, called *buff*, probably because belts were formerly made of that color. Until within a few years a separate belt was used for suspending the bayonet-scabbard, passing over the left shoulder and crossing the cartridge-box belt diagonally on the breast, which was ornamented with a plate at the crossing. The cartridge-box belt has sometimes been dispensed with, particularly for riflemen, the whole weight of the accoutrements, with, in this case, the addition of a heavy sword-bayonet and scabbard, being borne by the waist-belt, which of course had to be drawn very tight, forcibly com-

The United States, on account of Subsistence of the Army, in the month of ——, 188 , in account with —— Lieut. —— ——, —— Regiment of ——, A. A. C. S.

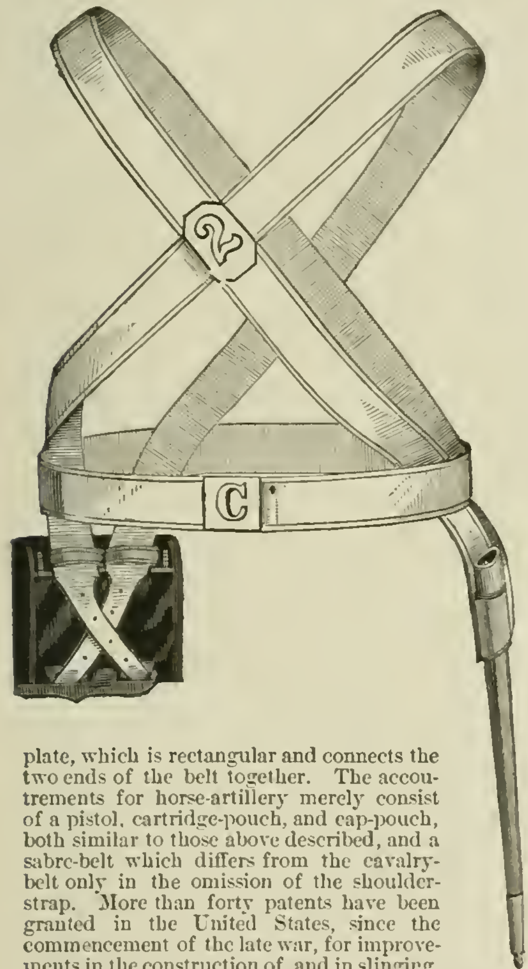
ACCOUTREMENTS—ACCOUTERMENTS.—The devices by which a soldier carries his arms, ammunition, etc. These vary in the different arms of the service according to the exigencies of the case. Those for infantry usually consist of a cartridge-box

pressing the abdomen, and causing great and unnecessary fatigue, or even permanent injury. This arrangement was, we believe, generally condemned by the Medical Department and in fact, by every one who thought on the subject; but as the weapon above mentioned was in very limited use, toward the close of the war especially, the evil was not so general as it might have been. The cartridge-box for cavalry resembles in exterior appearance that for the infantry, but is smaller, and its two loops are arranged so as to pass the sabre-belt through them. Those used by the troops in the late war were variously arranged in the interior to suit the supposed necessities of the cartridges of each particular kind of carbine, as Burnside's, Merrill's, etc. The cavalryman is also provided with a small box or pouch for revolver-cartridges and a cap-pouch. The sabre-belt, to which all the preceding are attached, consists of a waist-belt, with two brass rings for the shoulder-strap and sabre-slings, and a brass loop sewed at one end to receive the



plate, which is rectangular and connects the two ends of the belt together. The accoutrements for horse-artillery merely consist of a pistol, cartridge-pouch, and cap-pouch, both similar to those above described, and a sabre-belt which differs from the cavalry-belt only in the omission of the shoulder-strap. More than forty patents have been granted in the United States, since the commencement of the late war, for improvements in the construction of, and in slinging, accoutrements. The more important of these patents will be noticed under specific headings. The drawing shows the usual arrangement and adjustment of accoutrements. The Ordnance Department at present issues the following accoutrements to United States troops:

Infantry Accoutrements.—Bayonet-scabbard, leather; bayonet-scabbard, steel; cartridge-box; cartridge-box plate; cartridge-box belt; cartridge-box belt-plate; cartridge-belt, with buckle (belt of leather, covered with webbing, with loops of webbing), for calibre .45; gun-sling; shoulder or sword belt for non-commissioned officers or musicians; shoulder-belt plate; sliding frogs for waist-belts (for swords); waist-belt; waist-belt plate.

Cavalry Accoutrements.—Sabre-belts, buff leather, blacked; sabre-belts, grained leather, blacked; sabre-belt plates; sabre-knots; canteens; canteen-covers; carbine-slings, buff leather, blacked; carbine-slings, grained leather, blacked; carbine-sling swivels; carbine-cartridge boxes; carbine-cartridge pouches; cartridge-loops (worn on sabre-belt); haversacks; pistol-holsters, Smith & Wesson's; pistol-holsters, Colt's; pistol-cartridge pouches; snap-hooks; Stuart's attachments.

Sabre-belts and sabre-belt plates are issued as accoutrements for the artillery. The following directions should be observed for reblacking the leather parts of accoutrements: Brush them with a hard brush, to clean the surface; if they are very greasy, use a wire scratch-brush. Then, with a soft brush or sponge, apply the following mixture, viz.: one gallon soft water, two pounds extract of logwood, half a pound broken nutgalls, boiled until the logwood is dissolved. When cold, add half a pint of the pyrolignite of iron—made by dissolving iron-filings in pyroligneous acid, as much as the acid will take up. The dye thus made should be well stirred, and then left to settle. When clear, bottle it free from sediment, and keep it well corked for use. Dye the belts in the shade; then apply a little sperm or olive oil, and rub well with a hard brush. Should any bad spots appear, scratch up the surface with the wire brush, and wet two or three times with a simple decoction of gallnuts or sumach, and again apply the dye. Logwood is not essential, and a solution of copperas may be used instead of the acetate of iron.

ACCUMULATION OF POWER.—The quantity of motion in machines at the end of given intervals, during which velocity has been constantly accelerated. A simple case is the rammer of a pile driving machine, which descends by force of gravity in a certain time and falls upon some object. If the object does not move, the velocities of all the particles in the hammer, which had gone on increasing during the descent, are destroyed, and thus a shock is produced immensely greater than that which would result from the mere pressure of the hammer. The effect is directly proportional to the mass in motion, and to the square of the velocity at the instant of impact.

ACCUMULATOR.—An apparatus used in working hydraulic cranes and other machines where a steady and powerful pressure of water is required. The accumulator is intended as a substitute for a natural head, as being more compact. Sir William Armstrong, in the first applications he made of this principle to hydraulic cranes, employed a *natural* head of water as the motive agent, obtaining the same by pumping water into tanks at an elevation of about 200 feet; but subsequently he has employed the accumulator, as offering the advantages of greatly increased capacity for pressure, and a less prime cost of erection. The apparatus consists of a large cast-iron cylinder, fitted with a plunger, which works water-tight by means of a gland and packing. To this plunger is attached, by means of bolts and a strong cast-iron cross-head, a loaded weight-case. Thus a pressure is obtained upon the water in the cylinder equal to a column of water 1500 feet high, or 660 pounds upon the square inch. As the water is pumped into the cylinder by the pumping-engine, the piston with the weighted case rises, being guided by a strong framework, and is made to regulate the amount of water pumped in by actuating a throttle-valve in the steam-pipe of the pumping-engine, which it closes after having reached a certain height. When the cranes, etc., are in operation, the water passes from this cylinder to the pipes actuating the motion of the cranes, and the weighted plunger naturally descends, always keeping up a constant pressure upon the water: in descending, the same causes the throttle-valve to open again, and the water is again pumped in.

ACCURACY OF FIRE.—Firing for accuracy, whether with artillery or small-arms, may involve two entirely separate and distinct things: 1st. The determination of the personal skill of the individual using the weapon. 2d. The determination of the qualities as regards accuracy of the weapon itself. The most common way of determining the relative accuracy of guns is to ascertain their *mean differences of range* and *mean reduced deflection* for a given *mean range*, and compare them—that gun being the most accurate for which these quantities are smallest.

An exact definition of the accuracy of a gun is a matter of no little difficulty. Of two guns fired from the same place, the same number of rounds, at the same target, with their axis in the same direction, that would evidently be the more accurate which planted its shot more nearly together. But it is not always possible to test the practice of guns under precisely similar circumstances; therefore we must seek a definition equally true, but admitting, in addition, more elasticity in its application. Upon reflection, it becomes evident that an absolutely accurate gun is one with which, fired under identical circumstances, the chance or probability of striking the same spot twice amounts to certainty. Adopting the mathematical notion of probability, this will be represented by *unity*—guns less accurate having probabilities represented by fractions. Such a mode, though suggested, has not been accompanied by the requisite tables to render it of general use.

It is easier to determine, from the practice of the gun itself, a rectangle with which there would be an equal chance of any shot from the gun striking or not striking; or, if a given number of shots were fired, half the number might be expected to fall within the area. The accuracies of two guns would be inversely as these rectangles for the same range. This method was proposed by Captain Noble, R.A., who furnished the following formula for application. If a be the length, and b the width of the area or rectangle required, then

$$a = 3.12 \times .8453, \frac{\text{sum of differences of ranges}}{\text{one less than number of ranges}};$$

$$b = 3.12 \times .8453, \frac{\text{sum of reduced deflections}}{\text{one less than number of deflections}}.$$

The relative precision of small-arms is decided by various methods. To determine the *centre of impact*, let the piece be pointed at the centre of a target stationed at the required distance, and fired a certain number of times, and let the positions of the shot-holes, measured in vertical and horizontal directions from the lower left-hand corner of the target, be arranged as in the following table:

No. of Shot.	Distances from lower left-hand corner, in feet.	
	Above.	Right.
1	9	10
2	0	4
3	5	8
	3)14	3)22
	4.67	7.33

The sum of all the vertical distances divided by the number of shots gives the *height* of the centre of impact above the origin. Similarly the sum of all the horizontal distances divided by the number of shots gives the *horizontal distance* from the origin to the centre of impact. Thus from the above table the co-ordinates of the centre of impact are 4.67 and 7.33. The co-ordinates of the centre of the target being 6 each, the centre of impact is 1.33 below and 1.33 to the right of the centre of the target. The co-ordinates of the centre of impact being known, the point itself is known, and its distance from the centre of the target is called the *absolute mean deviation*. This is equal to the square-root of the sum of the squares of its vertical and horizontal distances from the centre of the target. To obtain the mean deviation it is necessary to refer each shot-hole to the centre of impact as a new origin of co-ordinates, and this is done by taking the differences between each tabular distance and the distance of the centre of impact and adding them. The sum of all the distances thus obtained in one direction divided by the number of shots gives the *mean deviation* or *figure of merit*. A shorter rule may be found: for if there are m distances greater, and n distances less than the distance from the origin to the centre of impact, $\bar{x}$, calling a the sum of the greater and b the sum of the less, we may write

$$\frac{a - m\bar{x} + n\bar{x} - b}{m + n} = \frac{a - b + (n - m)\bar{x}}{m + n} = \textit{figure of merit}.$$

In using this formula, due care must be paid to the sign of $(n - m)$. This method might be applied to the fire of cannon by reducing the grazes to an imaginary vertical target, the angles of descent being assumed equal for all shot fired at the same elevation. Applying this formula to the table given above, we get 3.11 feet vertically, 2.22 feet horizontally, for the *mean deviation* or *figure of merit*.

The mean horizontal error is found by adding the horizontal distances by which the balls have missed the centre of the target, and dividing this sum by the number of balls; this quotient indicates how much the average of the balls have missed horizontally the point aimed at. It may be directly and quite readily found by using the formula employed above, substituting for x the horizontal distance of the *centre of the target* from the origin. Similarly the *mean vertical error* may be found, by using the same formula, with the substitution for $\bar{x}$ of the height of the centre of the target above the origin. The result shows evidently by how much the average of the shots have missed vertically. To get the absolute mean error there are two methods. The first is short and simple, and consists in calculating the hypothenuse of a right triangle, in which the other two sides are the mean horizontal and mean vertical errors. The second, which should be called the calculation of the *mean* of the *absolute errors*, consists in measuring for each ball its *absolute error*, a distance from the point aimed at, and to take the mean of these absolute errors by dividing their sum by the number of balls fired. This method is very long, since to have the *absolute error* of each ball it is necessary to square two numbers and then extract the square-root of these sums as the distance of the points struck have been measured upon the vertical and horizontal lines passing through the point aimed at. The results are not exactly the same; the mean of the absolute errors will be greater than the absolute mean error.

ACCUSED.—In a military sense, the designation of one who is arraigned before a Military Court.

A-CHEVAL POSITION.—When troops are arranged so that a river or highway passes through the centre and forms a perpendicular to the front, they are said to be drawn up in *à-cheval position*. Wellington's army at Waterloo was *à-cheval* on the road from Charleroi to Brussels. In cases where a river forms a perpendicular to the front, secure possession of a bridge is necessary; otherwise one half of the troops might be routed, while the remainder stood idly as spectators.

ACIDS.—Chemical compounds distinguished by the property of combining with bases in definite proportions to form salts. The most striking characteristics of acids are a sour taste and the property of reddening vegetable blues. They are also mostly oxidized bodies; and at one time oxygen was thought to be essential to an acid, as the name *oxygen* (the acid-producer) indicates. Subsequent experience has extended the definition. There is an important class of undoubted acids that contain no oxygen; and silex or flint, which, being insoluble, neither tastes sour nor reddens litmus-paper, is held to be an acid because it combines with bases and forms compounds like acknowledged acids. The oxygen acids, which are by far the most numerous class, are formed of elements (sulphur, nitrogen, chromium, etc.) with two or more equivalents of oxygen. The elements that form the strongest acids with oxygen are the non-metallic, and most of them have more than one stage of acid oxidation. Thus sulphur, with two equivalents of oxygen, forms sulphurous acid, symbol SO_2; with three equivalents it forms sulphuric acid, symbol SO_3. Similarly arsenic gives rise to arsenious acid (AsO_3) and arsenic acid (AsO_5). The higher stage of oxidation forms the stronger and more stable acid. All metals, except arsenic, that form acids with oxygen, have also, at a lower stage of oxidation, one or more oxides. To these oxygen acids must be added the organic acids, composed either of carbon and oxygen, as oxalic acid (C_2O_3), or of these two along with hydrogen, as acetic acid ($C_4H_3O_3$) and formic acid (C_2HO_3). There are also acids found in animal fluids or resulting from their decomposition, which contain nitrogen in addition to the three elements above named; such is uric acid ($C_{10}N_4H_4O_6$). The *hydrogen acids* are formed of hydrogen and a radical, either simple or compound. The most important of these, and the type of its class, is hydrochloric or muriatic acid (ClH); others are hydriodic (IH) and hydrocyanic acids (NC_2H). As all acids, however, even oxygen acids, possess acid properties —i.e., combine with bases—only when in combination with water, a new view of the constitution of acids is beginning to prevail, which makes hydrogen the real acidifying element in all acids. Thus, instead of considering vitriol as a compound of sulphuric acid and water (SO_3+HO), the hydrated acid is held to be the real sulphuric acid, and its rational formula to be (SO_4H). It thus becomes analogous to hydrochloric acid (ClH). This view has not only the advantage of bringing all acids into one class, but makes the theory of their combination with bases and of their capacity of saturation uniform and simple.

ACINACES.—An ancient Persian sword, short and straight, and worn, contrary to the Roman fashion, on the right side, or sometimes in front of the body, as shown in the bas-reliefs found at Persepolis. Among the Persian nobility they were frequently made of gold, being worn as a badge of distinction. The *acinaces* was an object of religious worship with the Scythians and others.

ACLIDES.—A kind of missile weapon, in Roman antiquity, with a thong fixed to it whereby it might be drawn back again.

ACOLUTHI.—In military antiquity, *acoluthi* was a title given in the Grecian Empire to the Captain or Commander of the body-guards appointed for the security of the Emperor's Palace.

ACONITE.—A poisonous plant, whose extract was much used by ancient races for poisoning arrows. The virulent *bikh* poison of India, equally fatal in its effects whether introduced into wounds or taken into the stomach, is prepared from the roots of several species. The *aconite ferox* of Nepaul, from which much of it is obtained, has been identified by Drs. Hooker and Thompson with *aconite napellus*. Two other Himalayan species, *aconite palmatum* and *aconite luridum*, are equally employed in its preparation. *Aconite album*, or white-flowered monk's-hood, a native of the Levant, and *aconite lycoctonum*, yellow-flowered monk's-hood, or wolf's-bane, a native of the Alps, are not unfrequent in our flower-gardens.

ACONTIUM.—In Grecian antiquity, a kind of dart or javelin, resembling the Roman *spiculum*.

ACOUSTICS.—The velocity of sound has been determined by ascertaining the time intervening between the flash and report of a gun, as observed at a given distance, and dividing the distance by the time. After many experiments in various countries, Van der Kolk assigned 1091 feet 8 inches per second, with a probable error of 3.7 feet, as the velocity of sound in dry air at 32° Fahr. More recent experiments by the Astronomer Royal at the Cape of Good Hope give 1096 feet. To this velocity may be added 1.11 feet for each degree Fahr. But air is not a perfect gas, and the variations of elastic force caused by a wave of sound passing through it are not uniform; so these measures, though approximately, may not be absolutely, correct. Furthermore, the rapidity of transmission depends upon the loudness of the sound; and Captain Parry found, in the polar regions, that the discharge of a cannon at a distance of 2½ miles was heard perceptibly sooner than the word ordering to fire, which, of course, preceded the discharge. There is also a gradual falling off in the speed of sound; and Regnault determined that a sound decreased in speed by 2.2 feet per second in passing from a distance of 4000 feet to one of 7500 feet. He also found that the velocity depended upon the pitch, the lower notes travelling faster than the higher ones; thus, the fundamental note of a trumpet travels faster than its harmonics. Sound travels faster in liquids than in air, and faster in solids than in liquids. Through iron, sound travels ten and a half times faster than through air. Experiments on telegraph-wire produce almost identical results. Different metals transmit sound in widely different degrees. Wertheim assigned 16,822 for iron and 4030 for lead, at a temperature of 68° Fahr. Except in a few cases, the loudness of a sound is less as the distance increases between the source of the sound and the ear. In an unlimited and uniform medium, the loudness of the sound proceeding from a very small sounding body varies inversely as the square of the distance. But to verify this fact it would be necessary to make a test at a considerable elevation above the earth's surface, the ear and source of sound being separated by air of constant density. As the density of the air diminishes, it would be found that the loudness of a sound at a given distance would decrease. The decay of sound due to this cause is observable in the rarefied air of high mountain regions. De Saussure found that the report of a pistol at a great elevation appeared no louder than would a small cracker at a lower level. But it must be stated that when air-strata of different densities are interposed between the sound and the ear placed at a given distance, the intensity depends only on the density of the air at the source itself; whence it follows that sounds proceeding from the surface of the earth may be heard at equal distances as distinctly by a person in a floating balloon as by one situated on the surface itself; whereas any noise originating in the balloon would be heard at the surface as faintly as if the ear were placed in the rarefied air on a level with the balloon. This was exemplified by Glaisher, the aeronaut, who at an elevation of 20,000 feet heard with great distinctness the whistle of a locomotive passing beneath him. The prolonged roll of thunder, with its manifold varieties, is partly to be ascribed to the reflection of the sound by mountains, clouds, etc., but is mainly due to the comparatively low rate of transmission through air. The explanation will be more easily understood by noting the case of a volley fired by a long line of troops. A person at a given point in the line would hear the sound of the nearest musket first, and of the others in the order of distance, and the effect would be a prolonged roll, concluded by the musket most remote from the hearer, though all were fired at the same instant; and the roll would gradually decrease in loudness. If he stood exactly opposite the centre of the line, the reports from either end would reach him simultaneously and the effect would be more nearly a loud crash. If the soldiers formed a circle, the listener in the centre would hear a single explosion, since the report of every gun would reach his ear at the same instant, and the whole explosion would be equal to that of the sum of all the separate discharges. By varying the form of arranging the troops, corresponding variations in the sound would be produced. Keep in view, then, the fact that flashes of lightning may be regarded as representing lines of troops, at the points and along the ranks of which explosions are generated at the same instant of time; then consider the variety of distance and position relative to the electric discharge of the listener, and we find no difficulty in accounting for the rolling peals of thunder. In a mountainous region this rolling is greatly augmented by reverberations or echoes from the steep declivities.

ACQUEREAUX.—A machine of war, which was much used in the Middle Ages to throw stones.

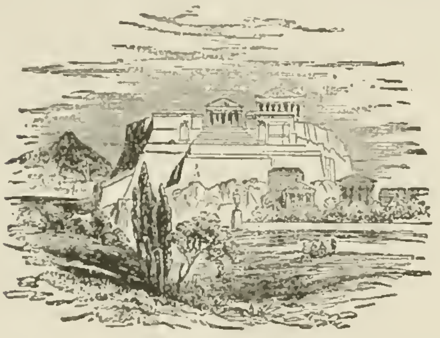
ACQUIT.—To release or set free from an obligation, accusation, guilt, censure, suspicion, or whatever devolves upon a person as a charge or duty; as, the Court *acquits* the accused. This word has also the reflexive signification of to bear or conduct one's self; as, the soldier *acquitted* himself well in battle.

ACQUITTANCE-ROLL.—In the British service, a document in which is shown the monthly settlement of the accounts of a troop, battery, or company, and to which the signature of the soldier is attached, countersigned by the Captain or Officer in Charge.

ACRE—ACRE-FIGHT.—An old duel fought by Warriors with sword and lance on the frontiers of England and Scotland. This dueling was also called *Camp-fight*.

ACROBALISTES.—A name given by the ancients to warlike races, such as the Parthians and Armenians, who shot arrows from a long distance.

ACROPOLIS.—The highest point of a city. Many of the important cities of Greece and Asia Minor were protected by strongholds so named. The acropolis occupied a lofty position, commanding the



Acropolis at Athens.

city and its environs; inaccessible on all sides except one, which had, for the most part, artificial defences. It contained some of the most important public buildings, especially temples, besides affording a last refuge in case of a hostile attack. The acropolis, like the castle of the Middle Ages, had formed the centre or nucleus around which the town gradually grew. Among the most celebrated of ancient times was that of Argos, whose name, Larissa, indicates its Pelasgic origin; that of Messenia, which bore the name of Ithome; that of Thebes, called Cadmea; that of Corinth, known as Acro-Corinthus; but especially that of Athens, which was styled preeminently the Acropolis.

ACTING ASSISTANT SURGEONS.—When it is necessary to employ a private physician in the military service, the Surgeon-General, the Medical Director, or, in emergencies, the Commanding Officer of a detachment may do so by a written contract at a stated compensation. An Acting Assistant Surgeon receives the quarters of an Assistant Surgeon of the rank of First Lieutenant, is furnished with fuel in accordance with the laws and regulations relating to commissioned officers, and when traveling under orders, the same traveling allowances as may be prescribed for commissioned officers of the Army by laws and regulations in force for the time; and when serving west of the Mississippi River, one daily ration in kind. He further receives, at the expiration of his term of service, traveling allowances as aforesaid, *for actual travel only*, to the place of making the contract, provided his contract shall not have been annulled for misconduct or neglect of duty. When a private physician is required to furnish medicines, he is allowed as compensation 25 to 50 per cent on the sum paid for his services, as may be determined by the Surgeon-General. In all cases, contracts are made in quadruplicate, two copies of which are forwarded, through the Medical Director, to the Surgeon-General with the prescribed oath of office; one copy being retained by the officer making the contract, and one copy by the physician contracted with.

The following is the form of Contract with a Private Physician for service as an Acting Assistant Surgeon, U. S. Army:

This contract, entered into this — day of ——, 18—, at —— in the State of ——, between —— ——, of the United States Army, and Dr. —— ——, of ——, in the State of ——, witnesseth: That for the consideration hereinafter mentioned the said Dr. —— —— promises and agrees to perform the duties of a medical officer, agreeably to Army Regulations, at —— [or elsewhere (1*)], [and to furnish the proper medicines (2*)]; and the said —— —— promises and agrees, on behalf of the United States, to pay, or cause to be paid, to the said Dr. —— ——, the sum of —— dollars for each and every month he shall continue to perform the services above stated. When on duty at a post or station where there are public quarters belonging to the United States, he shall receive the quarters in kind allowed by law to an Assistant Surgeon of the rank of First Lieutenant; when on duty at a post or station where there are no public quarters, he shall receive the commutation for quarters allowed by law to an Assistant Surgeon of the rank of First Lieutenant; he shall be furnished with fuel in accordance with the laws and regulations relating to commissioned officers, and when traveling under orders, the same traveling allowances prescribed for commissioned officers of the Army by laws and regulations in force for the time; and when serving west of the Mississippi River he shall receive one daily ration in kind. [And if the said Dr. —— —— shall be required to furnish his medicines, he shall be compensated therefor at the rate of —— per cent on his monthly pay, to be determined by the Surgeon-General (3*).] And it is furthermore agreed, that at the expiration of his term of service, the said Dr. —— —— shall receive traveling allowances, as aforesaid, for actual travel only, to the place of making the contract; provided said contract is not annulled for misconduct or neglect of duty, in which case no traveling allowances will be furnished. All of which shall be his full compensation, and in lieu of all allowances and emoluments. This contract to continue at least —— if not sooner terminated by the General commanding the Military Division or Department, the Medical Director, or the Surgeon-General.

It is furthermore expressly agreed and understood that, in conformity to the requirements of Section 3711 of the Revised Statutes, no member of, or delegate to, Congress shall be admitted to any share or part in this contract, or to any benefit to arise therefrom.

In this contract (1*) (2*) (3*) ha— been stricken out.

—— —— [Seal.]
—— —— [Seal.]

Signed, sealed, and delivered in the presence of

—— ——

The accounts of Contract Physicians are paid by Paymasters, and are made out in the ordinary form of an officer's pay-account, vouched for by a certificate thereon by the Commanding Officer that it is correct and according to contract, and that the services have been duly rendered, which certificate he does not make unless the contract has been approved by the Medical Director of the Department or by the Surgeon-General. The payments are made under the same rules that govern in the payment of officers at the same station. See *Contract Surgeons*.

ACTING SIGNAL OFFICER.—An officer temporarily serving as a Signal Officer. When an officer is detached from his regiment for Signal duty, he immediately reports for orders to the Chief Signal Officer of the Army, and thereafter is relieved from such detail only by orders from the Adjutant-General of the Army. When it is necessary to employ officers on Signal duty in the field, they may be temporarily assigned by orders of the Department Commander, but will not be part of the Department Staff. For this purpose officers who have been regularly instructed by the Chief Signal Officer of the Army are selected if practicable. The senior Acting Signal Officer of any command is the Chief of the Signal Parties serving in that command. Orders and instructions affecting their duties are transmitted through him. He is responsible that his officers and men are fully instructed and properly perform their duties. He keeps himself informed of the position of the Army and of the enemy, and, under the instruction of the General Commanding, establishes his stations to the greatest advantage. He takes care, by inspections and timely requisitions, that his parties are well supplied with equipments. He makes reports of his operations in the field from time to time to the General Commanding, and, with his assent, forwards certified copies of these reports to the Chief Signal Officer of the Army. He makes the usual returns and monthly statements, and at the end of each month a report to the Chief Signal Officer of the Army of the condition of his party, and all matters pertaining to its duties.

ACTINOMETER.—An instrument used in the laboratory and in powder-factories to measure the heat of the sun's rays; at first a common thermometer, the bulb blackened with nitrate of silver; then one with a large bulb filled with blue solution of ammonia and sulphate of copper, enclosed in a box with a plate-glass top, the expansion of the liquid to indicate the amount of heat. Prof. John W. Draper of New York next discovered that equal volumes of chlorine and hydrogen form chlor-hydric acid in direct proportion to the actinic intensity of the light and the time of exposure. Subsequently Bunsen and Roscoe hit upon the same plan. There are other actinic reactions; as, in a solution of chloride of gold and oxalic acid, the gold precipitates on exposure to actinic rays.

ACTION.—1. An engagement or battle between opposing forces; or some memorable act done by an officer, soldier, or detachment. The term is commonly used in artillery exercise when guns are brought into or change position with the view of attacking an opposing object. 2. In its large and general sense, a judicial proceeding before a competent tribunal for the attainment of justice; and in this sense it is applied to procedure, whether *criminal* or *civil*. In its more limited acceptation, it is used to signify proceedings in the *civil* courts, where it means the form prescribed by law for the recovery of a right or what is one's due. No action can be maintained by a citizen against a government without the government's express consent; except in rare special cases no suit can be brought by a citizen against the United States; relief must be sought by petition or in the Court of Claims. State Courts do not ordinarily contest acts of foreign states or sovereigns for anything done or omitted in their public character. Here negotiation takes the place of suit. Modern statutes have much simplified proceedings under this title, and many old forms have been abandoned. In New York an effort has been made to avoid all distinctive forms; there every other than a criminal is a civil action, having no other specific name; the design of the code being to give by this action every kind of relief which can be sought in civil causes.

ACTIVE SERVICE.—Duty against an enemy; operations in his presence. At present *active service* denotes serving on full pay, on the active list, in contradistinction to those who are virtually retired, and placed on the retired list.

ACTO—ACTON.—A kind of defensive tunic, made of quilted leather or other strong material, formerly worn under the outer dress and even under a coat of mail.

ACT OF GRACE.—In Great Britain, an Act of Parliament for a general and free pardon to deserters from the service and others.

ACTS OF HOSTILITY.—Proceedings of a diplomatic, commercial, or military character, involving a state of war between two or more nations. This was exemplified in 1870 in the altercation between Count Benedetti, the French ambassador, at the Court of Berlin, and the King of Prussia at the Kursaal of Ems. This is an instance of the first-named act of hostility. The second is shown in the case of the embargo laid on British shipping by the first Napoleon after the peace of Amiens in 1803. The third consists in the invasion of a friendly territory or firing on armed vessels of a friendly nation. A further act of hostility of a civil character is the forcible detention of the subjects of a friendly nation, which was exemplified in the seizing of non-belligerent British subjects residing in France in 1803.

ACTUARIUS.—A name given by the Romans to officers charged with the supplying of provisions to troops.

ADACTED.—A term applied to stakes or piles driven into the earth by large malls shod with iron, as in securing ramparts or pontons.

ADAMS BREECH-LOADER.—The distinguishing feature of this invention is the use and application of a piston for the purpose of loading, cleaning, and cooling a cannon *from* the breech. A rod passes through the breech or rear end of the gun and is fastened to a head or metallic piston, the circumference of which is equal to the bore of the cannon. Water is admitted at the breech to fill the bore when the piston is forced towards the muzzle. After the bore is cleaned and cooled, the new cartridge is attached to the piston and drawn back to the breech, in which condition the gun is loaded and ready to be again discharged.

ADAMS CUTTER.—This invention was made while the inventor was endeavoring to make two cutters, having exactly the same dimensions, for the Rodman pressure-gauge, having as a model a pressure-gauge designed for use with muskets. The knife-edge of this model was of the usual pyramidal form of the Rodman Cutter, and was .78 inch in length. Mr. Adams found that it was a mechanical impossibility to so file the faces of this pyramid as to have the two cutting or indenting edges identical in form and dimensions. He accordingly conceived the idea of turning a beveled edge with a circular profile upon the perimeter of a steel disk, as this could be accurately done in a lathe or mill, thus securing the perfect agreement of all cutters taken from that disk, and at the same time diminishing both the cost and time of fabrication. He took the Rodman Cutter above mentioned, and found by trial a circle which would pass through the three angular points of the edge. This circle, whose diameter he found to be 2.88 inches, he assumed as the one which should form the cutting edge of the new series of cutters to be fabricated. The steel disk was .233 inch thick. It was pierced with a central hole 1 inch in diameter for convenience of adjustment to an arbor of a lathe or mill. The bevels upon the two sides were equal. Hence the cutting edge itself is an arc of a circle with a diameter equal to 2.88 inches, and is formed by the intersection of two right cones, turned base to base (bases circular), and having a common axis. This makes the *bottom* of the cut, or indentation in the copper block, an arc of a circle, and the limiting lines of the *same* indentation upon the surface of the block arcs of two equal hyperbolas. The *cutter-block* is rectangular in shape, 1.18 inches long, .74 inch wide, and .74 inch thick. A groove is planed in one of the longer sides .2 inch deep, and sufficiently wide to receive the indenting edge. On the opposite side is drilled a hole .4 inch deep and .5 inch in diameter, for the reception of the larger end of the piston. In the bottom of this hole a smaller one is countersunk for a small screw which projects into the cutter-groove and serves to hold the indenting segment in position after insertion. This segment projects .3 inch from the cutter-block and is engaged .2 inch in that block. See *Benton Dynamometer*, *Circular Cutter*, and *Pressure-gauge*.

ADAPTER.—A gun-metal bush, used when shells having the obsolete Moorsom-gauge fuse-hole are fired with fuses which are not adapted to this fuse-hole. The pattern adapter now in use is known as the "G.S. adapter," which screws into the Moorsom fuse-hole. There are two distinct adapters, one for spherical shell, the other for rifled shell. Up to the year 1867 all shells for the larger rifled ordnance down to the 40-pdr. L.S. and the 20 pdr. S.S. common shell were made with the Moorsom or naval fuse-hole. Since then all new shells have been tapped with what is termed the G.S.-gauge fuse-hole, and shells already in service which have not this sized hole receive the G.S. adapter. The shape of the inside of the adapter is conical, the outside cylindrical.

ADARGA.—A Spanish-Moorish targe, made of supple leather, and 30 by 38 inches. It was used about the close of the sixteenth century.

ADDISCOMBE SEMINARY.—An Institution near Croydon, Surrey, England, for the education of young gentlemen intended for the military service of the East India Company. Closed in 1861. See *Cadet*.

ADIT.—A nearly horizontal passage opened for the purpose of draining a mine; it serves incidentally to explore the rock through which it passes; when filled with water, often used as a canal by which the products of the mine may be transported. Water raised from a depth greater than that reached by the adit is discharged through it, saving the cost of raising still farther to the top of the shaft. An adit opens in Cornwall at the level of the sea, and extends inland about 30 miles, draining the district of Gwennap. It meets some shafts at the depth of 400 feet. The "Ernest August" adit in the Hartz, completed in 1864, is 13 miles long. The "Joseph II." adit at Schemnitz, in Hungary, is 12 feet high, 10 feet wide, extends 12 miles to the valley of the Gran, and is used as a canal and a railway.

ADJOURN.—To suspend business for a time, as from one day to another; said of Military Courts. *Adjournment without delay* (*sine die*), indefinite postponement.

ADJUTANT.—As the derivation of the word implies (*adjuvare*, to help), *Adjutant* is the title of a Regimental Staff-officer who assists the Commanding Officer of a garrison or regiment in all the details of duty. He receives orders, and promulgates them to the several companies; he inspects escorts and guards before proceeding on their duty; attends to the drill of recruits, is accountable for the keeping of the regimental books, and ought to note every infraction of established rules. He is accountable to the Commanding Officer for the correctness of the regimental books, and is bound to bring to his notice all infraction of rules or orders. From the foregoing it will be seen that the duties of an Adjutant are unremitting. Agreeably to the Queen's Regulations, no officer is eligible for the appointment of Adjutant in the British service who has not obtained a first-class certificate at the School of Musketry, unless the regiment is on service abroad, and even then under certain restrictions. An Adjutant, generally holding the rank of Captain, is appointed to each brigade of artillery, to divisions of artillery of two or more batteries detached from their headquarters, and as his duties are somewhat different to those of a line or cavalry regiment, it may not be out of place to detail them. The duties, then, of an artillery brigade Adjutant are, to a great extent, confined to his office, as the several batteries composing his brigade are often stationed far from their headquarters. In his office are kept the books and records of the brigade; from it he circulates to detached batteries all orders received from the Commanding Officer and higher authority. He prepares correspondence on questions relating to the claims, services, enlistments, discharges, etc., of the men of his brigade; and when acting as the Staff-officer of the Royal Artillery in the division, he has to prepare all local returns which are submitted to the General Officer Commanding. He has, besides, to attend to the usual duties of the guards, prisoners, courts-martial, etc. As regards drill, Commanding Officers of batteries carry out or work their own drills independently, and recruits are trained at Woolwich, or at the centers of sub-divisions of districts. The Adjutant is responsible to the Commanding Officer for the state of exactness with which the regimental books are kept, and for the correctness of the duty rosters. He is to give his attention to everything appertaining to the discipline of his brigade, bringing to the notice of the Commanding Officer any irregularity or deviation from the established rules and regulations. In fact, nothing should escape his attention and observation.

ADJUTANT-GENERAL.—The principal organ of the Commander of an Army in publishing orders. The same organ of the Commander of a Division, Brigade, Geographical Division, or Department, is styled Assistant Adjutant-General. In the United States service, the main duties of the office of Adjutant-General are to publish orders, write out and issue instructions, receive and care for returns, keep account of the state of the army and the position of forces, regulate details of the service, carry on correspondence, preserve order; and in active war to establish camps, supervise hospitals, muster and inspect troops, form parades and line of battle, and care for prisoners and deserters. In the British service the Adjutant-General keeps an account of the strength of each regiment, distributes the orders of the day to the Brigade-Majors, and sees the troops drawn up for action. The *Adjutant-General of the Forces* is an officer of high rank at the Horse-Guards. To him all communications are addressed regarding leave of absence, discharging, recruiting, etc. Besides the Adjutant-General at the Horse-Guards, there are Deputy and Assistant Adjutants-General for special military districts.

ADJUTANT-GENERAL'S DEPARTMENT. — All General Orders which emanate from the Headquarters of the Army; the orders of detail, of instruction, of movement, and all general regulations for the Army, are communicated to the troops through the Office of the Adjutant-General. The record of all military appointments, promotions, resignations, deaths, and other casualties; the registry of all commissioned officers; the filling up and distribution of their commissions, and the preparation and issue of the Army Register, pertain to the Adjutant-General's Office. This Office is the repository for the records of the War Department which relate to the *personnel* of the military establishment, and to the military history of every commissioned officer and soldier of the Regular and Volunteer forces in the service of the United States. In this office the recruiting service is conducted; the names of all enlisted soldiers are enrolled, their enlistments and descriptive lists are entered, and all deaths, discharges, desertions, etc., are recorded; the general returns of the Army are consolidated; the monthly returns of regiments and posts and the muster-rolls of companies are preserved, the inventories of the effects of deceased officers and soldiers are entered, and the annual returns of the militia, required by law to be submitted to Congress, are prepared. The Adjutant-General's Department, as organized in the United States service, consists of one Adjutant-General, with the rank of Brigadier-General; two Assistant Adjutant-Generals, with the rank of Colonel, four Lieutenant-Colonels; and ten Majors; also, about four hundred enlisted clerks and messengers. The officers are generally on duty with General Officers who command Corps, Divisions, Departments, etc. The appointments to the lowest grade are selected from the Captains of the Army.

ADMINISTRATION.—The aim of a system of administration is to secure the performance of public duties, either directly, ministerially, or through the intervention of sub-agents. It is exercised over individuals or things, in civil matters, in courts of law, in political bodies, in the army and in the navy, and in general in all *financial* matters of government. Administration consists in establishing the ways and means of public receipts and expenditures; in watching over such employments; in the collection, care, and distribution of material and money; and in rendering and auditing accounts of such employments. Army Administration also embraces in war the means by which an army is supported in foreign countries by a General in campaign, when without regular supplies, without resorting to pillage. The wars of the French Revolution brought into use REQUISITIONS, a moderate kind of marauding, weighing more heavily upon countries than upon individuals. Requisitions are, however, an uncertain and unequal means of supply, and only enable an army to live from hand to mouth, and although practicable in offensive wars, are only justifiable in rapid movements, where time does not admit the employment of more certain means of supply. The system is less odious than pillage. Bonaparte skillfully adopted another method, in harmony with the spirit of wars of invasion, and also more reliable as a means of support. He substituted himself in place of the supreme authorities of the invaded country, and exacted *pecuniary contributions*, paying, or promising to pay, for all provisions and other supplies needed for his army. Some writers think that even this modified system can only succeed in gigantic operations, where an army upon a new soil successively gives repose to that previously occupied. Such a system was, however, well executed by Marshal Suchet in Spain, and a similar system was also matured and published in orders by General Scott while in Mexico. A treaty of peace, however, soon after was made, which put an end to military operations, and the system was therefore only partially executed. But with a sufficient army in a fertile country, the experience of the world has shown that if the inhabitants are protected from injuries, they will very generally sell to the best paymasters. It is therefore the interest of an invading army not to interfere with the ordinary avocations of citizens, and such is the modern usage. Bonaparte thought that an entire revolution in the habits and education of the soldier, and perhaps also in those of the officers, was essential to the formation of a veritable self-subsisting army. Such an army (he said) cannot exist with present ovens, magazines, administration, wagons, etc., etc. Such an army will exist when, in imitation of the Romans, the soldier shall receive his corn, shall personally carry his mill and cooking utensils, cook his own bread, etc., etc., and when the present frightful paper administration has been dispensed with. He added that he had meditated upon all those changes, but a period of profound peace was necessary to put them in practice. If he had been constrained to keep a large army in peace, he would have employed it upon the public works, and given it an organization, a dress, and a mode of subsistence altogether special. If such a scheme be practicable, no approach to it yet exists. The French have made some progress in developing a system of administration suited to a large army, but hardly a step in the direction pointed out by Napoleon. The French administrative service is a powerful means of moving armies in unforeseen emergencies. Its foresight provides resources, and the adversary soonest ready has the greatest chance of success. Not a century since, the French Government required six months' preparation before an army could move; now, in the language of General Lamarque, "The cannon is loaded, and the blow may be given at the same moment as the manifesto, and, if necessary, the blow may precede it." Ordinary army administration consists in the organization and other means by which various administrative duties are performed, necessary to provide for the wants of troops, and for all the foreseen demands of a state of war, including labor and the supplies for garrisons, sieges, etc. Such duties embrace subsistence-magazines, daily rations, forage, dress, encampments, barracks, hospitals, transportation, etc., etc., the administrative duties of Engineers, and of the Ordnance Department, estimates, accountability, payments, recruiting, and in general the receipt and proper application of money. The Secretary of War, under the orders of the President, is the head of military administration in the United States. The object of such administration is to provide, through the resources placed by law at his disposition, for the constant wants, regular or accidental, of all who compose the army. Good administration embraces a foreknowledge of wants, as well as the creation, operation, and watchfulness of the ways and means necessary to satisfy them; the payment of expenses, and the settlement of accounts. Army administration is divided into several branches determined by law. These different branches constitute the administrative service of an army, the operations of which should be so regulated that the Secretary of War will be always informed of the condition of each, and be able to exercise, subordinate to law, a complete financial control over each. The Adjutant-General of the army and the heads of administrative corps have each been assigned a bureau in the War Department, under the direction of the Secretary of War, for the management of the administrative duties with which they have been respectively charged. Administration and Command are distinct. Administration is controlled by the head of an Executive Department of the Government, under the orders of the President, by means of legally-appointed administrative agents, with or without rank, while Command, or the discipline, military control, and direction of military service of officers and soldiers, can be legally exercised only by the military hierarchy, at the head of which is the constitutional Commander-in-Chief of the army, navy, and militia, followed by the Commander of the Army, and other military grades created by Congress.

ADMISSIONS.—In a military sense, the Judge-Advocate is authorized, when he sees proper, to admit what a prisoner expects to prove by absent witnesses.

ADOBES.—Unburnt bricks made from earth of a loamy character containing about two thirds fine sand mixed intimately with one third or less of clayey dust or sand. The adobe under the action of the sun becomes a compact mass. Upon the Indian frontiers in New Mexico, in Mexico, and in Central America, adobe houses and adobe defences against the Indians are common structures. An adobe eighteen inches long, nine inches wide, and four inches thick is the best average size for moulding and for building. They are sometimes made sixteen inches long and twelve inches wide; in such cases they are all laid as *headers;* but with the eighteen-inch adobe they afford the means of binding the wall strongly by alternating headers and stretchers, as in brick-laying. In the hot spring and summer suns two or three days uninterrupted drying is sufficient at the first; the adobes are then carefully turned up on edge, so as to expose the under or still wet face to the southern and western sunshine. They should be left in this position from a week to fifteen days to dry thoroughly, when, if not wanted for immediate use, they may be stacked on edge and covered from the weather. Houses in New Mexico are seldom built over one story high. This enables the builder to place on the roof-covering at once, if necessary. But in all cases intervals in the work must be allowed, or the house will not only be unsafe, but, if immediately occupied, damp and disagreeable. The inside plastering with mud is most frequently done before the roof is covered in, so as to dry with the wall. If the wall must be left unfinished through the fall rains or the winter, the top of it is covered with a bushy weed called *cachanilla*, and this is covered with earth, to exclude water and protect it till the ensuing year. If door and window frames are at hand, the Mexicans prefer to put them in as they build; but oftener they leave gaps for doors and windows, unfilled with the frames, till the whole is finished. The adobes are laid with mud mortar made from the earth at the base of the wall; the holes thus formed are readily filled again with the rubbish from the house when completed. When the wall is ready to receive the roof-covering, heavy joists are laid, about two feet apart, on the top of the walls, strong enough to bear near a foot of earth all over the roof; the joists, as they rest upon the wall, are supported upon boards, or plates as they are called, to distribute the weight of the roof and prevent the joists from crushing into the walls. Across the joists, and over the whole roof, averaging about two inches in diameter, poles are now placed, the largest on the highest side of the roof to begin the slope, and on this is placed a close covering of the *cachanilla*, which is aromatic and keeps out bugs; it is evergreen, and a plant of the most suitable length to fill the interstices in the poles. Small willow brush is often used in the absence of *cachanilla*. The earth-covering of the roof is now put on, extending all round the roof to the parapet above the joists, which is only one half the width of the wall below; this brings the dirt roof to cover over one half the width or thickness of the wall, by which leaks in the room below are prevented. An adobe house, if well secured, is warmer in winter and cooler in summer than one of wood or brick. The brick is cold and damp; the adobe is dry and a much worse conductor of heat—no furrowing or lathing is necessary—and the rough inside can be whitewashed or slapped with plaster. The durability of adobe walls is extraordinary. The Pecos Church, not far from Santa Fé, is more than one hundred years old; its mud walls (adobe) are as firm to this day as a rock, and they cannot be less than fifty feet high.

ADVANCE—ADVANCED.—Any portion of an army which is in front of the rest. The term is figuratively applied to the promotion of officers and soldiers.

ADVANCED COVERED-WAY.—A *terre plein* on the exterior of the advanced ditch, similar to the first covered-way.

ADVANCED DITCH.—An excavation beyond the glacis of the enceinte, having its surface on the prolongation of that slope, that an enemy may find no shelter when in the ditch.

ADVANCED-GUARD.—To keep an enemy in ignorance of the state of our forces and the character of our position is one of the most indispensable duties in war. It is in this way that we oblige him to take every possible precaution in advancing; forcing him to feel his way, step by step, and to avoid risking his own safety in hazarding those bold and rapid movements which, when made against a feeble or an unprepared enemy, lead to the most brilliant results. This object is effected by placing between the position occupied by the main force and the presumed direction of the enemy a body detached from the main force, but acting always with reference to it, termed an *Advanced-Guard*. This term is used for any body of troops so separated from the main body, whatever its strength and composition, and whether the troops be in position or on a march. For a large force the advanced-guard is necessarily composed of troops of all arms; its strength being proportioned to that of the main force; the more or less resistance of an independent character it may be required to make; and the greater or less extent it may be found necessary to embrace, by its advanced-posts, on the front and flanks, to watch and anticipate every movement of the enemy. The proportion of the advanced-guard to the main body may vary from a third to a fifth of the total force. In armies of some strength, or large *corps d'armée*, particularly where the nature of the country requires a wide development of advanced-posts, the larger proportion is demanded; as at least one third or even one half of its strength will be required for the advanced-post service. In a small force of two or three thousand men, one fifth will usually be all that can be well spared for the same purposes. Our purpose, in all cases, should be to keep the enemy in a state of uncertainty as to our actual force and movements; and this can be effected only by keeping constantly between him and our main body a force of sufficient strength to offer an obstinate resistance, if necessary, to every attempt he may openly make to gain information; and even to act offensively against him, when occasion offers, so as to keep him in doubt as to the actual character and number of the troops before him; the old military axiom being always kept in mind, that "*a sword opportunely drawn frequently keeps another back in its scabbard.*" In all defensive positions the advanced-guard and its advanced-posts should retire slowly but circumspectly, so that the main body may have time to take all its defensive measures. In the offensive, the attack of the advanced-guard should be decided and vigorous; pressing upon the enemy at every point; and leaving nothing undone to demoralize him, by the confusion which so often follows from an impetuous onset. Whilst in position the advanced-guard should take advantage of the natural or other obstacles on its front and flanks which are within supporting distance; to strengthen itself, and gain supports for its advanced-posts. In this way its means of resistance, whether acting offensively or otherwise, may be greatly augmented. Ground of this character taken up by the troops should not be abandoned without very cogent reasons for it; since, should circumstances bring about a forward movement, it might cost more to regain what was given up than to have maintained it obstinately at first. The ground to be taken up by an advanced-guard and embraced within its advanced-posts should be carefully chosen. To take position where the movements of the enemy can be well watched, whilst our own troops are kept concealed and not liable to a sudden attack either in front or flank, are the *desiderata* in such cases. If, in following this guide, it should lead to a development of advanced-posts which would be too weak at any point for a tolerable resistance, there remains but the alternative to retire slowly before the enemy,—taking care that he do not slip behind the outposts and their supports,—upon some central point to the rear, where the advanced-posts, united to the troops in reserve, may make a good stand, and from which, if the chances are favorable, they may advance upon the enemy and make him pay dearly for his temerity. In all affairs of advanced-guards great circumspection is to be shown, both by the officer in command of the advanced-guard, in throwing forward fresh troops to strengthen a point assailed, as well as on the part of the General-in-Chief, in sustaining the advanced-guard by weakening his main body. These are points that can only be decided on the spot. The safer rule, in all cases, is not to weaken the main defence, or main attack, by detaching from it to support a feeble point. If the force engaged, under such circumstances, does not suffice for its own defence, it is best for it to fall back in time and, taking position with the main body, endeavor, by their combined efforts, to turn the scales of victory in their favor. The duties of advanced-guards being so much more frequently to feel and occupy an enemy, preparatory to some decisive blow by the main body, than to engage him with a view to follow up any advantage gained, it follows, as a matter of course, that they should be composed of the most efficient and active light troops at the General's disposal. Such troops, in the hands of a bold, energetic, but prudent leader, will be the right arm of an army: prompt on all occasions; never taken at fault, they keep the enemy constantly occupied; harass him with fatiguing precautions to secure his flanks and rear; whilst their own force is kept relieved from these annoyances, and always fresh for any great emergency.

ADVANCED-LUNETTES.—Works resembling bastions or ravelins, having faces or flanks. They are formed upon or beyond the glacis.

ADVANCED-POSTS.—Positions taken up by a force in advance of the main body of an army, and in such a situation that they shall be within easy communication of it and of one another. The duties of the advanced-posts are the same whether the troops are stationary or in movement. They are: 1. To keep a good lookout for the enemy, and when in his immediate presence to take all means to be accurately informed of his strength, position, and movements; 2. Should the enemy advance, to hold him in check long enough to give the main body ample time to be prepared for his attack. By a faithful discharge of these duties, the whole army can, at all times and under all circumstances, be kept in a state of readiness for action without subjecting the soldier to any fatigue beyond the ordinary physical endurance of a well-developed manhood; as but a small portion, comparatively, of the force present is required to watch over the safety of the rest, and can therefore be frequently relieved, so that every one may have time sufficient for the repose demanded after extraordinary exertions. The object being to secure the front and flanks of the position occupied by the main body from any attempt either to reconnoiter or attack it, the detachments which form the advanced-posts must be so distributed as to embrace all the avenues by which the enemy can approach the position. The system adopted, in most services, to effect this object consists of two or three concentric lines of posts, disposed in a *fan-shaped* order. The exterior line, which forms the *Outposts*, embraces a wide circumference, and by means of a chain of *Sentinels*, posted in advance, prevents any one from penetrating to the rear between the posts without being seen. The second line, which is one of *Grand-Guards*, embraces a narrower circumference than the line of outposts, occupying the more important avenues from the outposts to the interior, so as to be in a position to support the outposts in case of necessity, and to receive them if driven in. The interior line consists of several strong detachments, termed *Pickets*, posted upon the main avenues to the position. They serve as supports to the two exterior lines, upon which they rally if forced to retire before the enemy. Besides these dispositions for security, *Patrols* are kept up between the line of posts, to keep the one informed of the state of the other; and also between the outposts and chain of sentinels, to see that the duties of the latter are well performed; and to search any ground not brought well under the eyes of the sentinels. The whole, in this way, forms a connected system for observing the enemy and for mutual support in case of attack. The ground taken up by the advanced-posts will depend on the capabilities which its natural features offer for defence; on the number and character of the approaches it presents to an enemy for attacking the front or flanks of the position occupied by the main body; and upon the facilities it may afford for communication between the posts. See *Outposts*.

ADVANCED-WORKS.—Works placed beyond the covered-ways of the enceinte and its outworks, but connected with them in a general system of defence, are termed *advanced* and *detached works*. The term *advanced-works* is applied to such works as, placed beyond the outworks, are still under the fire of either the enceinte or the outworks, so that the ground in advance of them will be swept by this fire; their ditches flanked by it; and their interior so exposed to it that, if the work were seized by an open assault, the assailant could be driven from it by this fire. Advanced-works are placed in positions which the assailant must necessarily make himself master of before he can approach nearer to the main work; or on points which overlook ground that cannot be swept by the fire of the enceinte; and sometimes on points which, inaccessible to the assailant, give good position from which a flank-fire can be brought to bear upon ground over which the assailant will be obliged to make his approaches. Restricted to these purposes, an advanced-work may be of great value in prolonging the defence; and every precaution should be taken to secure it from a surprise, and to give its garrison a safe means of communication with the main work upon which they can retire when forced to abandon their work. When there are full and strong garrisons, advanced-works, by judicious combination with those in their rear, may greatly enlarge the field of action of the garrison, by keeping the assailant at a distance and annoying him by frequent sorties in large bodies. See *Detached-Works*.

ADVANTAGE-GROUND.—That ground which affords the greatest facility for annoyance or resistance.

ADVERSARY.—A term generally applied to an enemy, but strictly an opponent in single combat.

ADVISING TO DESERT.—A crime punishable with death or otherwise as a Court-Martial may direct. The Articles of War provide that any officer or soldier who advises or persuades any other officer or soldier to desert the service of the United States shall in time of war suffer death or such other punishment as a Court-Martial may direct, and in time of peace any punishment excepting death which a Court-Martial may direct.

ADYNATI.—An ancient name for invalid soldiers receiving pensions from the public treasury.

AEEN.—A tree which grows in the Madras Presidency at Coimbatore. It is very hard, heavy, and durable under water. It is said to be found in all the teak-forests of India and Burmah. A cubic foot of unseasoned wood weighs from seventy to seventy-three pounds. It is used in the Bombay Gun-carriage Agency for shafts, handspikes, and yokes.

ÆGIDE.—A name, according to Homer, for a protecting covering wound around the left arm in the absence of a shield; used by Jupiter, Minerva, and Apollo.

ÆGIS.—The shield of Jupiter, which had been fashioned by Hephæstus (Vulcan). When Jupiter was angry, he waved and shook the ægis, making a sound like that of a tempest, by which the nations were overawed. The ægis was the symbol of divine protection, and became, in course of time, the exclusive attribute of Jupiter and Minerva.

ÆNEATORES.—In military antiquity, the musicians in an army, including those who sounded the trumpets, horns, etc.

ÆRARIUM MILITAIRE.—The war-treasury of Rome, founded by Augustus. In addition to other revenues, the one-hundredth part of all merchandise sold in Rome was paid into it.

ÆRO.—A basket used by the Roman soldiers for carrying earth to construct fortifications.

AÈRODYNAMICS.—That branch of science which treats of air and other gases in motion. It examines first the phenomena of air issuing from a vessel, which correspond in many respects with those of water. Much depends, as in the case of water, upon the nature of the orifice, whether a mere hole in the side of the vessel, or a tube or adjutage. Another subject of aerodynamics is the motion of air in long tubes, where the resistance of friction, etc., has to be ascertained. That resistance is found to be nearly in proportion to the square of the velocity, to the length of the tube, and inversely to its width. Aerodynamics examines also the velocity of air rushing into a vacuum, of wind, etc. The instrument used for the latter purpose is called an anemometer. Air is found to rush into a void space at the rate of from 1300 to 1400 feet per second. One of the most important inquiries in aerodynamics is the resistance offered to a body moving in air, or—which is the same thing—the pressure exerted by air in motion upon a body at rest. The law may be stated, with sufficient accuracy for practical purposes, as follows: *The resistance or pressure is proportional to the square of the velocity.* We might conclude from reason, without experiment, that such would be the case; for if one body is moving through the air four times faster than another of the same size, not only will it encounter four times as many particles of air, but it will give each of them four times as great an impulse or shock, and thus encounter 4×4, or sixteen times as much resistance. This resistance is greatly increased by another circumstance, especially with great velocities. The air in front of the moving body becomes accumulated or condensed, and a partial or even entire vacuum is formed behind it. With a velocity of 1700 feet per second, for instance, the resistance is found to be about three times as great as the simple law of the square of the velocity would give. By the operation of these laws of resistance, a heavy body let fall with a parachute attached to it, comes, after a certain time, to move with a velocity approaching more and more nearly to a uniform motion.

AEROKLINOSCOPE.—An instrument to show differences of barometric pressure at remote stations. It consists of a vertical axis 30 feet high, turning on a pivot, carrying at the top a horizontal arm, of which the inclination can be varied according to the difference of barometric pressure at different sides of the station; the amount of dip being indicated by a sliding rod held in position by graded notches at the lower part of the axis, each notch corresponding with one millimeter in pressure. It is used in the weather service.

AEROSTATICS.—That branch of science which treats of the equilibrium and pressure of air and other gases, and of the methods of measuring it by the barometer and other instruments. The expansive force or pressure of atmospheric air varies with time and place. In a medium condition of the atmosphere, and near the sea-level, barometrical observations give the pressure or weight equal to that of a column of mercury 30 inches high, or of a column of water about 34 feet high. This makes the mean pressure of the atmosphere nearly 15 lbs. on every square inch. This mean pressure of the atmosphere is generally taken as the unit or measure of expansive or elastic forces generally: any particular pressure is said to be equal to so many atmospheres. Aerostatics also investigates the phenomena of the compression of gases; in other words, the relation between the elasticity and the density or volume of a gas. According to the law of Mariotte, the expansive force of one and the same body of gas is proportional to its density; or, which is the same thing, the expansive force of a body of gas under different degrees of compression varies inversely as the space which it occupies. If its elastic force, at one stage, be measured by 50 lbs., when compressed into half the space that force will be 100 lbs. Connected with this is the investigation of the variation of density and pressure in the several vertical strata of the atmosphere. It is obvious that the weight of the atmosphere must diminish as we ascend, as part of it is left below; and it results from Mariotte's law that, at different distances from the earth's surface, increasing in arithmetical progression, the atmospheric pressure diminishes in geometrical progression. This principle furnishes the means of measuring heights by the barometer. The elastic force of air and other gases is very much increased by heat, and consequently, when allowed, they expand. It is found that a rise of temperature of 1° of Fahrenheit causes any gas to expand $\frac{1}{480}$ of its own bulk; and this expansion is uniform. If adding 10° to the temperature of a body of gas increases its bulk 3 cubic inches, an addition of 20° will give an increase of 6 inches; of 50°, 15 inches; and so on. This law was discovered by Gay-Lussac, and has been verified by subsequent investigators. Both it, however, and that of Mariotte, can be looked upon as only nearly true, and that within certain limits.

ÆRUMNULA.—A wooden pole or fork, introduced among the Romans by Consul Marius. Each soldier was provided with one of these poles, which had attached thereto a saw, hatchet, a sack of wheat, and baggage. The soldier was compelled to carry it on a march.

AFABUAR.—A color-bearer of the ancient Icelanders. Every war-vessel had one of these officers aboard, who commanded the soldiers. The Afabuars were selected for this duty for their bravery.

AFFAIR.—An action or engagement not of sufficient magnitude to be termed a battle, but usually of more importance than a skirmish; as, the affair of outpost, or the affair of rear-guard.

AFFAMER.—To besiege a place so closely as to starve the garrison and inhabitants.

AFFIDAVIT.—In military law, an oath duly subscribed before any person authorized to administer it. In the United States, Judges, Justices, Notaries, Commissioners, and Commissioned Officers have authority of law to take affidavits. All the States appoint Commissioners in other States (residents of such other) to exercise the power. By New York law, affidavits may be taken anywhere for use in New York, if the person taking is authorized at the time and place to do so. Generally the authority of foreign officials to take affidavits must be certified or verified in court. When a Judge takes an affidavit in court his signature must be authenticated. Ministers and Consuls abroad have power to take affidavits, and so have British Consuls and nearly all similar officers. No particular form of affidavit is prescribed. An affidavit of merit is one made by a defendant, which sets forth that he has stated his case to counsel and is by him advised that he has a good defence to the pending action on its merits. This is required to protect plaintiffs from delay by frivolous shows of defence, but does not always effect the purpose.

AFFIRMATION.—A substitute for swearing, or taking an oath. In most of the States a witness may, at his own option, either swear or affirm, and with the same legal effect. In the act of affirming the right hand is raised while the formula is spoken. Formerly, in England, no evidence could be given except upon oath; but the privilege of making a solemn affirmation, instead of swearing on the Bible, has been extended to Quakers, Moravians, and Separatists in all cases; and to persons alleging conscientious motives in civil proceedings. Before native Courts-Martial in India, evidence is given on solemn affirmation. For Quakers and Moravians the formula is: "I do solemnly, sincerely, and truly declare and affirm." In the case of Separatists this affirmation further bears to be emitted "in the presence of Almighty God." The penalties of perjury are imposed on those who shall be proved to have affirmed falsely. A later statute has extended the privilege of substituting an affirmation for an oath to all persons who refuse to be sworn from conscientious motives—*the Judge being satisfied that the motives are conscientious.*

AFFORCIAMENT.—An old term for a fortress or stronghold: now obsolete.

AFRANCESADOS.—A name given to the Spaniards who upheld the oath of allegiance to King Joseph Bonaparte; also called Josephins (in the Peninsular War).

AGA—AGHA.—The Turkish title of a superior Military Commander; also of the higher officers of the seraglio.

AGAVE.—A genus of plants belonging to the natural order *Amaryllideæ*, and having a tubular perianth with 6-partite limb, and a triangular, many-seeded inferior capsule. They are herbaceous plants, of remarkable and beautiful appearance. There are a number of species, all natives of the warmer parts of America. By unscientific persons they are often confounded with aloes. The agaves have either no proper stem, or a very short one, bearing at its summit a crowded head of large, fleshy leaves, which are spiny at the margin. From the midst of these shoots up the straight, upright scape, 24 to 36 feet high, and at the base often 1 foot in diameter, along which are small, appressed, lanceolate bracteæ, with a terminal panicle, often bearing as many as 4000 flowers. In South America these plants often flower in the eighth year, but in our hot-houses not until they have reached a very advanced age; whence arises the gardeners' fable of their flowering only once in a hundred years. After flowering, the plant always dies down to the ground, but the root continuing to live sends up new shoots. By maceration of the leaves, which are 5 to 7 feet long, are obtained coarse fibers, which are used in America, under the name of *maguey*, for the manufacture of thread, twine, ropes, hammocks, etc. This fiber is also known as pita flax. It is now produced to some extent in the south of Europe. It is not very strong or durable, and if exposed to moisture it soon decays.

The ancient Mexicans employed it for the preparation of a coarse kind of paper, and the Indians use it for oakum. The leaves, cut into slices, are used for feeding cattle. A species known as *Agave mexicana* is particularly described by Humboldt upon account of its utility. When the innermost leaves have been torn out, a juice continues to flow for a year or a year and a half, which, by inspissation, yields sugar; and which, when diluted with water and subjected to four or five days' fermentation, becomes an agreeable but intoxicating drink, called *pulque*, to which the Mexican Indians not unfrequently sacrifice both fortune and life.

AGEMA.—A kind of soldiery, in the ancient military art, chiefly in the Macedonian army. The word is Greek, and denotes vehemence, to express the strength and eagerness of this corps.

AGENCY.—A certain proportion of money which is ordered to be subtracted from the pay and allowances of the British Army for transacting the business of the several regiments comprising it.

AGENT.—In the British service, a person authorized by the government to manage the monetary affairs of regiments in the army, as a kind of military banker. In early times, persons were employed to effect the purchase and sale of commissions in the British army (the only army in which this strange system of purchase existed), without much reference to honesty or fitness; but to prevent pernicious trafficking, no one was after 1809 permitted to manage these transactions except the authorized Army Agent, under a heavy penalty. The Agents were also bound down by restrictions, in relation to any pecuniary advantage derivable by themselves from the sale and purchase. Their business, however, is now confined to the regular expenditure of government money. Every regiment has an Agent, selected by the Colonel, and empowered by him to be his representative in the monetary arrangements of the Corps. The Colonel is responsible to the Crown for the honesty of the Agent; but the Agent is in many ways regarded as a servant of the public. When money is wanted for the regular expenses of the regiment, the Agent applies to the War Office; whereupon the Secretary of State for War issues an order to the Paymaster of the forces to advance the requisite sum; the Paymaster does so, and takes a receipt from the Agent. There is an annual settlement of accounts between the Paymaster and the Agent, each one paying or receiving, according to the side on which excess or deficiency may appear. The Agent then distributes the pay and other charges of the regiment. The tendency of recent alterations has been greatly to reduce the public functions of the Agents, who now only receive £15,000 from the State, while in 1858 they had £40,000. The percentage allowed to Agents for their trouble in paying the full pay of officers was allowed for by the State, and was included among the annual army estimates; but the officer generally bore this charge in relation to half-pay and allowances. The Agent conducted all correspondence, and sent all the requisite notices concerning pay and payment; the Colonel of the regiment took no part in the matter. The details of the system varied considerably at different times, and in different portions of the British dominions. Sometimes the Agent received twopence in the pound on the amount of pay; sometimes three halfpence in the pound, with an addition varying from sixpence to one shilling per day for each company of infantry or troop of cavalry; sometimes (in Ireland and in the Colonies) a fixed annual salary. When the Colonels of regiments provided the men's clothing, under a system now abandoned, the Agents were very intimately mixed up with the transactions; but at present the duties of those Agents are limited to the following: applying monthly to the War Office for the money required for each regiment; receiving that money; applying part of it to the payment of officers; disbursing the regimental paymasters' bills for the cost of the expenditure; paying soldiers' remittances for the benefit of their families; settling the effects and credits of soldiers. Many experienced government officers have recommended the abandonment of the system, and the paying of all moneys by the War Office direct, as a measure of simplification and economy.

AGGER.—The middle part of a military road raised into a ridge, with a gentle slope on each side to make a drain for the water and keep the way dry. The term also denotes a work or fortification used both for the defence and attack of towns, camps, etc., termed among the moderns, lines. Agger is also used for a bank or wall erected against the sea or some great river to confine or keep it within bounds, and called by modern writers a sea-wall.

AGIADES.—A kind of pioneers in the Turkish armies, or rather field Engineers, employed in fortifying the camp, etc.

AGIEM-CLICH.—A very crooked saber, rounded near the point; an arm much in use in Persia and Turkey.

AGMEN.—The name given by the Romans to an army when on the march.

AGMINALIS.—The ancient name given to a horse which carried baggage, equipments, etc., on his back; now termed pack-horse.

AGUERRI.—A term frequently applied to an officer or soldier who is known to be experienced in war.

AIDE-DE-CAMP.—An officer who may be regarded as a kind of superior confidential attendant upon a General in active service. The Aide-de-Camp is the organ of the General. He carries all orders on the field of battle: these he is to deliver in the plainest terms, so as to be distinctly understood; and when so understood, the orders are to be as implicitly obeyed as if the General himself were present and speaking. As an example of the importance of this matter may be adduced the brilliant but disastrous light-cavalry charge at Balaklava in the autumn of 1854. Lord Raglan sent a message, partly verbal and partly written, to the Earl of Lucan concerning a particular piece of strategy at a certain time and place; the message was misconceived, and the Earl of Cardigan was directed to make a military movement perfectly hopeless in its character, resulting in a very serious cavalry loss; although the incident presented a fine display of heroism united with discipline. An Aide-de-Camp also acts as Secretary to the General, and assists him in his correspondence when he has not specifically a Military Secretary. He aids likewise in dispensing the courtesies of the General's house or tent. Generals are much accustomed to appoint their sons or other relations to this confidential post. Aide-de-camps vary in number according to the rank of the General Officer. In the British service, before an officer can be appointed as Aide-de-Camp, he must have been two years with his regiment, and must pass an examination. Aide-de-camps are not removed from the list of their regiments; and, most commonly, are Captains. Besides these Aide-de-Camps to Generals, the Queen has the power to appoint any number of Aide-de-Camps to herself, in her capacity of nominal Head of the Army. There are no particular duties attached to the office; but it is much sought after, both as an honor, and as conferring on the holder the rank of Colonel in the Army. There are six who receive daily pay as Aide-de-Camps, and who take it in turn to attend the Queen on State Occasions. In the year 1876 there were no fewer than 33 military Aide-de-Camps to the Queen, of whom 8 were Peers of the Realm; but of the 33, only 19 belonged to the army; the rest, except two of the marines, being militia officers, whose appointments are purely honorary. In addition to all the above, there are naval Aide-de-Camps to the Queen.

AID-MAJOR.—The French name for the Adjutant of a Regiment. It is still in use.

AIGREMORE.—A term used by the artificer in the laboratory to express the charcoal in a state fitted for the making of powder.

AIGUILLE.—An instrument used by Engineers to pierce a rock for the lodgment of powder, as in a mine, when blasting or blowing up is to be effected.

AIGUILLETTE.—A decoration, consisting of bullion cords and loops, which was formerly worn on the right shoulder of a General Officer, but is now chiefly confined to officers of the Life-Guards and Horse-Guards in England, and to officers of the Adjutant-General's Department, Aides-de-Camp, and Adjutants of regiments in the United States Army. The Aiguillette, instead of being permanently attached to the shoulder-knot, may be made separate so as to be attached to the coat underneath the knot by means of a strap or tongue passing through the lower fastening of the knot. Aides-de-Camp and the Military Secretary, who have *increased* rank, wear the Aiguillette with the uniform of the General Staff. Aides-de-Camp to Major- and Brigadier-Generals wear the Aiguillette with the uniform of their regiments and corps. See *Shoulder-knots*.

AILE.—A French term denoting a wing or flank of an army or fortification.

AILETTES.—Appendages to the armor worn by knights in the thirteenth century. They were sometimes made of leather, covered with a kind of cloth called *carda*, and fastened with silk laces. The form was sometimes circular, sometimes pentagonal, cruciform, or lozenge-shaped, but more usually square. Sometimes they were not larger than the palm of the hand; in other instances as large as a shield. In most instances, the Ailettes were worn behind or at the side of the shoulders. Whether the purpose of these appendages was as a defense to the shoulders in war, as an ensign or mark to indicate to the followers of the knight his place in the field, or as armorial bearings, is not now clearly known; but the first supposition is the most probable. Ailettes are figured on many effigies, monumental brasses, and stained windows in cathedrals and old churches.

AIM.—A word of command for bringing a musket, piece of ordnance, or any other missive weapon to its proper line of direction with the object intended to be struck. To aim a musket, raise the piece with both hands, and support the butt firmly against the right shoulder, the left elbow down, the right elbow as high as the shoulder, the body inclining slightly forward; incline the head upon the stock so that the right eye may quickly perceive the notch of the rear-sight, the front-sight, and the object aimed at; the left eye closed, the right thumb extended along the stock, the forefinger on the trigger. When recruits are formed in two ranks, the front-rank men lower the right elbow slightly, in order to facilitate the aim of the rear-rank men. Each rear rank man in aiming carries the right foot about eight inches to the right, toward the left heel of the man next on the right, inclining the upper part of the body forward, bending slightly the right knee.

The men, in squads of from twelve to twenty, are first instructed in the principles of aiming, which may be taught in-doors. To this end a target is made, having a black circle six inches in diameter for the center; exterior to it are four concentric rings, alternately white and black, each ring from two to four inches wide. The target is posted at various distances from a table, tripod, or other support, on which rests a sand-bag, the upper surface of which should be at the height of the shoulder. In the first lessons, a small white wafer will be pasted over the center of the target. The wafer and sand-bag being arranged, the instructor, who is always a commissioned officer, indents the sand-bag slightly, and, placing the musket on it, aims it accurately at the target. He then requires the men separately to examine the aim, causing them to close the left eye. He next deranges the piece and causes the men successively to direct it on the wafer, verifying each aim, and deranging it before the next man steps forward. The instructor next aims the piece above, below, to the right or left of the target, and requires the men to state the error and correct it. These lessons are repeated at different distances, the instructor exposing faults and requiring the men to correct them. To aim at objects beyond the *point-blank*, the instructor commands: (1) *At three hundred* (or *so many*) *yards*, (2) AIM. At the first command, the men seize the slide between the thumb and forefinger, open the leaf to the front, and move the slide until the upper line coincides with the distance marked on the leaf; the leaf is then placed at right angles to the axis of the piece. At the command *aim*, the men aim through the notch in the slide, and the front-sight. After firing, the leaf is turned back to its proper position.

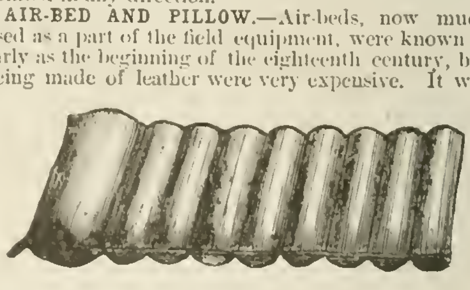
Having taught the principles of aiming, the instructor next impresses upon the minds of the men that accuracy of fire depends on pulling the trigger steadily. The piece being in the position of *ready*, the instructor directs each man to place the forefinger on the trigger, so that the second joint shall touch the right side. The trigger is pulled by a steadily-increasing pressure of the finger in the direction of the axis of the piece, the breath always being held from the commencement of the pressure till the hammer strikes. The men having become accustomed to the pressure necessary to discharge the piece, are next required to aim it carefully, either sitting or standing, and to pull the trigger, preserving the aim, keeping the right eye still directed on the object. If the trigger be pulled by a convulsive motion, the muzzle will be moved to the right. After learning to pull the trigger without deranging the aim, the men are taught to support the recoil by pressing the butt firmly against the shoulder with the right hand; the left hand supports the weight of the piece, and steadies it in aiming. The trigger is pulled as before. If the particular rifle carries higher or lower than the average, it must be remedied by aiming with a fine or a coarse sight. The men are next given blank cartridges to accustom them to the noise of the piece and further confirm them in the principles of aiming and firing. See *Manual of Arms*, Fig. 16.

AIM-FRONTLET.—A piece of wood hollowed out to fit the muzzle of a gun so as to make it level with the breech, formerly in use among gunners. Wooden front-sights on a similar principle are still used on board ship in case of emergency, as when an accident occurs to the proper metal sights.

AIMING-DRILL.—A military exercise of great importance as a preliminary step in teaching men to aim fire-arms.

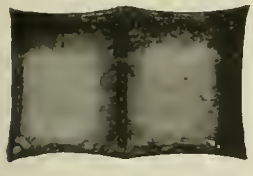
AIMING - STAND.—An instrument employed in teaching the theory of aiming with a musket. It usually consists of a tripod with a device mounted upon it which holds the gun and allows it to be pointed in any direction.

AIR-BED AND PILLOW.—Air-beds, now much used as a part of the field equipment, were known as early as the beginning of the eighteenth century, but being made of leather were very expensive. It was only after the invention of air-tight or Macintosh cloth that it became possible to use air in this way at a moderate cost. An air-bed as usually made consists of a sack in the form of a mattress, divided into a number of compartments, each air-tight; a projection at one end forms a bolster. Each compartment has a valve, through which the air is blown in by a bellows. The advantages of such beds in point of cleanliness, coolness, lightness, and elasticity are quite obvious. They are specially valuable in cases of sickness in the field, and in adding to the comforts of troops subjected to rapid move



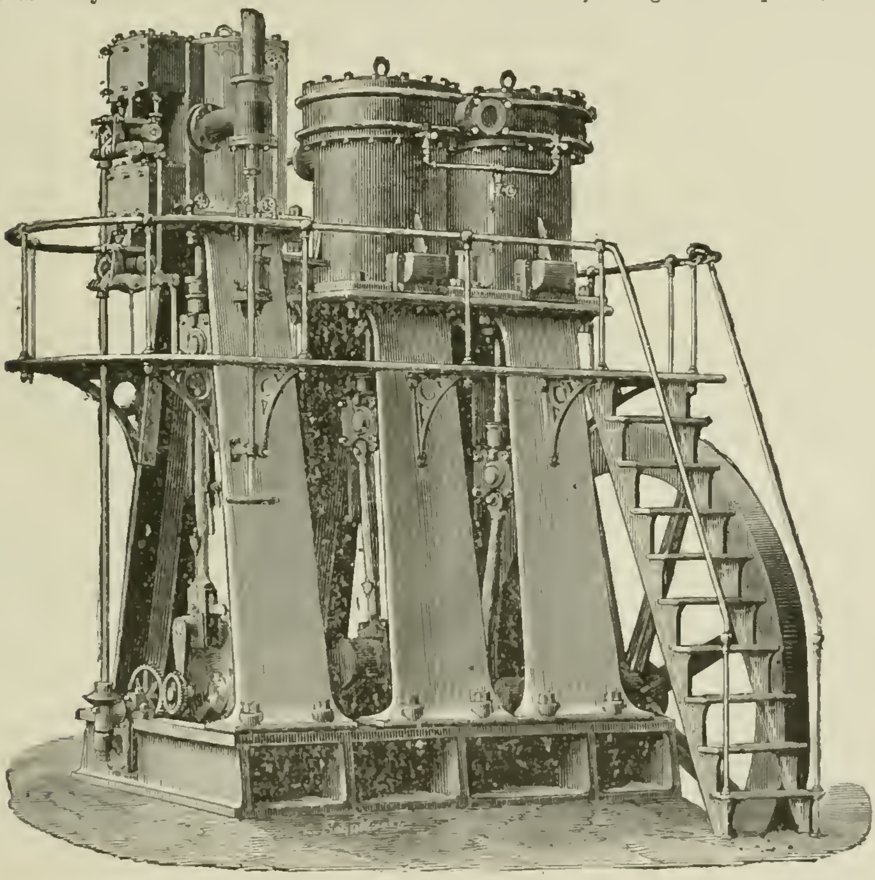
Air-Bed.

ments with limited means of transportation. The *air-pillow* is another contrivance of the same kind. Recently, vulcanized India-rubber, instead of cloth, has been used in the fabrication of such articles. The chief drawback to these contrivances is the liability to being spoiled by a rent or other injury. For use in localities where water is plentiful, these articles are constructed so as to be filled with water; but the air-filling is more satisfactory in all respects



Air-Pillow.

AIR-COMPRESSOR.—An obvious mode of employing air as a motive power is to compress it and then apply it in the manner of high-pressure steam. Although compressed air has been used for working small engines in confined situations, such as tunnels, it is not at all likely that it will ever come into extensive use, owing to the great waste of power attending it. This waste arises from two causes: first, the friction due to forcing the compressed air along a great length of pipe; and secondly, the loss from the dissipation of the great heat which results from its compression. If, say, 100 cubic feet of air is compressed into 1 cubic foot, it will become very hot, and although it is very easy to keep in the air, it is impossible to keep in the heat. In spite of every precaution, the heat will find its way through the vessel in which the air is confined, and through the pipes in which it is being transmitted, and this is equivalent to a portion of the air itself leaking out, because when the air is permitted to expand in working the engine, it will not attain the bulk it originally had of 100 cubic feet. The greater the original compression of the air, the higher its temperature will rise; and as this caloric, which cannot be kept from escaping, is practically a part of the bulk of the air, it follows that the loss of power from this cause will increase with the pressure or tension of the air. Even were it possible to prevent the escape of the heat by covering the vessels and pipes with some non-conducting substance, it would not be practicable to use the hot air in the same way as steam is used, because the lubricating material necessary to keep the piston and slide-valves from "tearing" would be decomposed by the high temperature. In steam-engines there is always a small quantity of water in the cylinders and slide-valves, arising from the condensation of a portion of the steam, and this suffices to lubricate the piston and valves. It is well known that when steam is *superheated* so highly as to prevent a slight condensation in the cylinder and slide-valves, they are very rapidly destroyed. Air rises in temperature when very much compressed, and we cannot use it until its temperature falls; and as this involves a great waste of power, it follows that where economy is of great consequence, air cannot be used as a mode of transmitting mechanical power. Indeed, no fluid can be economically used for transmitting power for any great distance. We have just seen that compressed air is very unsuitable; steam is even more wasteful, because it condenses into water in long pipes. Water itself loses much of its force from friction in passing through long pipes, unless they are of very large size; and in applying it to hydraulic cranes, where the weight to be raised varies, great waste of power arises from the fact that the cylinder in which the ram works has to be filled every time the crane is worked with water at the full pressure of 600 or 700 pounds to the square inch, even when a pressure one tenth of that amount would suffice to raise the weight. In short, the power actually used in working an hydraulic crane is always the maximum, even when the weight to be raised is a minimum. It



Burleigh Air-Compressor.

uses as much power to lift a hundred-weight as it does to lift a ton. The extreme handiness and other practical advantages possessed by the hydraulic cranes leave a large balance in their favor, notwithstanding their waste of power. In boring the Mont Cenis tunnel, air was compressed at the mouth of the tunnel by the abundant water-power easily obtainable there, and forced along to the working face through small iron pipes, for working the boring-machines. The tunnel through the Hoosac Mountain in Massachusetts has also been bored by compressed air working the rock-drills. The drawing represents the Burleigh Air-Compressor used in that work. It consists of a steam-engine connecting by means of a crank-shaft with two single-acting air-pumps. Want of space will not permit a description of this beautiful machine in detail; nor is it necessary. It is a compactly built, close-working machine, whose lines of motion are all the same, and whose action is such, and the play of the various parts so nicely balanced, that the strain upon them is equalized, counteracted, and brought within itself. By a nice adjustment of the cranks in their relation to each other, the greatest power of the engine is applied at the exact point of greatest resistance, so as to produce the best results at the least cost. The air, when compressed, is taken into a tank, or air-chamber, and thence carried to any desired point in pipes, in the same manner that steam is carried. Connection between the permanent pipes and drills upon the carriages is made by flexible rubber pipe, which is uncoupled when the carriage is run back for a blast. In reference to this machine, it may be added that drilling by compressed air is only one of the uses to which it may be applied, and to which it will eventually be made available: such as the ventilation of buildings; transmitting messages, packages, or passenger-cars in pneumatic tubes; driving street-cars; or supplying a very convenient and perfectly safe motor for running machinery. The feasibility of compressing air at any convenient point, and conveying it in iron pipes exactly as gas or water is carried along the streets of our cities, to be tapped and used wherever required, has already been demonstrated, and it cannot be doubted that ere long the plan will come into general use. It thus constitutes an efficient, handy, and safe power; makes no dirt or obnoxious gases; but, when exhausted into a room, after doing its work in the machines, furnishes the most ample and desirable ventilation. In this manner, power may be carried a great distance at comparatively small expense. At the Hoosac Tunnel the Burleigh Rock-Drill Company have carried it over three miles with no material loss of power.

AIR-CYLINDER.—A pneumatic buffer used in America to absorb the recoil of large guns. For 10-inch guns, one cylinder is used; for 15-inch guns, two. They are placed between the chassis-rails, to which they are firmly secured by diagonal braces. A piston traversing the cylinder is attached to the rear transom of the top carriage. When the gun recoils the piston-head is drawn backwards in the cylinder, and the recoil is absorbed by the compression of the air behind it. Small holes in the piston-head allow the air to slowly escape while the gun is brought to rest. The Hydraulic Buffer, largely used abroad, operates in the same way, water being used instead of air. See *Pneumatic Buffer*.

AIR-DRILL.—A drill driven by the elastic pressure of condensed air, and employed in mining and tunneling. The construction usually resembles the reciprocating steam-engine, compressed air being substituted for the steam; the drill-stock is attached to the piston-rod. See *Pneumatic Drill.*

AIR-ENGINE.—It is a well-known law, applicable to all thermo-dynamic engines, that (presupposing the merely mechanical part of the machine to be perfect) the heat converted into work bears the same proportion to the total heat given to the fluid that the range of temperature bears to the highest *absolute* temperature of the fluid. Thus, supposing an engine to receive steam at the temperature of 275° F. and discharge it at that of 120° F., the fraction of heat which it can convert into work will be $\frac{275-120}{275+461}$, or about 21 per cent of the total heat of the fluid. This proportion would be, of course, greatly reduced in practice, owing to imperfections in the machinery; but these being equally likely to occur in all prime movers, we need not consider them here. The *lowest* limit of temperature available being practically constant, fixed either by the temperature of the atmosphere or that obtainable in a condenser, it follows that greater economy can only be looked for

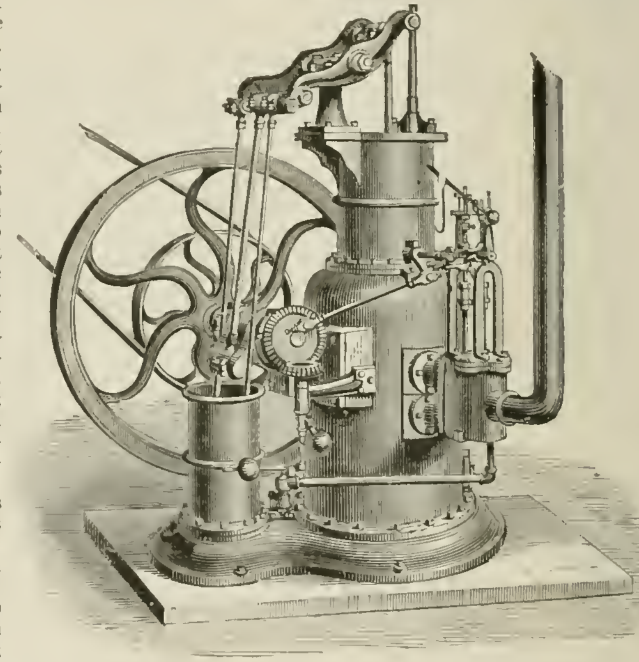


Fig. 1.

in the direction of increase of initial temperature. In ordinary steam-engines, in which the pressure and temperature increase simultaneously, the latter is limited by the former, which in its turn is kept, by considerations of safety, comparatively low. When, however, *superheated* steam (steam to which additional heat has been imparted without the corresponding addition of pressure) or heated air is used, the temperature is limited only by the power of the metals composing the machine to resist the destructive action of heat, or the chemical action of the fluid at that temperature. Heated air possesses the advantage over superheated steam as a motive power, that with it an explosion, in the usual sense of the word, is rendered almost impossible, and that, if one were to occur, it would be comparatively harmless. It also, of course, enables the boiler to be dispensed with.

Air-engines, in their principal working parts, are very similar to ordinary steam-engines. The heated air is introduced into a cylinder, as in Fig. 1, in which works a tightly-fitting piston, which is thus compelled to move up and down, and transfers its motion to a revolving shaft by means of a piston and connecting-rod in the usual manner. The motion of the piston results in all cases from the expansion of the heated air; the air is heated by means of a furnace, is introduced below the piston, raises it, and then is allowed to escape into the atmosphere. Air-engines are almost invariably single-acting; they are sometimes worked simply by heated air, and sometimes with the air which, having passed through the furnace, is mixed with all the gaseous products of combustion. The latter method has the immense advantage that it utilizes the heat which would otherwise be rejected into the chimney. The total efficiency of the machine is thus increased, although the efficiency of the engine proper, between the given pair of temperatures, remains the same.

The more heat carried away by the discharged air (the higher its temperature, in other words) the smaller evidently is, *cæteris paribus*, the range of temperature of the machine, and the less, therefore (as already explained), will be its efficiency. The distinctive principle of the Messrs. Stirling's air-engine consists in utilizing a great part of this wasted heat, and thus economizing fuel. This is effected by means of a "regenerator," or, more properly, "economizer," consisting of a chamber filled with metallic sieves of wire-gauze, through which the hot air is

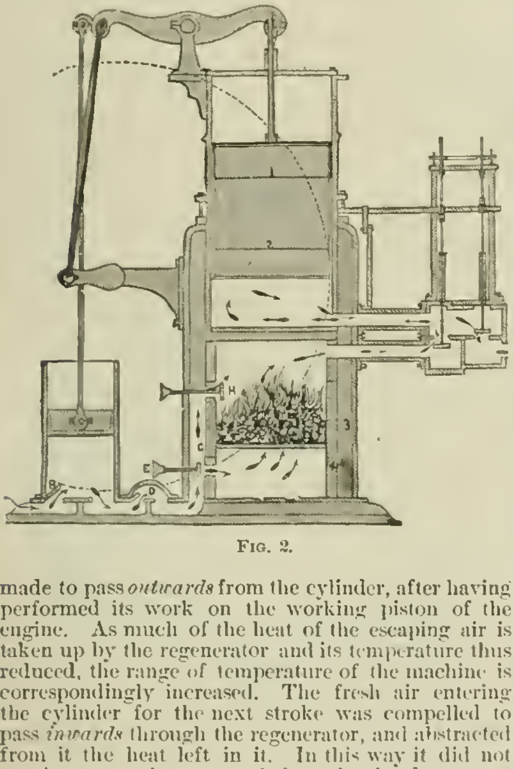

Fig. 2.

made to pass *outwards* from the cylinder, after having performed its work on the working piston of the engine. As much of the heat of the escaping air is taken up by the regenerator and its temperature thus reduced, the range of temperature of the machine is correspondingly increased. The fresh air entering the cylinder for the next stroke was compelled to pass *inwards* through the regenerator, and abstracted from it the heat left in it. In this way it did not require to receive so much heat in the furnace as would otherwise have been the case, and thus economized fuel. This method of preventing waste of heat was first discovered by the Rev. Dr. Stirling, who obtained a patent for it in 1816. In working with air at the ordinary pressure of the atmosphere, however, the engine was found to require to be of large dimensions as compared to a steam-engine of the same power; and in order to obviate this objection, compressed air was used. Several other difficulties were successfully surmounted by the Messrs. Stirling, and eventually two improved engines were constructed, one of which was tested to fully 40 horse-power. This latter engine did all the work of the Dundee Foundry Company regularly for upwards of three years, during which period they employed no other motor. At the end of this period it was laid aside, principally owing to the repeated failure of one of the heating vessels.

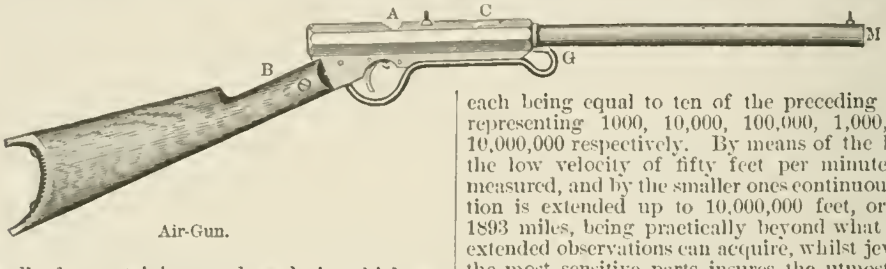
Captain Ericsson, in his attempt to introduce his caloric engine in the ship which bore his name, experienced precisely the same difficulties and disappointments, and tried nearly the same remedies, as the Messrs. Stirling. There seems little doubt, however, that he actually believed his "regenerator" was to make the *same heat* do work over and over again—to be a kind of perpetual motion—and under these circumstances it is not to be wondered at that his machines (notwithstanding some not very creditable maneuvering on the part of their upholders) entirely failed, and that in two years they were replaced by steam-engines. Air-engines have recently been constructed, in which the solar rays, concentrated by means of an arrangement of mirrors, are utilized as the source of heat. These have been called Solar Engines.

The improved Roper Engine, shown in section in Fig. 2, is regarded as a most satisfactory power for the light work of the Arsenal and Foundry. It is not an experiment, but a reliable power within the range of the sizes manufactured, built in a strong and substantial manner by skilled mechanics, and has proved by years of constant use that it really possesses the advantages claimed for it. Coal and air are the agencies employed in a way which insures the most perfect economy of the former and greatest expansion of the latter. The air at the temperature of the surrounding atmosphere is drawn into the air-pump and then forced directly into the fire, which burns in an air-tight furnace; combustion and expansion ensue, and as a result of the expansion of the air and gases produced by combustion a pressure is obtained in the fire-box, which is admitted to the cylinder and exhausted through valves, as a steam-pressure would be operated. The furnace is lined with heavy fire-brick, and as the air is brought in contact with the *fire*, and not hot iron plates, there are no heating surfaces to be destroyed by use.

During the past few years a number of small steam-engines have been placed in some of the Arsenals, being from their low price attractive to the managers. But however small such an engine may be, or however skillfully made, the fact remains that a steam-boiler requires the constant attention of an experienced man, and, as shown by frequent explosions, is dangerous under the most favorable circumstances. Any inexperienced person can, with a few instructions, take care of an air-engine as well as the best engineer, and in such a short time that his other duties would scarcely be interfered with. The wages of an engineer is a large item where a small amount of power is used, and is in many cases more than the power is actually worth. When this sum is added to the amounts saved in fuel and insurance, the result will show that an air-engine will pay for itself in a very short time, while the satisfaction of having a power which is in any case absolutely safe is a point not to be overlooked. No water being used either to make steam or condense air, the trouble and expense of keeping pipes in order is avoided, and there is no moisture about the engine to cause rust when not in use. The exhaust air can be conducted away in pipes, and used to warm rooms, heat japanning-ovens, or other industrial uses.

AIR-FURNACE.—A foundry term used to signify a furnace having a natural draft, no blast.

AIR-GUN.—An instrument resembling a musket, used to discharge bullets or darts by the force of compressed air instead of gunpowder. Various forms of construction have been adopted. The most usual plan is to insert a condensing syringe in the stock of the gun. The piston of this syringe is worked by an apparatus which passes through to the exterior of the gun; and this working causes a small body of air to be condensed into a chamber. The chamber has a valve opening into the barrel, just behind the place where the bullet is lodged. The gun is loaded from the muzzle, as ordinary muskets or fowling-pieces; and there is at that time just behind it a small body of highly compressed air, ready to rush out at any opening. This opportunity is afforded by a movement of the trigger, which opens the valve; the air rushes forth with such impetuosity as to propel the bullet. By a certain management of the trigger, two or three bullets, successively and separately introduced, can be fired off—if firing it can be called—by one mass of condensed air. Another form of Air-gun contains several bullets in a receptacle or channel under the barrel; by the movement of a cock or level one of these bullets can readily be shifted into the barrel; and thus several successive discharges can be made after one loading—on a principle somewhat analogous to that of the revolving pistol. Some varieties of Air-gun have the condensing syringe detached, by which means a more powerful condensation of air may be produced; this done, the air-chamber is replaced in its proper position behind the bullet in the barrel. Those Air-guns which present the external appearance of stout walking-sticks, and are thence called Air-canes, have a chamber within the handle for containing condensed air, which can be unscrewed and subjected to the action of the condensing syringe. One inventor has devised a form of Air-gun with two barrels—one of small bore for the reception of the bullets, and another of larger bore for the reservoir of condensed air; the condensing syringe being within the stock of the gun. An attempt has more recently been made to combine the action of elastic springs with that of compressed air in an Air-gun; springs of gutta-percha, or of vulcanized India-rubber, are employed in substitution of or in co-operation with a condensing syringe. No form of Air-gun hitherto made has had power enough to propel a bullet to any considerable distance, and therefore the instrument is scarcely available in war; there are, however, circumstances in which such an arm may be useful—seeing that there is no expense for gunpowder, no noise, no smoke, no unpleasant odor. The Air-gun was known in France more than two centuries ago; but the ancients were acquainted with some kind of apparatus, by which air was made to act upon the shorter arm of a lever, while the larger arm impelled a bullet. The drawing represents an Air-gun, operated in the following manner: Place the hollow of the right hand against the breech (B), the muzzle (M) upon the floor or against some firm object, and push the barrel into the cylinder (C) as far as possible, or until the trigger catches the piston and holds it. Insert the dart or bullet well into the barrel at the opening (A), and draw out the barrel forward as far as it will go. To make the trigger pull off easier, tighten the set-screw in it. To pull off harder, loosen it a little. Should the gun lose its force and require cleaning, take it apart, wipe clean the piston and inside of cylinder, and return the parts to their places as before. If the barrel works hard, or does not slip freely, apply a drop of *thin* oil around it at the opening (A) and guard slot (G). See *Quackenbush Air-gun.*

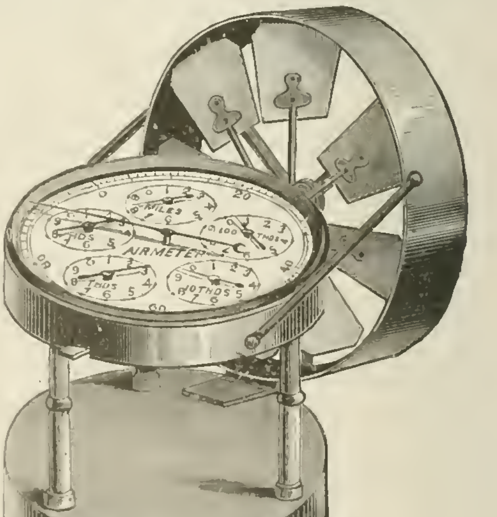


Air-Gun.

AIR-HOLE.—1. A hole or cavity in a gun-casting produced by bubbles of air in the liquid metal; also, a vent-hole in a mould for casting. 2. A draught-hole in a furnace. It is sometimes guarded by a register, but more frequently stopped by a luting or plug of clay.

AIRING-STAGE.—A platform on which powder, etc., is dried by exposure to sun and air.

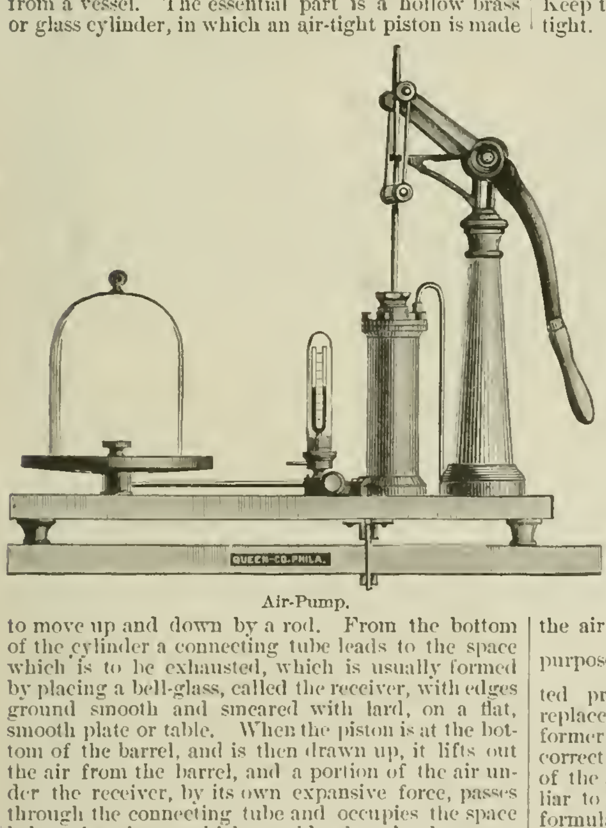
AIR-METER.—An apparatus for measuring the quantity of air passing along a pipe, or passing into or from a chamber. There are various forms: the fan, rotating spiral vane, expanding bag, cylinder and piston, revolving partially submerged meter-wheel, etc.,—all more or less used in Arsenals, Hospitals, and Laboratories. The drawing represents the Casella Air-meter, specially adapted for measuring the velocity of currents of air passing through mines, and the ventilating spaces of hospitals and other public buildings. The graduations for each instrument are obtained by actual experiment by means of machinery made for the purpose, so that the indications of all are as comparable with each other as the weight or measure of ordinary substances. The indications are shown by means of the large dial and hand, and five smaller ones, as shown in the drawing. The whole circumference of the large dial is divided into 100 parts, and represents the number of feet up to 100 traversed by the current of air. The five smaller dials are each divided into ten parts only, one revolution of each being equal to ten of the preceding dial, and representing 1000, 10,000, 100,000, 1,000,000, and 10,000,000 respectively. By means of the large dial the low velocity of fifty feet per minute may be measured, and by the smaller ones continuous registration is extended up to 10,000,000 feet, or equal to 1893 miles, being practically beyond what the most extended observations can acquire, whilst jewelling in the most sensitive parts insures the utmost delicacy of action. By moving a small catch backwards or forwards the work is put in or out of gear without affecting the action of the fans; this prevents the in-



Air-Meter.

jurious effect of stopping them suddenly, and enables the observer to begin or end his observations to a second. A small handle with universal joint accompanies the instrument, and may be screwed in at the base; by putting a stick through this it may be raised or lowered to any required height and used in any position. To use the Air-meter, write down the position of all the hands. For this purpose place the instrument before you, with the 0 on the outer circle facing you. The first circle on the left hand indicates hundreds of feet, the next thousands, the third tens of thousands, the fourth hundreds of thousands, and the last circle to the right of the 0 marks millions. Begin to write down the position of the hands with the million circle, and then go round from right to left, always writing down the lower of the two numbers if the hand is between two. Let us say that the hand on the million dial is at 0, the one-hundred-thousand hand between 2 and 3, the ten-thousand between 7 and 8, the thousand between 1 and 2, the hundred at 5, and the large hand which marks units and tens at 73. The million hand would be omitted as it has not reached 1, and the remaining numbers would run 271,573. The instrument is then put in the current to be measured, and when removed after a given time is read in the same way; the first being deducted from the second reading gives the velocity (uncorrected) in feet during the time. A simple table accompanies each Air-meter, by means of which (in strict observations) allowance may be made for the difference caused by inertia at high and low velocities. See *Anemometer*.

AIR-PUMP.—An instrument for removing the air from a vessel. The essential part is a hollow brass or glass cylinder, in which an air-tight piston is made



Air-Pump.

to move up and down by a rod. From the bottom of the cylinder a connecting tube leads to the space which is to be exhausted, which is usually formed by placing a bell-glass, called the receiver, with edges ground smooth and smeared with lard, on a flat, smooth plate or table. When the piston is at the bottom of the barrel, and is then drawn up, it lifts out the air from the barrel, and a portion of the air under the receiver, by its own expansive force, passes through the connecting tube and occupies the space below the piston, which would otherwise be a vacuum. The air in the receiver and barrel is thus *rarefied*. The piston is now forced down, and the effect of this is to close a valve placed at the mouth of the connecting tube and opening inwards into the barrel. The air in the barrel is thus cut off from returning into the receiver, and, as it becomes condensed, forces up a valve in the piston, which opens outwards, and thus escapes into the atmosphere. When the piston reaches the bottom and begins to ascend again, this valve closes; and the same process is repeated as at the first ascent. Each stroke thus diminishes the quantity of air in the receiver; but from the nature of the process it is evident that the exhaustion can never be complete. Even theoretically there must always be a portion left, though that portion may be rendered less than any assignable quantity; and practically the process is limited by the elastic force of the remaining air being no longer sufficient to open the valves. The degree of rarefaction is indicated by a *gauge* on the principle of the barometer. By means of the partial vacuum formed by the air-pump a great many interesting experiments can be performed, illustrating the effects of atmospheric pressure and other mechanical properties of gases.—The air-pump was invented by Otto Guericke, in 1654; and though many improvements and varieties of structure have been since devised, the principle of all is the same. Two barrels are generally used, so as to double the effect of one stroke. In some air-pumps, stop-cocks turned by the hand take the place of valves, and in others the entrance of the connecting tube into the cylinder is so contrived that the valve through the piston is not required. The air-pump is used with much frequency in the Laboratory and Arsenal. That used in connection with the densimeter is of the ordinary construction. The precautions to be observed in using the pump are: 1. Always keep the piston-rod and piston well oiled. 2. Keep the cocks, and the connections of the tube, air-tight. 3. Screw down the vacuum-gauge case securely before commencing to exhaust. The vacuum-gauge will show whether air is admitted, and the leak may be located by the hissing sound made by the air rushing in.

AIR-RESISTANCE.—This subject, with reference to projectiles, is of the highest importance in the science of Ballistics. The resistance increases in a high ratio with the velocity. Without this resistance a musket-ball would, at an angle of 25°, be thrown seventeen times further than with it. Hutton's experiments led him to believe that the resistance of the air increased a little more rapidly than the square of the velocity. The French experiments have led to an expression involving the square and the cube of the velocity. It is of the following form for spherical projectiles:

$$\rho = 0.0005213\,\pi\,Rv^2 \left(1 + \frac{v}{1426.4}\right)\frac{\delta}{534.5},$$

in which ρ represents the resistance of the air in pounds weight; π, the ratio of the circumference to the diameter; R, the diameter of the projectiles in feet; v, the velocity in feet per second; and δ, the density of the air at the time of observation. For ordinary purposes $\frac{\delta}{534.5}$ may be taken as unity. For elongated projectiles the coefficient 0.0005213 = A is replaced by 0.0003475; but in some instances the former coefficient has been found to be the more correct even for elongated projectiles. The resistance of the air gives rise to a ballistic coefficient C, peculiar to each projectile. This is calculated from the formulæ

$$C = \frac{1}{2g}\,\frac{P}{A\pi R^2} = \frac{2}{3}\,\frac{R\,D}{gA},$$

in which g, A, π, R are the same as before; P, weight of projectile in pounds; D, the density of the projectile; and A, its appropriate value, according as the projectile is spherical or elongated. The coefficient C is one of the data required in finding the multipliers B (a point), D, etc., used in the formulæ for the trajectory in the air. Colonel Majefsky, of the Russian artillery, has proposed a formula involving the square and the fourth power of the velocity, which is said to give results even closer to practice than the French formulæ above detailed. The following table, calculated by the formulæ, will give an idea of the amount of the resistance of the air:

Velocity of Projectiles.	Resistance in lbs. Avoirdupois			
	24 pdr. Shot	12 pdr. Shot	Musket Bullet.	10-inch C.Shell.
1600 feet	479	302	7	...
1400 "	343	216	5	...
1200 "	231	147	8	...
1000 "	150	95	2	462
800 "	88	56	1	271
600 "	45	28	0 7	139
400 "	18	11	0.3	56

On examining the above, it appears that the resistance decreases very rapidly with the velocity. In effect, at a velocity of 800 feet the resistance is less than one fifth of that corresponding to the double velocity of 1600 feet. Comparatively to the 24-pdr. round shot, the resistance to the 12-pdr., one half its weight, is only about two thirds of the former; that to the musket-bullet, weighing $\frac{1}{314}$ of the same round shot, is but the 68th part. The 10-inch common shell, weighing nearly four times as much, meets with a resistance which is only three times that of the 24-pdr., despite the inferiority of its density. At a velocity of 1600 feet per second, the resistance opposed to the 24-pdr. shot is 479 lbs., or twenty times its own weight; at a much smaller velocity of 600 feet per second, the resistance to projectiles is still in proportion to their weight; thus, nearly double for the 24-pdr., more than double for the 12-pdr., nearly ten times for the musket-bullet, and nearly half as great again for the 10-inch shell.

AIR-SHAFT.—A shaft in a mine, usually vertical or nearly so, by which the mine is ventilated.

AITCH PIECE.—In mining, the part of a plunger-lift in which the clacks are fixed.

AKETON.—A quilted leathern jacket worn under the armor of knights in the thirteenth and fourteenth centuries; also written *Hacqueton*. See *Gambeson*.

AKINDSCHI.—A sort of Turkish cavalry, employed during the war between the Turks and the German Emperors.

ALA.—A word signifying the wing of an army; also sometimes used to designate a brigade of cavalry occupying a position, in battle, on either wing.

ALACAYS.—A name given by the ancients to a kind of soldiery, and afterwards to servants following an army.

ALAGE.—A mounted guard of the Byzantine Emperors, doing duty in the Palace of Constantinople, and defending, in case of danger, the person of the Emperor.

ALAIBEG.—A Turkish commander of regiments of levied troops.

ALANDA.—The name of a legion formed by Julius Cæsar from the best warriors of the Gauls.

ALARES.—The name given by the Romans to troops which were placed on the wings of an army. These troops were generally furnished by the Allies.

ALARM.—In military matters, the word alarm has a more defined meaning than mere terror or fright. An alarm, among soldiers in an army, is not so much a danger as a warning against danger. An alarm, signified by the firing of a gun or the beating of a drum, denotes to an army or camp that the enemy is suspected of intending a sudden surprise, or that the surprise has actually been made. There is an *alarm-post* in camp or garrison arrangements, to which the troops are directed to hasten on any sudden alarm being given.

ALARM GUN.—A gun prepared to give an alarm. Formerly, in the British service, three guns were placed in front of a camp, one hundred paces from the artillery-posts, ready to be fired, as an alarm to the troops, in case of a sudden attack by the enemy.

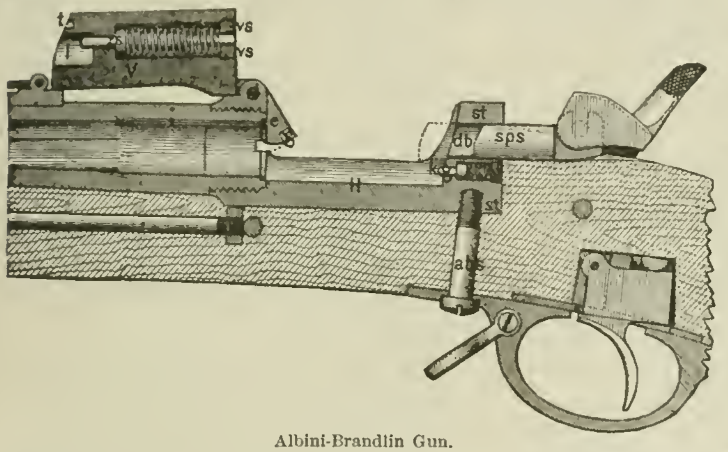
ALARM POST.—A place designated on the arrival of a force into a new quarter, camp, or bivouac, where the men are to repair in case of any sudden alarm by day or night. The parade is generally looked upon as the alarm post; officers and men should proceed there ready armed, on the alarm being sounded, should no other place be appointed. When an army is in the field, there are two alarm-signals: 1. For general concentration, on which everybody acts according to instructions; 2. Partial, when regiments reassemble at their own rendezvous. The second alarm-signal should be frequently practised, for it is very important to know how long it takes to get the men together at any hour. It is ordered in the Queen's Regulations that although a regiment or a division may remain for only a single night in a quarter, yet an alarm-post, or place of assembly, is invariably to be established in each regiment, and the troops are to be made acquainted with its position, and officers commanding regiments with that of the brigade to which they belong.

ALAY.—A Turkish ceremony on the assembling of the forces at the breaking out of a war; essentially a public display of the sacred standard of Mohammed, which may be looked upon only by Moslems and touched only by Emirs. Once when the standard had been shown the rule was forgotten, but when remembered all the Christians who had innocently looked at the banner were slaughtered.

ALBESIA.—In antiquity, a kind of shield; otherwise more frequently called *decumana*.

ALBIGENSES.—A name applied loosely to the "heretics," belonging to various sects, that abounded in the south of France about the beginning of the thirteenth century. The chief sect was the Cathari; but they all agreed in renouncing the authority of the Popes and the discipline of the Roman Church. The name arose from the circumstance that the district of Albigeois in Languedoc—now in the Department of Tarn, of which Albi is the capital—was the first point against which the crusade of Pope Innocent III., 1209, was directed. The immediate pretence of the crusade was the murder of the papal legate and inquisitor, Peter of Castelnau, who had been commissioned to extirpate heresy in the dominions of Count Raymond VI. of Toulouse; but its real object was to deprive the Count of his lands, as he had become an object of hatred from his toleration of the heretics. It was in vain that he had submitted to the most humiliating penance and flagellation from the hands of the legate Milo, and had purchased the papal absolution by great sacrifices. The legates Arnold (Abbot of Citeaux) and Milo, who directed the expedition, took by storm Beziers, the capital of Raymond's nephew, Roger, and massacred 20,000—some say 40,000—of the inhabitants, Catholics as well as heretics. "Kill them all," said Arnold; "God will know his own!" Simon, Count of Montfort, who conducted the war under the legates, proceeded in the same relentless way with other places in the territories of Raymond and his Allies. Of these, Roger of Beziers died in prison, and Peter I. of Aragon fell in battle. The conquered lands were given as a reward to Simon of Montfort, who never came into quiet possession of the gift. At the siege of Toulouse, 1218, he was killed by a stone, and Counts Raymond VI. and VII. disputed the possession of their territories with his son. But the papal indulgences drew fresh crusaders from every province of France to continue the war. Raymond VII. continued to struggle bravely against the legates and Louis VIII. of France, to whom Montfort had ceded his pretensions, and who fell in the war in 1226. After hundreds of thousands had perished on both sides, a peace was concluded, in 1229, at which Raymond purchased relief from the ban of the Church by immense sums of money, gave up Narbonne and several lordships to Louis IX., and had to make his son-in-law, the brother of Louis, heir of his other possessions. These provinces, hitherto independent, were thus, for the first time, joined to the kingdom of France; and the Pope sanctioned the acquisition in order to bind Louis more firmly to the papal chair and induce him more readily to admit the inquisition. The heretics were handed over to the proselytizing zeal of the Order of Dominicans and the bloody tribunals of the inquisition; and both used their utmost power to bring the recusant Albigenses to the stake, and also, by inflicting severe punishment on the penitent converts, to inspire dread of incurring the Church's displeasure. From the middle of the thirteenth century, the name of the Albigenses gradually disappears. The remnants of them took refuge in the East, and settled in Bosnia.

ALBINI-BRANDLIN GUN.—The system of alteration which has been adopted in the Belgian service is known as the Albini-Brandlin. It is peculiarly fitted for transforming small-arms to breech-loaders, and, with the exception of the locking and firing arrangements, closely resembles what is known as the Springfield system of this country. The parts are shown in the drawing. The breech-block, V, is hinged at its forward end, and in opening swings upward and forward. The recoil is taken on the rear portion of the receiver by the vertical part, *s t*. At the centre of this part is the hole, *d b*, through which passes the locking-bolt, *s p s*. This locking-bolt is jointed to the hammer, and pushed forward by it when the lock is sprung so as to penetrate the recess, *l*, of the breech-block and hold it securely in place at the moment of firing. At the same time that the



Albini-Brandlin Gun.

locking-bolt enters the recess it strikes against the head of the firing-pin, *z s*, the point of which impinges against and explodes the primer of the cartridge. As the firing-bolt does not lock the breech-block when the hammer is at half or full cock, the spring catch-pin, *k g*, is provided, which penetrates the recess, *t*, and prevents the block from getting loose under ordinary disturbing causes. The firing-pin, *z s*, is provided with a spiral spring to push it back and keep its point below the face of the block at all times except when pressed by the locking-bolt; this spring is kept in place by the screw-nut, *v s, v s*. The forward guard-screw, *a b s*, penetrates into the rear portion of the receiver, thereby securing the barrel to the stock. The extractor is formed of two lever-disks, *e*, pivoted to the hinge-pin and outside of the ears of the hinge. Each disk is provided with a hook-point, *g*, which passes through a cut in the receiver and barrel and takes hold on opposite sides of the head of the cartridge beneath the rim. When the breech-block is thrown forward to open the breech, its upper and forward edge strikes against the short arm of the extractor-disks and pushes them downward; at the same time the opposite or long arm is thrown to the rear, carrying with it the cartridge-shell. To throw the shell clear of the receiver the forward motion of the breech-block should be very quick toward its close. This extractor is very efficient, inasmuch as it gets a double hold on the rim of the cartridge-shell. See *Small-arms*.

ALCAIDE—ALCAYDE.—A Moorish title, applied by Spanish and Portuguese writers to a military officer having charge of a fortress, prison, or town. It is to be distinguished from *Alcalde*, which indicates a civil officer.

ALCANTARA.—The Order of Alcantara, a religious order of Spanish knighthood, was founded (1156) as a military fraternity for the defense of Estremadura against the Moors. In 1197 Pope Celestine III. raised it to the rank of a religious order of knighthood; bestowed great privileges on it, and charged it with the defense of the Christian faith, and the maintenance of eternal war with the infidel. Alphonso IX., having taken the town of Alcantara, ceded it in 1218 to the Order of Calatrava; but the knights of this order, unable to hold it along with their other great possessions, yielded it to the knights of St. Julian, who transferred it to their seat, and henceforth were known by its name. At length the grand-mastership of the order was, by Pope Alexander VI., united to the Spanish crown in 1495. The order is still richly endowed. The knights, who follow the rule of St. Benedict, take now only the vows of obedience and poverty, having, since 1540, been absolved from that of celibacy. A special vow binds them to defend the immaculate conception of the Virgin. At their nomination they must prove four generations of nobility. For a time the knights of Alcantara acknowledged the superiority of the knights of Calatrava, but they were latterly absolved from it. Both the costume, however, and the cross are still the same, with the exception of the color, which is green. The crest of the order is a pear-tree.

Order of Alcantara.

ALCOHOL.—A term of Arabic origin, implying the pure spirit obtained by distillation from all liquids which have suffered the vinous fermentation. Alcohol is transparent, colorless, and inflammable. It unites easily with resins, camphor, antimony, and volatile oils. It is known as "spirits of wine." Its specific gravity on becoming absolute alcohol is from .796 to .800, and it boils at 176°. It is used in the preparation of laboratory stores, such as fulminate of mercury, quick-match, shell-lac to form varnish for percussion-caps, etc.

ALDER.—A genus of plants of the natural order *Betulaceæ*. The genus consists entirely of trees and shrubs, natives of cold and temperate climates; the flowers in terminal, imbricated catkins, which appear before the leaves; the male and female flowers in separate catkins on the same plant; the male or barren catkins loose, cylindrical, pendulous, having the scales 3-lobed, and each with three flowers whose perianth is single and 4-partite; the fertile catkins oval, compact, having the scales sub-trifid, and each with two flowers destitute of perianth; styles, two; fruit, a compressed nut without wings. The common alder is a native of Britain and of the northern parts of Asia and America. It has roundish, wedge-shaped obtuse leaves, lobed at the margin and serrated. The bark, except in very young trees, is nearly black. It succeeds best in moist soils, and helps to secure swampy river-banks against the effects of floods. It attains a height of 30 to 60 feet. Its leaves are somewhat glutinous. The wood is of an orange-yellow color, not very good for fuel, but affording one of the best kinds of charcoal for the manufacture of gunpowder, upon which account it is often grown as coppice-wood. Great numbers of small alder-trees are used in Scotland for making staves for barrels. The wood is also employed by turners and joiners; but it is particularly valuable on account of its property of remaining for a long time under water without decay, and is therefore used for the piles of bridges, for pumps, sluices, pipes, cogs of mill-wheels, and similar purposes.

ALDERSHOTT CAMP.—When England and France declared war against Russia in 1854, in relation to Turkish affairs, the British army was known to be in an unsatisfactory state; thirty-nine years of peace had allowed many important elements in military organization to fall into a state of inefficiency. Among others, the power of acting well together in brigades and divisions had scarcely been taught to the soldiers, who had been familiar with little more than the discipline and tactics of battalions and companies. To remedy in part these defects was the object held in view in establishing the Camp at Aldershott. It was to be a permanent camp, with barracks and huts, instead of mere canvas tents; and was to be provided with all the appliances for a military school, valuable to officers as well as to privates. A dreary waste, on the confines of Surrey, Hants, and Berks, called Aldershott heath, was purchased by the government as the locality for the new camp. The area was 7063 acres, and the purchase-price about £130,000. The spot was deemed suitable as being distant from any thickly inhabited district; as being within easy reach of three or four stations on the Southwestern and Southeastern railways; and as being conveniently placed for the quick transmission of troops to any part of the southern coast. The camp was ready for the reception of troops in 1855. At first, no brick structures were attempted. The soldiers were accommodated in wooden huts, each furnishing living and sleeping room for about twenty-five men. When the camp was inaugurated, in April of the year last named, by a review at which the Queen was present, there were 18,000 troops, regulars and militia, temporarily stationed there. The huts for each regiment were grouped apart, for the better maintenance of regimental discipline. Each hut had a range of iron bedsteads on either side, capable of being doubled up; and a long table through the middle, in a line with two doors at the ends of the huts. The officers' huts, though of course superior in construction and convenience, were as simple as they could well be. The cooking was performed in huts especially set apart for that purpose, provided with efficient cooking apparatus. The wooden huts have gradually been superseded by brick barracks, at a cost of more than a quarter of a million sterling. The Basingstoke Canal, running directly across the heath, has occasioned a division into North Camp and South Camp; but each of these is susceptible of a good deal of extension. Reviews and sham fights are frequently held, at some of which the Queen has been present, and there are various important operations carried on daily, and known to very few besides those immediately concerned. There are many square miles of plain, heath, shrub, morass, valley, and hill surrounding the camp, on which soldiers, and especially the militia regiments, are exercised in the various evolutions and strategic movements connected with the battle-field and siege-works. It is no child's play; the men are often severely worked, and gain a foretaste of some of the fatigues of military life. On other days they are exercised in various quiet duties of tents and huts, barracks and kitchens, intended to teach them many of the useful knacks in which French soldiers are acknowledged to be more skilled than the English. Different regiments, regulars as well as militia, artillery as well as cavalry and infantry, take it in turn to experience camp-life at Aldershot. There are usually about from 10,000 to 15,000 troops at the camp, comprising infantry, cavalry, artillery, and militia. The Authorities some years ago purchased or leased a portion of forest-land between Aldershott and Winchester; camping arrangements of a temporary kind are made, and the troops are occasionally exercised with a tough march of a dozen miles. A thriving town has sprung up near the camp. An unfortunate circumstance is that the barracks have been built at the very edge of the ground belonging to the government; as a consequence, private speculators built beer-houses and haunts of dissipation close to the barracks, greatly to the demoralization of the soldiers; and it is not easy to buy up these people, owing to the rise in value of the land. Some alleviation has arisen from the operation of the Contagious Diseases Acts of 1866 and 1869.

ALDIONAIRE.—A sort of equerry, who in the army was kept at the expense of his master. Under Charlemagne, the *Aldionaires* were of an inferior rank.

ALEM.—The imperial standard of the Turkish Empire.

ALEMDAR.—An official who carries the green banner of Mohammed when the Sultan assists in ceremonies of solemnity.

ALERT.—In military phraseology an expression made use of to signify that an outpost has been threatened or attacked. Thus, "We have had an alert," is a military phrase. A bugle-sound is also so named, which is given by way of warning to put soldiers on their guard, and to keep them vigilant. This warning is also sounded by an outpost which may be attacked in the night, to give notice to the one that is destined to support it. The word is frequently used by old writers to express a sudden alarm caused by a merely harassing attack of the enemy.

ALEUROMETER.—An instrument invented about 1849, by M. Boland, a Parisian baker, for determining the quality of the gluten in different specimens of wheaten flour, and their consequent adaptation for bread-making. A tube of about six inches in length is divided into two parts, of which the smaller one, about two inches in length and holding a given amount of gluten, is screwed on to the longer tube, which is fitted with a piston having a graduated stem. The apparatus is then exposed to a moderate degree of heat, when the gluten expands, forcing up the piston, the amount of expansion being indicated by the distance the stem protrudes from the tube. It was found that gluten obtained from flour of good quality would expand to four or five times its original bulk, and had the smell of warm bread, while that of bad flour became viscid, with a tendency to adhere to the tube, and in some instances emitting an unpleasant odor. This instrument is indispensable to purchasing-officers of the Subsistence Department.

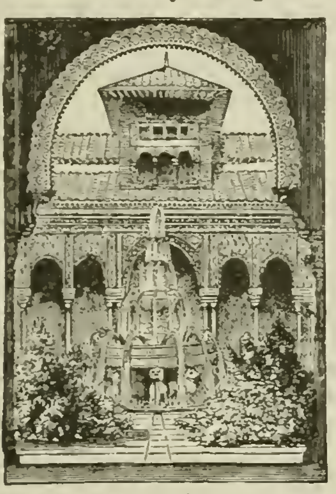
ALFERE — ALFEREZ. — Standard-bearer; ensign; cornet. The old English term for ensign; it was in use in England till the civil wars of Charles I.

ALGEBRA.—A branch of pure mathematics much used in the solution of problems of gunnery. The name is derived from the Arabs, who call the science *al-gebr wal mokâbala*—i.e., supplementing and equalizing—in reference to the transposition and reduction of the terms of an equation. Among the Italians in early times it was called *arte maggiore*, as having to do with the higher kinds of calculation, and still oftener *regola de la cosa*, because the unknown quantity was denominated *cosa*, the "thing;" hence the name of *cossike art*, given to it by early English writers. The term algebraical is generally used somewhat vaguely, to denote any expression or calculation in which signs are used to denote the operations, and letters or other symbols are put instead of numbers. But it is perhaps better to restrict the name algebra to the doctrine of equations. Literal arithmetic, then, or multiplying, dividing, etc., with letters instead of Arabic ciphers, is properly only a preparation for algebra; while analysis, in the widest sense, would embrace algebra as its first part. Algebra itself is divided into two chief branches. The first treats of equations involving unknown quantities having a determinate value; in the other, called the diophantine or indeterminate analysis, the unknown quantities have no exactly fixed values, but depend in some degree upon assumption.

ALGER BREECH-LOADER.—A substitute for the Armstrong vent-piece, which must be lifted out of its seat. It consists of a cross-plug forming a continuation of the bore when the handle is vertical, and closes the bore, being set up firmly by the breech-screw, when the handle is horizontal. A suitable gas-check might be placed through the hollow screw, in a recess in the cross-plug, by revolving the latter through half a circle.

ALGHISI-DI-CARPI SYSTEM OF FORTIFICATION.—In this system the curtain forms a tenaille; the main ditch encloses a flat space, and the bastions are small, having orillons and casemated flanks, with a cavalier inside the gorge. See *Fortification*.

ALHAMBRA.—The name given to the fortress which forms a sort of acropolis or citadel to the city of Granada, and in which stood the palace of the ancient Moorish Kings of Granada. The name is a corruption of the Arabic *Kal-'at al hamra*, "the red castle." It is surrounded by a strong wall, more than



Entrance to the Court of the Lions—Alhambra.

a mile in circuit, and studded with towers. The towers on the north wall, which is defended by nature, were used as residences connected with the palace. One of them contains the famous *Hall of the Ambassadors*. The remains of the Moorish Palace are called by the Spaniards the Casa Real. It was begun by Ibnu-l-ahmar, and continued by his successors, 1248–1348. The portions still standing are ranged round two oblong courts, one called the *Court of the Fish-pond*, the other the *Court of the Lions*. They consist of porticos, pillared halls, cool chambers, small gardens, fountains, mosaic pavements, etc. The lightness and elegance of the columns and arches, and the richness of the ornamentation, are unsurpassed. The coloring is but little altered by time. The most characteristic parts of the Casa Real have been reproduced in the "Alhambra Court" of the crystal palace at Sydenham. A great part of the ancient palace was removed to make way for the palace begun by Charles V., but never finished. It is long since any part of the Moorish Palace was inhabited; but it is kept in a state of preservation as a work of art, and as a memorial of the tragic legend of the Abencerrages.

ALI BEY.—A Colonel of Turkish Cavalry; also the rank of a District Commander.

ALIBI.—A defence resorted to in criminal prosecutions, when the party accused, in order to prove that he could not have committed the crime with which he is charged, tenders evidence to the effect that he was in a different place at the time the offence was committed. When true, there can be no better proof of innocence; but as offering the readiest and most obvious opportunity for false evidence, it is always regarded with suspicion. In the case of crimes the place of committing which is immaterial—as, for example, the act of fabricating the plates, or of throwing off the spurious notes, in a case of forgery—a proof of *alibi* is of no avail.

ALIDADE.—The movable arm of a graduated instrument carrying sights or a telescope, by which an angle is measured from a base-line observed through the stationary or level line of sights. It is used in plane tables, theodolites, astrolabes, demi-circles, and numerous other angulometers. Four varieties of the Alidade are in common use. The simplest Alidade consists of a brass rule or straight-edge, twenty inches long and two to three inches wide, at the ends of which are screwed sight-vanes, like those of the ordinary compass; the edge of the rule being chamfered and in line with the slots of the vanes. To another form of simple Alidade is fitted the telescopic sight, having a level, clamp and tangent, and vertical circle reading to five minutes, attached to the telescope, which is also supplied with micrometer wires. The telescope is placed in line with the straight-edge as before. Another style of Alidade is shown in the article "Plane Table," the brass rule being now two inches wide, except where it is expanded one third from the end to receive the base of the column. The column supports the telescope with its attachments, the vertical circle being divided on silver and reading to single minutes. The telescope is nine inches long, of a power of 20 diameters, provided with stadia, and adjusted and used like that of the Transit; it is also in line with the chamfered edge of the rule. In another form of Alidade, the telescope is precisely the same as that used on the best Transits, being also supplied with level, clamp and tangent, vertical circle on silver reading to single minutes, and micrometer wires for measuring distances. It is placed on the brass rule precisely like that of the one last described, and is adjusted and used in the same manner. In using the plane table the tripod is set up firmly, and the table covered with paper, placed upon the flange of the socket, and secured by the screws, *e e;* the nut, *d*, being now loosened, the table is moved by the pressure of the hand on different parts of the board, until the levels on the plate will come into the centre on any part of the table. The nut, *d*, is then screwed up and the table made firm; any place on the paper can then be assumed as the starting-point, its position over a given point on the ground being determined by the plumbing-bar and plummet. From the given point on the paper, sights can then be taken to different corners of the field, and lines drawn on the paper along the edge of the Alidade, and thus a miniature of the tract be traced on the paper, the bearing of any line being ascertained by applying the side of the compass-plate to the edge of the Alidade placed on that line. The table can be moved horizontally either by hand on releasing the screws, *e e*, or by a tangent-screw. See *Plane Table* and *Theodolite*.

ALIEN.—The citizen of one State, when resident in another, unless naturalized, is an alien. The condition of an alien does not necessarily result from foreign birth. The son of a natural-born or naturalized Englishman is not an alien, wherever he may be born. This privilege even extends to the second generation on the father's side; and thus a man whose paternal grandfather was an Englishman is an Englishman himself, unless either his father or grandfather be liable to the penalties of felony, have been attainted of treason, or be serving in the army of a Prince at war with England, at the period of his birth. Neither is this privilege affected by the fact that the mothers of such persons were foreigners. The children of aliens born in England, except in the case of a hostile invasion, are natural-born subjects; but the children of Englishwomen by aliens are aliens, unless born within the British dominions. The allegiance due by an alien or stranger to the Prince in whose dominions he resides is usually called *local* or *temporary allegiance*. It differs from natural allegiance chiefly in this, that whereas natural allegiance is perpetual and unaffected by change of residence, local allegiance ceases when the stranger transfers himself to another kingdom.

ALIGNMENT.—A term used in military tactics, equivalent to *in line*. Thus, the alignment of a battalion is effected when the men are drawn up in line; the alignment of a camp is a rectilinear arrangement of the tents according to some prearranged plan. The instructor first teaches the recruits to align themselves man by man, the better to comprehend the principles of alignment; to this end, he advances the two men on the right three or more yards, and having aligned them, commands: (1) *By file*, (2) *Right* (or *left*), (3) DRESS, (4) FRONT. At the command, *dress*, the recruits move up successively, in quick time, shortening the last step so as to find themselves about six inches behind the alignment; each recruit then moves on the line, which must never be passed, taking steps of two or three inches, casting his eyes to the right so as to see the coat-buttons of the second man from him, keeping his shoulders square to the front, and touching with his elbow that of the man on the right without opening his arms. At the command, *front*, given when the rank is well aligned, the recruits cast their eyes to the front and remain firm. The recruits having learned to align themselves man by man, the instructor next aligns the squad by the commands, (1) *Right* (or *left*), (2) DRESS, (3) FRONT. At the command, *dress*, the entire rank, except the men established as a basis, moves forward, and dresses up to the line, as previously explained. The instructor verifies the alignment by placing himself outside the right flank, and orders forward or back such files as may be in rear or in advance of the line; this done, he commands, *front*. Alignments to the rear are executed on the same principles, the recruits stepping back a little beyond the line, and then dressing up, by short steps of two or three inches. The comands are: (1) *By file, right* (or *left*) *backward*, (2) DRESS, (3) FRONT; or, (1) *Right* (or *left*) *backward*, (2) DRESS, (3) FRONT.

ALKALIES.—The word *alkali* is of Arabic origin, *kali* being the name of the plant from the ashes of which an alkaline substance was first procured. The name now denotes a class of substances having similar properties. The alkalies proper are four in number—potash, soda, lithia, and ammonia. The first three are oxides of metals; the last is a compound of nitrogen, hydrogen, and oxygen, and, being in the form of a gas, is called the volatile alkali. Potash, being largely present in the ashes of plants, is called the vegetable alkali; and soda, predominating in the mineral kingdom, is designated the mineral alkali. The *alkaline earths*, as they are called—lime, magnesia, baryta, and strontia—are distinguished from the former by their carbonates not being soluble in water. The distinguishing property of alkalies is that of turning vegetable blues green, and vegetable yellows reddish brown. Blues reddened by an acid are restored by an alkali. The alkalies have great affinity for acids, and combine with them, forming salts, in which the peculiar qualities of both alkali and acid are generally destroyed; hence they are said to neutralize one another. In a pure state alkalies are extremely caustic, and act as corrosive poisons. Combined with carbonic acid, especially as bicarbonates, they are used to correct acidity in the stomach; but the injudicious and continued use of them is attended with great evil.

ALLECRET—ALLECRETE.—Light armor used by both cavalry and infantry in the sixteenth century, especially by the Swiss. It consisted of a breast-plate and gussets, often reaching to the middle of the thigh, and sometimes below the knees.

ALLECTI MILITES.—A name given by the Romans to a body of men who were drafted for military service.

ALLEGIANCE.—It is but recently that foreign governments have come to recognize the right of persons to change their allegiance as well as their residence. The United States always held it to be a natural right, and our legislation so recognizes it. The difference was strikingly manifest in the War of 1812, when the Prince Regent proclaimed that every native-born Briton taken prisoner while fighting for the Americans should be shot for treason, to which President Madison replied that if any naturalized American of the United States should suffer death in such manner he would execute two British prisoners. There were no executions of the sort which England had threatened. Very recently the question has been discussed as to the right of a government to subject to military service men who were once its citizens but were afterwards citizens of another country; and late decisions tend to show that most governments are abandoning the old claim, "once a citizen always a citizen." For instance, Germans naturalized in the United States on returning to Germany were formerly required to enter the army; but now they plead American citizenship, and with success. Allegiance is often transferred *en masse*, as on the treaty of peace in 1783, when British subjects who should so elect became Americans; also, when Louisiana and Florida were purchased and Texas was annexed; no inquiry was made about allegiance, but the official transfer made the Creoles and the Texans as completely citizens owing allegiance as though born under the United States flag. The law of Congress, July, 1868, very clearly sets forth the extent and obligations of allegiance. The preamble states that the right of expatriation is natural and inherent in all people and indispensable to the enjoyment of rights to life, liberty, and the pursuit of happiness; that, recognizing this right, our government has received emigrants from all nations and given them citizenship and protection; that it is necessary for the maintenance of public peace that the claim of foreign allegiance as to such adopted citizens should be promptly and firmly disavowed; and therefore it was enacted that any declaration, opinion, order, or decision of any officer of this government which denies, impairs, restricts, or questions the right of expatriation is inconsistent with the fundamental principles of the government; that all naturalized citizens of the United States, while in Foreign States, are entitled to, and shall receive from this government, the same protection of person and property that is accorded to native-born citizens in like circumstances. This broad declaration of our rights and duties was followed in May, 1870, by the British Parliament in an act revising all British laws on alienage, expatriation, and naturalization—the government for the first time recognizing the right of subjects to renounce allegiance to the Crown.

ALLEN BRAKE.—A contrivance for checking violent recoil. It consists of a wooden wedge, shod with iron, attached to the bracket immediately in rear of the truck by jointed bars of iron, the upper of which are bolted to the bracket, while from the joint another bar passes horizontally through the axle-tree arm, forming the linch-pin. The wedge rests upon the ground in rear of the truck, following it as the carriage is run up, but on recoil the truck overtakes and rides upon the wedge. A rope-lanyard is attached to the wedge and an iron cleat upon the side of the carriage, so that, if it is wished not to use the brake, the wedge can be secured so as not to come into action on recoil. See *Brake*.

ALLEZOIR.—A frame of timber firmly suspended in the air with strong cordage, on which is placed a piece of ordnance with the muzzle downwards. In this situation the bore is rounded and enlarged by means of an instrument which has a very sharp and strong edge made to traverse the bore by force of machinery or horses, and in a horizontal direction.

ALLEZURES.—The metal taken from cannon and other guns by boring.

ALLIAGE.—A term used by the French to denote the composition of metals used for the fabrication of cannon, mortars, etc.

ALLIANCE.—In a military sense, a treaty entered into by Sovereign States for their mutual safety and defence. In this sense, alliances may be divided into such as are offensive, where the contracting parties oblige themselves jointly to attack some other power; and into such as are defensive, whereby the contracting powers bind themselves to stand by and defend one another in case of being attacked by any other power. Alliances are variously distinguished according to their object, the parties in them, etc. Hence we read of equal, unequal, triple, quadruple, grand, offensive, defensive alliances, etc. See *Treaty*.

ALLIGATI.—A name given by the Romans to prisoners of war and their captors. A chain was attached to the right wrist of the prisoner and the left wrist of the warrior who captured him.

ALLOCUTIO.—An oration addressed by a Roman General to his soldiers to animate them to fight, to appease sedition, or to keep them to their duty.

ALLODIAL.—Independent; not feudal. The Allodii of the Romans were bodies of men employed in any emergency, in a manner similar to our volunteer associations.

ALLONGE.—A pass or thrust with a rapier or small sword, frequently contracted into *lunge;* also a long rein used in the exercising of horses.

ALLOWANCE.—Money granted in addition to the regular pay of an officer or soldier for some particular purpose, or to a regiment to meet certain expenses. For instance, what is termed *Colonel's Allowance* is granted to General Officers in the British army when selected by the Commander-in-Chief to fill the post of "Colonel of a Regiment"; this takes place when vacancies by death occur. In the Indian Staff Corps the Colonel's Allowance is granted to each officer after a stated period, viz., thirty-eight years' service, provided he has served twelve years in the rank of Lieutenant-Colonel. *Lodging Allowance* is granted to Officers, Non-commissioned Officers, and men, when accommodation cannot be provided for them in barracks; it includes *fuel* and *light allowance*. The two latter allowances are granted to Officers, irrespective of Lodging Allowance. Agreeably to a late warrant, the allowance granted to Non-commissioned Officers has been fixed as follows: Class I., 1*s.* 9*d.* a day; Class II., 1*s.* a day; Class III., 6*d.* a day. A Non-commissioned Officer on the married roll continues to receive lodging, fuel, and light allowance for the benefit of his wife and family when he may be in hospital or temporarily separated from them, on service, provided no married soldiers' quarters become available for their use. *Horse Allowance* is granted to Officers when forage has not been issued by the Commissariat. *Contingent Allowance* is granted for any particular expenditure permitted by the regulations. *Servants' Allowance* is given to certain Officers who are not allowed soldier-servants. *Field Allowance* is passed to Officers to enable them to provide themselves with baggage-animals and equipment in the field. The term *Allowance* is also applied to the amount of rations, forage, etc., served out periodically to any one man or to a body of men. See *Allowances*.

ALLOWANCE OF QUARTERS.—In the United States army, in allotment of quarters, officers have choice according to rank, but the Commanding Officer may direct the officers to be lodged convenient to their troops. An officer may select quarters occupied by a junior; but, having made his choice, he must abide by it, and cannot again at the post displace a junior, unless himself displaced by a senior. The set of rooms to each quarters will be assigned by the Quartermaster, under the direction of the Commanding Officer; attics are not counted as rooms. Officers cannot choose rooms in different sets of quarters. The following table shows the number of rooms, the quantity of fuel, and the allowance or cooking and heating stoves to be supplied for the use of officers in Public Quarters and Barracks:

	Rooms			Cords of wood per month.		Increased allowance from Sept. to April, both inclusive		For quarters.		For office
	As quarters	As kitchen.	As office.	From May 1 to Aug 31.	From Sept 1 to April 30.	Between 36th and 43d deg. N. latitude one fourth.	North of 43d deg one third.	Heating-stoves.	Cooking-stoves or ranges	Heating-stoves.
The General (allowed by law for quarters and fuel, $125 per month).										
The Lieutenant-General or a Major-General	5	1	Variable	1	5	1¼	1⅔	5	1	Variable.
A Brigadier-General or Colonel	4	1		1	4	1	1⅓	4	1	
A Lieutenant-Colonel or Major	3	1		1	3½	⅞	1⅙	3	1	
A Captain or Chaplain	2	1		¾	3	¾	1	2	1	
A Lieutenant	1	1		½	2	½	⅔	1	1	

ALLOWANCES.—In the British army—and to various degrees in the armies of other countries—military officers, besides their recognized pay, receive certain allowances for special duties or when placed under exceptional circumstances. Without detailing the actual amount of these allowances, it may be well to enumerate the principal modes in which they arise. An officer commanding and paying a troop or company receives a contingent allowance as an indemnification for the expense of repairing arms, swords, and scabbards; for burials; and for the debts of soldiers who become non-effective. A kind of general average is struck for the probable amount of these charges. An officer on duty in the United Kingdom, in a situation entitling him to be lodged at the public expense, and whose lodging is not otherwise paid for by the public, receives an allowance as "lodging-money," varying in amount according to his rank. An officer marching with troops in the United Kingdom, on a route determined by competent authority, if unable to mess with his regiment or detachment on a particular day, receives an allowance in compensation. An officer sent on permanent or temporary duty from one place to another receives a travelling allowance of so much per mile. An officer serving on a court-martial receives an allowance of so much per day, besides a travelling allowance if the place be distant. An officer temporarily detached on duty, where he cannot join his regimental mess, has an allowance for mess-money. Besides those here enumerated, there are allowances for detention at ports of embarkation, etc., and others of a minor kind. See *Allowance* and *Mileage*.

ALLOY.—A mixture of two or more metals, either natural, or produced artificially by melting them together. The mixture has often different properties from the component metals, and bears a distinct name. Thus, bell-metal is an alloy of copper and tin; tombak, of copper and zinc; brass, of copper with a larger proportion of zinc, etc. Alloys are generally harder than the metals that compose them, and this is the motive for alloying the precious metals. Alloys seldom possess the density which theory or calculation from the specific gravity of their constituents would indicate. Thus, many alloys possess a greater density than the mean density of their constituents, while others have a less density. The increase in density of the alloy indicates that the metals have contracted: in other words, that the metallic molecules have approached each other more closely; while the decrease in density denotes a separation of the molecules to greater distances from each other.

ALLOYS which exhibit a greater density than the mean density of the metals composing them.	ALLOYS which possess a less density than the mean density of the metals composing them.
Gold and zinc.	Gold and silver.
" " tin.	" " iron.
" " bismuth.	" " lead.
" " antimony.	" " copper.
" " cobalt.	" " iridium.
Silver " zinc.	" " nickel.
" " tin.	Silver " copper.
" " bismuth.	Iron " bismuth.
" " antimony.	" " antimony.
Copper " zinc.	" " lead.
" " tin.	Tin " lead.
" " palladium.	" " palladium.
" " bismuth.	" " antimony.
Lead " antimony.	Nickel " silver.
Platinum and molybdenum.	Zinc " antimony.
Palladium and bismuth.	

The strength or cohesion of an alloy is generally greater than that of the mean cohesion of the metals contained therein, or even of that of the most cohesive of its constituents. Thus, the breaking weight of a bar of copper or tin (meaning the longitudinal strain it can bear) is very much lower than the breaking weight of a bar composed of an alloy of tin and copper. The following table represents the

COHESION OF METALS.

	Bar 1 in. square breaks with lbs.		Bar 1 in. square breaks with lbs.
Barbary copper....	22,570	Malacca tin	3,211
Japan "	22,570	Bismuth..........	3,008
English black tin..	20,272	Zinc..............	2,689
" tin-plate...	6,650	Antimony	1,060
Banca tin.........	3,679	Lead	885

When any two of the above metals combine together, they generally—though not always—yield an alloy which is much stronger than we should expect; thus the

COHESION OF ALLOYS.

	Bar 1 in. square yields with lbs.
10 parts of copper and 1 part of tin...........	32,093
8 " " 1 " "	36,088

4 " English tin " 1 " zinc....... ..	10,258
4 " " " " 1 " antimony.....	11,323

The power of conducting electrical currents is not so great in an alloy as the mean conducting power of its components. The composition of the more commonly occurring and commercially important alloys is as follows: Plumber's solder, 1 tin and 2 lead; soft solder, 2 tin and 1 lead; common pewter, 4 tin and 1 lead; gun-metal, 9 copper and 1 tin; bronze, 9 copper and 1 tin and zinc; cymbals and Chinese gongs, 4 copper and 1 tin; bell-metal, 3 copper and 1 tin; speculum-metal, 2 copper and 1 tin; pot-metal or cock-metal, 2 copper and 1 lead; gilding-metal, 16 copper and 1 to 1¼ zinc; Mannheim gold—pinchbeck or bath-metal, 16 copper and 4 zinc; Bristol brass, for soldering, 16 copper and 6 zinc; ordinary brass, for casting, 16 copper and 8 zinc; Muntz sheathing-metal, 16 copper and 10⅔ zinc; spelter-solder for copper and iron, 16 copper and 12 zinc; spelter-solder for brass-work, 16 copper and 16 zinc; Mosaic gold, 16 copper and 16½ zinc; hardest silver-solder, 4 silver and 1 copper; hard silver-solder, 3 silver and 1 copper; soft silver-solder, 2 silver and 1 copper; German silver, 100 copper, 60 zinc, and 40 nickel; type-metal, ordinary, 15 lead, 4 antimony, and 1 tin, or 14 lead, 5 antimony, and 1 tin—small types, 4 lead and 1 antimony—large types, 6 lead and 1 antimony; stereotype-metal, 48 lead, 6 antimony, and 1 tin; Britannia metal, 50 tin, 4 antimony, 4 bismuth, and 1 copper.

ALLUMELLE.—A thin and slender sword which was used in the Middle Ages to pierce the weak parts or joints of armor.

ALLY.—A term implying, in a military sense, any nation united to another under a treaty either offensive or defensive, or both.

ALMADIE.—A kind of military canoe or small vessel, about 25 feet long, made of the bark of a tree, and used by the negroes of Africa. *Almadie* is also the name of a long boat used at Calcutta, often from 80 to 100 feet long, and generally 6 or 7 broad; they are rowed with from 10 to 30 oars.

ALMAN-RIVETS.—A sort of light armor derived from Germany, characterized by overlapping plates which were arranged to slide on rivets, by means of which flexibility and ease of movement were promoted.

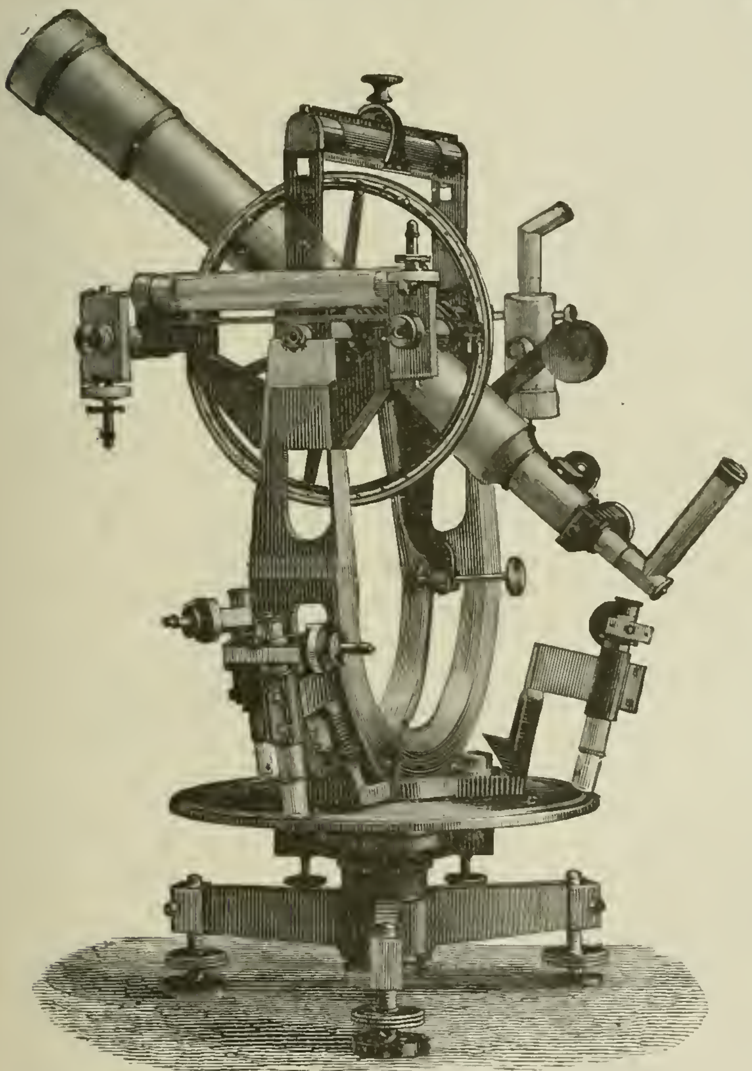
ALTISCOPE.—An invention consisting of an arrangement of lenses and mirrors in a vertical telescope-tube, by means of which a person is able to overlook objects intervening between himself and the object he desires to see. When the sections of the tube are extended, the view is received upon an upper mirror placed at an angle of 45°, and reflected thence down the tube to a lower mirror, where it is seen by the observer. The image is magnified by lenses intervening between the mirrors. The telescopic tubes are so connected that each in turn acts upon the next in the series, as it comes to the end of its own range, and thus the desired elevation is arrived at. The means of extension are a winch and cords.

This contrivance affords a means for training guns to a given angle with the axis of the vessel, or on an object, while the gunner remains beneath the deck. There is attached beneath the deck, to the pintle of the pivoted gun, a graduated index-plate, by which its horizontal bearing may be read. A telescopic tube, with two rectangular bends and with reflecting mirrors at the angles, is so placed as to be used from beneath the deck; two of these may be so situated as to form a base of sufficient length to obtain, by simultaneous observation, the distance by triangulation. The upper and lower limbs of the telescopic tube are parallel; the upper one is presented towards the object, the other to the eye. The image of the object after being twice reflected reaches the eye of the observer, whose person is not exposed.

ALTITUDE AND AZIMUTH INSTRUMENT.—Altitude, in astronomy, is the height of a heavenly body above the horizon. It is measured, not by linear distance, but by the angle which a line drawn from the eye to the heavenly body makes with the horizontal line, or by the arc of a vertical circle intercepted between the body and the horizon. Altitudes are taken in observatories by means of a telescope attached to a graduated circle which is fixed vertically. The telescope being directed towards the body to be observed, the angle which it makes with the horizon is read off the graduated circle. The Altitude thus observed must receive various corrections—the chief being for parallax and refraction—in order to get the true Altitude. At sea, the Altitude is taken by means of a sextant, and then it has further to be corrected for the dip of the visible horizon below the true horizon. The correct determination of Altitudes is of great importance in most of the problems of astronomy and navigation.

The Azimuth of a heavenly body is the angle measured along the horizon between the North or South point and the point where a circle, passing through the zenith and the body, cuts the horizon. The word comes from the Arabic, and is said to be derived from a word signifying a quarter of the heavens. It is usual to measure the Azimuth westward from the point most remote from the elevated pole, beginning at 0° and returning to it at 360°. Thus, in northern latitudes, where the north pole is elevated, the Azimuth is measured from the south point, so that the east point, for instance, has an Azimuth of 270°. Azimuth circles are those which extend from zenith to nadir, cutting the horizon at right angles, or those in which all the points have the same Azimuth.

An Altitude and Azimuth Instrument consists essentially of a vertical circle with its telescope so arranged as to be capable of being turned round horizontally to any point of the compass. It thus differs from a Transit Instrument, which is fixed in the meridian. The drawing represents one of these instruments, made by Fauth & Co., which was on exhibition in the International Exhibition at Philadelphia. It is of superior construction, and differs from other instruments of this class in many important particulars. Although not a "repeating instrument," strictly speaking, and, therefore, not liable to the defects inherent to repeaters, yet both the horizontal and vertical circles can be shifted for position, so as to bring a different part of the graduation under the microscopes. The circles are divided on silver into five-minute spaces, reading by micrometer microscopes to single seconds. The standards radiate out from the centre, and are high enough to let the telescope swing through. The pivots of the telescope axis rest on agate, and are made of phosphor-bronze; a delicate striding level, reading to seconds, over the pivots, is provided; illumination through pivots; the horizontality of the microscopes for the vertical circle is controlled by a chambered level reading to seconds. Both circles are entirely free of clamps and tangent screws, these being attached to a collar, so as not to produce any strain. — See *Theodolite* and *Transit Instrument*.



From Gebbie & Barrie's "Masterpieces of the U. S. International Exhibition, 1876."

ALUM.—A whitish, astringent, saline substance; properly it is a double salt, being composed of sulphate of potash and sulphate of alumina, which, along with a certain proportion of water, crystallize together in octahedrons or in cubes. Its formula is $KOSO_3 + Al_2O_33SO_3 + 24HO$. Alum is soluble in eighteen times its weight of cold water, and in its own weight of hot water. The solution thus obtained has a peculiar astringent taste, and is strongly acid to colored test-papers. When heated, the crystals melt in their water of crystallization; and when the water is completely driven off by heat, there is left a spongy white mass, called burnt or anhydrous alum. Alum is much used as a mordant in dyeing. This property it owes to the alumina in it, which has a strong attachment for textile tissues, and also for coloring matters; the alumina thus becomes the means of fixing the color in the cloth. The manufacture of the colors or paints called lakes depends on this property of alumina to attach to itself certain coloring matters. Alum is also used in the preparation of leather from skins, and, in medicine, as a powerful astringent for arresting bleeding and mucous discharges. Its use in the making of bread, to give a white appearance and more pleasing consistence to bread made from indifferent flour, is highly objectionable. The potash in alum can be replaced partly or altogether by soda or ammonia; the alumina by oxide of chromium or sesquioxide of manganese; or the sulphuric acid by chromic acid or peroxide of iron, without altering the form of the crystals. There are thus soda, ammonia, chrome, etc., alums, forming a genus of salts of which common alum is only one of the species. The more important members of the class, expressed in symbols, are:

$KOSO_3 + Al_2O_3 3SO_3 + 24HO$, potash alum.

$NaOSO_3 + Al_2O_3 2SO_3 + 24HO$, soda alum.

$NH_4OSO_3 + Al_2O_3 3SO_3 + 24HO$, ammonia alum.

$KOSO_3 + Cr_2O_3 3SO_3 + 24HO$, chromic potash alum.

$FeOSO_3 + Al_2O_3 3SO_3 + 24HO$, ferrous alum.

ALUMINIUM.—A white metal, somewhat resembling silver, but possessing a bluish hue which reminds one of zinc. It is very malleable and ductile, in tenacity it approaches iron, and it takes a high polish. When heated in a furnace, it fuses, and can then be cast in moulds into ingots. Exposed to dry or moist air, it is unalterable, and does not oxidize as lead and zinc do. Cold water has certainly no action upon it, and in the majority of experiments hot water has not sensibly affected it. Sulphuretted hydrogen, the gas which so readily tarnishes the silver in households, forming a black film on the surface, does not act on aluminium, which is found to preserve its appearance under all ordinary circumstances as perfectly as gold does. When fused and cast into moulds, it is a soft metal like pure silver, and has a density of 2.56; but when hammered or rolled it becomes as hard as iron, and its density increases to 2.67. It is therefore a very light metal, being lighter than glass, and only one fourth as heavy as silver. This property was taken advantage of by Napoleon III., who ordered the eagles surmounting the standards of the French army to be made of aluminium instead of silver; and thus the same-sized eagle was reduced to one fourth of its former weight. Aluminium is very sonorous; and when a rod or small bell made of it is struck, it gives out a very sweet, clear, ringing sound. Aluminium forms with copper several light, very hard, white alloys; also a yellow alloy, which, though much lighter than gold, is very similar to it in color. By itself, aluminium is used for jewelry, small statuettes, and other works of art. It is also employed for the tubes of field-glasses Its bluish color can be whitened by hydrofluoric and phosphoric acids, and also by a heated solution of potash. On the whole, considering its valuable properties, this metal has not received such extensive application in the arts as might have been expected.

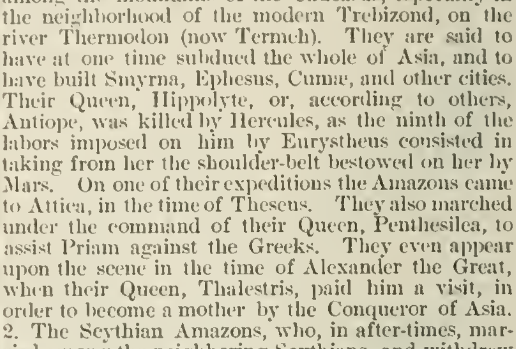
ALUMINIUM-BRONZE.—An alloy of copper and aluminium, having great strength and hardness. See *Cannon-Metals*.

ALUM-LEATHER.—A leather much used in the Armory, tanned by a composition of alum and salt. Three pounds of salt and four of alum are used to one hundred and twenty middle-sized skins, which are placed in a tumbling-box with a sufficient quantity of water, and treated in the usual manner. Alum was first used as a tanning agent by the Saracens.

ALURE.—An old term for the gutter or drain along a battlement or parapet wall.

AMAZONS.—According to a very ancient tradition, the Amazons were a nation of women, who suffered no men to remain among them, but marched to battle under the command of their Queen, and formed for a long time a formidable State. They held occasional intercourse with the men of the neighboring States. If boys were born to them, they either sent them to their fathers, or killed them. But they brought up the girls for war, and burned off their right breasts, that they might not be prevented from bending the bow. From this custom they received the name of Amazons; that is, "breastless." Such is the ordinary tale; the origin of which is perhaps to be accounted for by supposing that vague reports, exaggerated and poetically embellished, had reached the Greeks of the peculiar way in which the women of various Caucasian districts lived, performing military duties which elsewhere devolved on husbands, and also of the numerous examples of female heroism which, travellers inform us, still distinguish the women of that region. In later times, however, the word Amazon has been supposed to have some connection with the Circassian word "Maza," signifying the moon, as if the myth of the Amazons had taken its origin in the worship of the moon, which prevailed on the borders of Asia. Three nations of Amazons have been mentioned by the ancients. 1. The Asiatic Amazons, from whom the others branched off. These dwelt on the shores of the Black Sea, and among the mountains of the Caucasus, especially in the neighborhood of the modern Trebizond, on the river Thermodon (now Termeh). They are said to have at one time subdued the whole of Asia, and to have built Smyrna, Ephesus, Cumæ, and other cities. Their Queen, Hippolyte, or, according to others, Antiope, was killed by Hercules, as the ninth of the labors imposed on him by Eurystheus consisted in taking from her the shoulder-belt bestowed on her by Mars. On one of their expeditions the Amazons came to Attica, in the time of Theseus. They also marched under the command of their Queen, Penthesilea, to assist Priam against the Greeks. They even appear upon the scene in the time of Alexander the Great, when their Queen, Thalestris, paid him a visit, in order to become a mother by the Conqueror of Asia. 2. The Scythian Amazons, who, in after-times, married among the neighboring Scythians, and withdrew further into Sarmatia. 3. The African Amazons, who, under the command of their Queen, Myrina, subdued the Gorgons and Atlantes, marched through Egypt and Arabia, and founded their capital on the lake Tritonis, but were then annihilated by Hercules.

AMBULANCE.—A military term which is somewhat differently applied in different countries. In France, an ambulance is a portable hospital, one of



which is attached to every division of an army in the field, and provided with all the requisites for the medical succor of sick and wounded troops. Such an ambulance is stationed at some spot removed from immediate danger; and soldiers are sedulously employed after a battle in seeking out those who have fallen, and conveying them to the ambulance. Baron Larrey, during the great wars of the first Napoleon, brought this department of medical business to a high degree of efficiency, and set an example to the rest of Europe. When England engaged in war with Russia in 1854, the ambulance arrangements, like many others relating to the army, were in a very imperfect state. In the English army, ambulance, strictly speaking, means a field-hospital with all its wagons, litters, tents, cooking-canteen, etc.; but sometimes the name is applied to a four-wheeled wagon or a two-wheeled cart fitted up for the reception of wounded men. When Lord Raglan was about to be sent out with the army, Dr. Guthrie, President of the College of Surgeons, devised a new form of ambulance-cart; while Dr. Andrew Smith, Director-General of the Army and Ordnance Medical Department, invented a new ambulance-wagon. In the Guthrie cart, the badly wounded were laid on it at full length, while those slightly hurt sat in front and rear and on the sides. A stretcher was slung from the top for the accommodation of the former. The back-board was let down for cases requiring amputation. The hospital-chests were lashed underneath. After the battle of the Alma, the English were almost entirely destitute of means for conveying their wounded down to the beach; but the French had for this purpose a large number of *cacolets*, suggested to them by their experience in Algeria. Each of these consists of two easy-chairs, slung, like panniers, across the back of a mule, as shown in the drawing on page 40. These were especially available along tracks where no wheel-carriage could pass. These cacolets have since been adopted in the English army, as well as improved hand-litters, wheeled litters, or barrows, and ambulance-wagons on a more modern model than those of Smith and Guthrie, but having the same general character. The American war, the wars of 1866 and '70, and, above all, the growth of volunteer aid-societies under the influence of the Geneva Convention of 1866 (which gave to the wounded and their attendants the privileges of neutrality), have largely developed the ambulance equipments of every European army. Every international exhibition now contains an immense number of designs for the safe transport of the wounded. The most remarkable step taken in this direction has been the organization of railway ambulances. Trains of carriages either built for the purpose, or adapted from the ordinary rolling-stock, can now be fitted up as moving hospitals, with their staff of surgeons and attendants; and by means of these railway ambulances the wounded can be safely and rapidly removed from the encumbered field-hospitals to the permanent hospitals of the great cities of their own country. All the fittings for thus adapting railway trains to hospital purposes are now kept permanently in store in many of the countries of the Continent.

The following are the rules for a uniform system of ambulances in the armies of the United States: The Medical Director, or chief Medical officer, of each army corps shall, under the control of the Medical Director of the army to which such army corps belongs, have the direction and supervision of all ambulances, medicine and other wagons, horses, mules, harness, and other fixtures appertaining thereto, and of all officers and men who may be detailed or employed to assist him in the management thereof, in the army corps in which he may be serving. The Commanding Officer of each army corps shall detail officers and enlisted men for service in its ambulance corps upon the following basis, viz.: One Captain, who shall be Commandant of said ambulance corps; one First Lieutenant for each division; one Second Lieutenant for each brigade; one Sergeant for each regiment; three privates for each ambulance, and one private for each wagon. The officers and non-commissioned officers of the ambulance corps shall be mounted. The officers, non-commissioned officers, and privates detailed for each army corps shall be examined by a board of Medical officers of the same as to their fitness. Such as are found to be not qualified shall be rejected, and others detailed in their stead. There shall be allowed and furnished to each army corps two-horse ambulances, upon the following basis: Three to each regiment of Infantry of five hundred men or more; two to each regiment of Infantry of more than two hundred and less than five hundred men; and one to each regiment of Infantry of less than two hundred men; two to each regiment of Cavalry of five hundred men or more; and one to each regiment of Cavalry of less than five hundred men; one to each battery of Artillery, to which it shall be permanently attached; to the headquarters of each army corps, two such ambulances; and to each division train of ambulances two army-wagons. Ambulances shall be allowed and furnished upon the same basis to divisions, brigades, and commands not attached to any army corps. Each ambulance shall be provided with such number of stretchers and other appliances as shall be prescribed by the Surgeon-General.

During the late war in America, much attention was given to the subject of ambulances, and many forms were proposed possessing merit, as was demonstrated by their successful use in the Franco-German war of 1870. The drawing shows a form of ambulance used in the United States with satisfaction. The two stretchers shown are detachable, and may be placed inside the wagon when moving over level roads, or may be removed and transported by men when moving over rough and rocky country, or when it becomes necessary to take the wagons apart in

order to get them up or down very steep places. The stretchers are so constructed with hinges and hooks as to be folded into a very small space when not needed, and to permit the supports to be used as handles. In the United States service, litters are adopted or authorized by the Secretary of War, in lieu of ambulances, when judged necessary, under such rules and regulations as may be prescribed by the Medical Director of each army corps. See *Guthrie Ambulance-cart*.

AMBULANCE CORPS.—A body of men usually unknown in peace-time, but formed on the outbreak of war to attend upon the sick and wounded. The *personnel* of such a body in England would be taken from the Army Hospital Corps; and the ambulance carriages attached to the transport would form the *matériel*.

AMBULATOR.—An instrument, sometimes called Perambulator, for measuring distances. The term is often erroneously applied to a velocipede and to a traction engine, whose mode of propulsion is by oscillating bars whose feet come in contact with the ground in somewhat similar manner to the natural action of the legs of animals or of man. See *Odometer*.

AMBUSCADE.—In planning an ambuscade, we should be well acquainted with the enemy's force, and the state of discipline shown by it. The position chosen for the attempt must be favorable to the concealment of troops, and if practicable it should be reached by night, every precaution being taken to insure secrecy. The best positions are those where the enemy is enclosed in a defile or village and has not taken the proper precautions to secure himself from an attack. By seizing the outlets of the defile by infantry, in such cases, and making an impetuous charge of cavalry into it, the enemy may be completely routed. Ambuscades may frequently be attempted with success in the affairs of advanced- and rear-guards; by pushing the enemy vigorously and then falling back, if he offers a strong resistance, so as to draw him upon a point where troops are posted in force to receive him. To trace anything more than a mere outline, as a guide in operations of this kind, which depend upon so many fortuitous circumstances, would serve but little useful purpose. An active, intelligent officer, with an imagination fertile in the expedients of his profession, will seldom be at a loss as to his best course when the occasion offers; to one without these qualities, opportunities present themselves in vain. See *Ambush* and *Surprise*.

AMBUSH.—Another name for Ambuscade. In former days, when soldiers fought hand to hand more frequently than at present, the ambush was much resorted to; but the tactics of modern times render it less available. It was by an ambush on the part of the revolted Sepoys that so many British soldiers were killed and wounded in that adventure which was known, during the wars of the Indian Mutiny, as the "Disaster at Arrah," in July, 1857. An ambush is neither an "attack" nor a "surprise," in military language; it is something more sudden and unexpected than either. See *Surprise*.

AME.—A French term, similar in its import to the word *chamber*, as applied to cannon, etc.

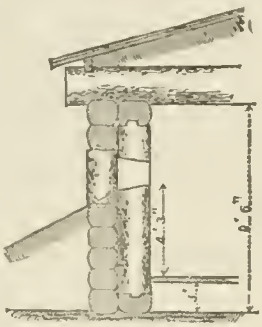
AMENDE HONORABLE.—In the old armies of France, this expression signified an apology for some injury done to another, or satisfaction given for an offence committed against the rules of honor or military etiquette, and was also applied to an infamous kind of punishment inflicted upon traitors, parricides, or sacrilegious persons, in the following manner: The offender being delivered into the hands of the hangman—his shirt stripped off, a rope put about his neck, and a taper in his hand—was led into the Court, where he begged pardon of God, the Court, and his Country. Sometimes the punishment ended there; but often it was only a prelude to death or banishment to the galleys. The *amende honorable* prevails yet in some parts of Europe.

AMENTATÆ.—A sort of lance used by the Romans, which had a leathern strap attached to the center of it.

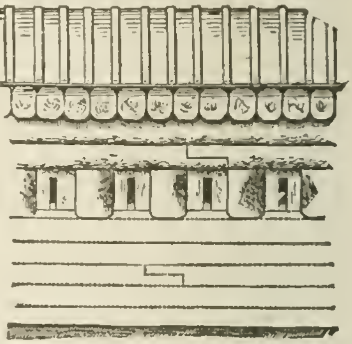
AMENTUM.—A leathern strap used by the Romans, Greeks, and Galicians to throw lances. It was fastened around the second and third fingers, and a knot was tied on it, which at the throwing of the lance loosened itself.

AMERICAN BLOCK-HOUSE.—In the more recent block-houses erected in the United States for the protection of bridges, railroad-stations, etc., the sides and roof are constructed with a double thickness of logs eighteen inches in diameter, hewn to a face of eight inches where they are in contact. The inner logs are placed upright, the outward horizontal. A space is left in the outward casing sufficient for the fire from the loop-holes made through the inner. The horizontal logs above the loop-holes are held up by short uprights, mortised into them and into those just below. The ceiling is covered with earth, as shown in the section, three feet thick at the ridge and sloping towards the eaves to about six or nine inches, where it is confined by a pole-plate. The earth is protected from the weather by a board roofing. Tin or sheet-iron ventilators are made through the roofing and ceiling, and a brick flue to receive the pipe of the stove used in cold weather. Some of these structures are built in the form of a cross, consisting of a square central chamber, twenty-four feet on a side, and of four wings of the same form and dimensions when the block-house is for cannon. An embrasure is pierced in each of the three sides of each wing to serve a single gun. The cheeks of the embrasures are faced with logs, and the mouth is secured by a musket-proof shutter with a loop-hole in it. The embrasures are below the level of the loop-holes, allowing these to be used whenever necessary. Arrangements for magazines and store-rooms are made under the floor of the block-house in the most secure parts. The entrance to the block-house may be either through a postern, the bottom of which is on the level of that of the ditch, a ramp leading from this level outwards, a door properly secured, and steps, forming the inner communications; or it may be arranged with a plank thrown across the ditch on the same level as the natural ground, the entrance to the door being masked by a double stockade, leaving the same passage-way as that of the doorway. Loop-holes in the door and sides of the building sweep this passage.

The block-house is sometimes arranged with two stories, the corners or the sides of the upper story projecting over the sides of the lower. Either of these methods is sufficient for the defence of the lower story; but the first is the best to procure a fire in the direction of its angles. It can only be used, however, as a defence against infantry. When artillery cannot be brought to bear against the top of the block-house, it may be constructed like an ordinary floor, and be covered with nine or twelve inches of earth to guard against fire. The application of wood to the purposes of defence is one of paramount importance in our country. A block-house, surrounded by a defensive stockade, is impregnable to the attack of infantry if



Section.



Elevation.

properly defended, and is therefore peculiarly suitable to either wooded or mountainous positions, where a train of artillery cannot be taken without great labor, owing to the impediments that may be thrown in its way, by rendering the roads impassable from obstructions easily obtained. In positions covered by extensive earthen works, such as those that would be required for the defence of the towns on our seaboard, and which would be occupied during a war, a defensive arrangement of the barracks for the troops, so that they might serve, in case of the main works being forced, as rallying-points, under cover of which the main body of troops may retreat with safety, is a subject that commends itself to the serious attention of the engineer. From the details already entered into, an efficient combination for this purpose will suggest itself to the reader, without entering further into particulars. See *Block-house*.

AMERICAN FLAG.—On the 14th of June, 1777, the Continental Congress resolved that the Flag of the United Colonies should show thirteen stripes of red and white alternating, to represent the number of the Colonies, with thirteen stars in a blue field. This became the Flag of the United States, and a star is added for every State added to the Union. The width of the Flag should be two thirds its length. Seven of the stripes, beginning with the outermost, are red. The blue field, or union, is square and has the width of seven stripes. The United States Revenue Flag has sixteen vertical stripes, alternately red and white, with a white union bearing the National Arms in dark blue. See *Flags*.

AMES GUN.—A wrought-iron rifled gun made on the *built-up* principle. Bars of wrought-iron are bent around a mandrel and their ends are welded so as to form rings. After turning them in a lathe, two or more of these rings are fitted one within another to form a disk. These disks are then welded in succession to a concave breech-piece. The shape of the gun is that of the Dahlgren. The trunnions are attached by being screwed into the body of the gun. These guns have shown remarkable endurance. One was fired 1630 times with a 37-pound rifle-shot and $3\frac{1}{2}$ pounds of powder. The chambers have shown some stretching at the welds, and with this a weakness to resist longitudinal strains. The latter is effectually overcome by employing *Dahlgren's breech-strap.* See *Ordnance.*

AMICUS CURIÆ.—Counsel, or at least Amici Curiæ (Friends of the Court), are allowed to prisoners in all cases; but no person is permitted to address the Court, or interfere in any manner with its proceedings, except the parties themselves.

AMMUNITION.—Sometimes this name is given to cannon and mortars, as well as to the projectiles and explosive substances employed with them; but more usually ammunition is considered to apply to the latter—such as shot, shell, gunpowder, cartridges, fuses, wads, grenades. Muskets, swords, bayonets, and other small-arms are sometimes, but improperly, included under this term. The Royal Laboratory at Woolwich is the place where ammunition is chiefly prepared for the British army and navy. The cannon-balls may be cast at some of the great iron foundries in the North; the shells may be cast or forged in the shell-factory at Woolwich; the muskets may be made at Birmingham, and the rifles at Enfield; the bullets at the shot-factories; the gunpowder at Waltham Abbey—and so on; but the "making up" of the ammunition is mostly conducted at the establishment above mentioned. In the United States, ammunition is prepared at the various Arsenals and by numerous private Manufacturing Companies. Bags of serge, in enormous number, are cut out and made, and filled to form the cartridges for large ordnance. Bags or tubes of paper are made and filled to constitute blank cartridges for small-arms; while the ball-cartridges are enclosed in thin copper cylinders. The tubes and combustibles for war-rockets and fuses are also manufactured. The cartridges for small-arms (rifles, muskets, carbines, and pistols) are made in millions; since it is on those that the main offensive operations of an army depend. It has been calculated by the Woolwich Authorities that a British army of 60,000 men, comprising a fair average of infantry, cavalry, artillery, and engineers, ought to be provided with no less than 18,000,000 ball-cartridges for small-arms, for six months' operations. These would require 1000 ammunition-wagons and 3600 horses to convey them all at once. It is therefore deemed better that, under any such circumstances, there should be established *entrepôts* for supplying the troops from time to time. The wagons constructed for this kind of service will carry 20,000 rounds of small-arm ammunition each; the cartridges are packed in boxes, and the wagons are drawn by four horses each. Several wagons are organized into an "equipment," under the charge of a detachment of artillery; and there are several such equipments for an army of the magnitude above mentioned—one for each division of infantry, a small portion for the cavalry, and the rest in reserve. It has been laid down that an army of 60,000 men ought to have 2,680,000 cartridges *with them*, besides those in reserve; and that the conveyance of such a quantity, with a few forges and stores, would require 150 ammunition-wagons, 830 men, and 704 horses. The equipment would return to the *entrepôt* for a new supply when needed. In the Peninsular War, and at Waterloo, the English used two-horse carts, carrying about 10,000 rounds of small-arm ammunition each; but a superior kind of wagon has been since introduced. In the field, an infantry soldier usually carries about 60 rounds, put in compartments in his pouch. When the word ammunition is used in connection with artillery matters, the "fixed" ammunition comprises the loaded shells, cartridges, and carcasses; whereas the "unfixed" are the unfilled case-shot, grape-shot, and shell. During peace, the Woolwich laboratory serves out little less than 1,000,000 lbs. of gunpowder annually, in ammunition for the army and navy, for purposes of exercising, saluting, etc. The chief kinds of ammunition will be found briefly described under their proper headings. See *Ammunition-boxes, Breaking up Ammunition, Cartridge, Center-fire Metallic-case Cartridge, Field and Mountain Ammunition, Fixed Ammunition, Metallic Ammunition for Small-arms, Paper Ammunition for Small-arms, Preservation of Ammunition and Fireworks, Siege and Garrison Ammunition, Stand of Ammunition*, and *Strapped Ammunition.*

AMMUNITION-BOXES.—Packing-boxes for field-ammunition are made of well-seasoned stuff (generally white pine), 1.25 inch thick, dovetailed with the tenon on the ends. The top of the box is fastened with six 2-inch screws; the box has two handles of 1¾-inch rope, attached to brackets at the ends. The boxes are painted on the outside different colors to indicate the contents of the box. Those containing shot are painted *olive;* shells, *black;* spherical case-shot, *red;* and canisters, a *light drab.* The kind of ammunition is marked on each end in large white letters. The place and date of fabrication are marked on the inside of the cover. The boxes are packed as follows:

For Smooth-bore Guns.—*Shot, spherical case* and *canisters, fixed.*—Laid in two tiers across the box, the shot or canisters alternating with the cartridges at each side. The shot or canisters of the upper tier rest on those of the lower and not on the cartridges. Canisters are packed in the same manner, omitting the strips of wood in the bottom of the box.

For 12-pdr. Mountain-howitzer.—*Shells* and *case-shot, fixed.*—Placed upright, the balls down, resting on strips of wood as for the other howitzer. *Canisters* are packed in the same manner, resting on the bottom of the box.

For Rifled Guns.—*Shells* and *case-shot.*—Placed upright, the balls down, resting on strips of wood as for the howitzer. The iron part of the balls rests against strips of wood 4 inches wide and .25 inch thick, nailed to the side and ends of the box at the bottom, and similar strips placed between the rows of the balls to prevent the soft metal cups from bearing against the box or against each other and being bruised; the cartridges are placed on top of the projectiles. *Canisters* are packed in the same manner as the case-shot, omitting the strips of wood on the bottom of the box.

In all the boxes the small stores are placed in the vacant spaces on top of the ammunition. A layer of tow is placed in the bottom of each box, and the whole contents are well packed in tow, filling the box so as to be pressed down by the cover. About three pounds of tow are required for a box. See *Ammunition* and *Madigan Ammunition-box.*

AMMUNITION-CHESTS.—Chests placed on field-limbers and caissons for the transportation and safe-keeping of ammunition. The limber has one and the caisson has three such chests, which will seat twelve cannoneers if necessary. The interior compartments of the ammunition-chests vary according to the nature of the ammunition with which they are loaded.

AMMUNITION-SHOES.—Shoes made for soldiers and sailors in the British service, and particularly for use by those frequenting the magazine, being soft and free from metal.

AMMUNITION-WAGON.—A carriage employed for the transportation of ammunition. The points essential in the general construction of field-artillery carriages apply equally in that of the ammunition-wagon, so far as the traveling conditions are concerned. It need only be observed that the general form of a limber-carriage can be most effectively retained in the ammunition-wagon by substituting a perch for the trail of the gun-carriage, and furnishing it with an eye in front for an attachment to the limber-hook. The arrangement of the ammunition-boxes on the platform of the body must be such as to insure the center of gravity of the entire load falling between the wheels and limber-hook, the pressure on the latter being regulated with particular reference to stability and ease of draught.

AMNESTY.—An act of pardon or oblivion, and the effect of it is that the crimes and offences against the State, specified in the act, are so obliterated that they can never again be charged against the guilty parties. The amnesty may be either absolute or qualified with exceptions. Instances of the latter are to be found in ancient and modern history: thus, Thrasybulus, when he overthrew the oligarchy in Athens, caused an amnesty to be proclaimed, from the operation of which the thirty tyrants, who had formed the oligarchy, and some few persons who had acted under them, were excluded. Again, Bonaparte, on his return from Elba in 1815, issued a decree, which was published at Lyon, declaring an amnesty, from the benefits of which he excepted thirteen persons whom he named. In the absence of specific statutes on the subject, the exercise of amnesty in the United States was assumed to lie with the President. Washington, without participation by Congress, granted amnesty, or pardon, to persons who took part in the "Whisky Rebellion." John Adams proclaimed full pardon of those engaged in the House-tax Insurrection, and Madison did the same in the case of the Barataria Pirates. During the Rebellion, Lincoln and Johnson issued four or five proclamations of amnesty, one of the latest being so broad in its conditions that it raised in Congress the question whether the President had the right to such action, and the Judiciary Committee of the Senate, in February, 1869, decided that he had not. Amnesty is so closely connected with "pardon" and "reprieve" that it is difficult to distinguish them. In one message President Lincoln asserted his exclusive authority under the Constitution, and his independence of Congress in respect to the pardoning power, even more emphatically than in the proclamation. In 1862 Congress had passed an Act giving full power to the President, but he considered the Act unnecessary, claiming that the Constitution gave him the necessary authority. Then, in 1867, the Act of 1862 was repealed; and all amnesty proceedings were remanded to their original basis in the Second Article of the Constitution, until further defined in later amendments. The Supreme Court had decided in the case of Garland that for pardon the President's power was perfect; yet that is not held to include general amnesty. But in 1868 the Fourteenth Amendment to the Constitution, prohibiting rebels from holding certain offices unless their disabilities should first "be removed by a vote of two thirds of each House," seemed to diminish the range of executive authority. Still, the Supreme Court has held in several cases to the absolute power of the President to grant amnesty and pardon, and that neither Congress nor any authority less than an express change of the Federal Constitution can reverse, abridge, or direct that power. The Court, through Chief-Justice Chase, says: "It is the intention of the Constitution that each of the great co-ordinate departments of the government, the legislative, the executive, and the judicial, shall be in its sphere independent of the others. To the executive alone is entrusted the power of pardon, and it is granted without limit. Pardon includes amnesty. It blots out the offense pardoned, and removes all its penal consequences."

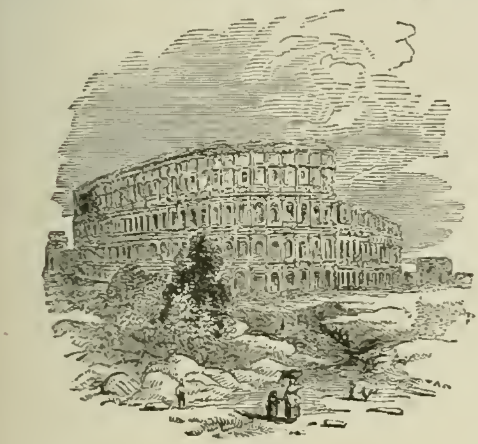
AMORCE.—An old military word for fine-grained powder, such as was sometimes used for the priming of great-guns, mortars, and howitzers; as also for small-arms, on account of its rapid inflammation. The term is also applied to a port-fire or quick-match.

AMORCER.—A French word meaning to decoy, and used in the sense of making a feint in order to deceive the enemy and draw him into a snare.

AMORCOIR.—An instrument used by the French for priming muskets; also a small copper box in which are placed the percussion-caps.

AMPHICTYONIC COUNCIL.—This central politico-religious Court of several Grecian tribes was held twice a year. In spring, the members assembled in the temple of Apollo, at Delphi; in autumn, in the temple of Ceres, at the village of Anthela, near Thermopylæ. Their purpose was twofold: 1. To determine questions of International Law; 2. To preserve the Religious Institutions of the Greeks. As there were many Amphictyonies in the early days of Greek history—of which, however, by far the most important was that which forms the subject of our article—it has generally been supposed that they originated out of a desire for social union, and were, consequently, a result of the national instinct for civilization. Like the Olympic games of a later period, their tendency was to develop a spirit of brotherhood where it was greatly required. The restless Greek intellect, in its application to political life, had naturally an excessive and perilous love of individualism, out of which rose the numerous strifes and animosities of the various States. These Councils, on the other hand, were calculated to exert a wholesome centralizing influence. They knit together, for a time, the distracted tribes in a bond of common interest and piety. Like the Olympic games, too, they became the occasion of vast gatherings of the Greek peoples, who crowded thither for every variety of purpose, sacred and secular; and thus a feeling of unity and pure national patriotism was, temporarily at least, excited in the popular mind. The special origin of the Amphictyonic Council or League is unknown, though we know that it was composed of twelve tribes. The ancient writers differ in the names of these; but the list given by the orator Æschines, though containing only eleven, is perhaps the safest to adhere to: the Thessalians, Bœotians, Dorians, Ionians, Perrhæbians, Magnetes, Locrians, Œtæans, Phthiots, Malians, and Phocians. Probably the remaining tribe was the Dolopians, who are mentioned in other accounts. It has been justly concluded that the great preponderance of the northern tribes, who were of the old Pelasgic race, proves the antiquity of the Council. It must have been older than the descent of the Dorians upon the Peloponnesus, or the emigration of the Ionians to the coasts of Asia Minor. Each of the twelve tribes sent to the Amphictyonic Council two members. These twenty-four Representatives possessed equal authority, although some of the tribes were very small and hardly independent. They bound themselves by an oath that "they would destroy no city of the Amphictyons, nor cut off their streams in war or peace; and if any should do so, they would march against him and destroy his cities; and should any pillage the property of the god, or be privy to, or plan anything against, what was in his temple at Delphi, they would take vengeance on him with hand, and foot, and voice, and all their might." It is only right to state, what indeed most people would naturally conclude for themselves, that so excellent an oath was very indifferently kept. In the primitive period of Greek history, it, in all likelihood, exerted the beneficial and civilizing influence of which we have spoken; but it opposed only a feeble check to the passions and ambition of a more powerful age. The members at times connived and even took part in many political crimes, and thus violated their oath.

AMPHITHEATER.—A spacious building, generally elliptical in form, used by the Romans for exhibiting gladiatorial combats, fights of wild beasts, and other spectacles. The Amphitheater differed from a theater for dramatic performances in this, that whereas the theater had only a semicircle of seats fronting the stage, the Amphitheater was entirely surrounded by them; and hence the name of Amphitheater. Till a late period at Rome, these erections were of wood, and merely temporary, like a modern race-stand. They seem, however, to have been of enormous size, as Tacitus mentions one, during the reign of Tiberius, which gave way and caused the death or injury of 50,000 spectators. Amphitheaters of stone had begun, however, to be erected at an earlier period than this, the first having been built at the desire of Augustus. The Flavian Amphitheater at Rome, known as the Colosseum, which was begun by Vespasian, and finished by Titus 80 A.D., ten years after the destruction of Jerusalem, was probably the largest structure of the kind, and is fortunately also the best preserved. It covers about five acres of ground, and was capable of containing 87,000 persons. Its greatest length is 620 feet, and its greatest breadth 513. On the occasion of its dedication by Titus, 5000 wild beasts were slain in the arena, the games having lasted for nearly 100 days. The exterior is about 160 feet in height, and consists of three rows of columns, Doric, Ionic, and Corinthian, and above all a row of Corinthian pilasters. Between the columns there are arches, which form open galleries throughout the whole building; and between each alternate pilaster of the upper tier there is a window. There were four tiers or stories of seats, corresponding to the four external stories. The first of these is supposed to have contained twenty-four rows of seats, and the second sixteen. These are separated by a lofty wall from the third story, which is supposed to have contained the populace. The *podium* was a kind of



Colosseum.

covered gallery surrounding the arena, in which the Emperor, the Senators, and Vestal Virgins had their seats. The building was covered by a temporary awning or wooden roof, called *velarium*, the mode of adjusting and fastening which has given rise to many antiquarian conjectures. The open space in the centre of the Amphitheater was called *arena*, the Latin word for sand, because it was covered with sand or saw-dust during the performances. The taste for the excitement of the Amphitheater which existed at Rome naturally spread to the provinces, and large amphitheaters were erected not only in the provincial towns of Italy, as at Capua, Verona, Pompeii, etc., but at Arles and Nismes, in France; and even in England, at Cirencester, Silchester, and Dorchester.

AMPLITUDE.—In gunnery, the range of a shot, or the horizontal right line, which measures the distance over which it has passed.

AMPOULETTE.—A wooden cylinder which contains the fuse of a hollow projectile.

AMPUTATION.—A surgical process of frequent necessity on the field of battle. The amputation of a limb was in ancient times attended with great danger of the patient's dying during its performance, as Surgeons had no efficient means of restraining the bleeding. They rarely ventured to remove a large portion of a limb, and when they did so they cut in the gangrened parts, where they knew the vessels would not bleed ; the smaller limbs they chopped off with a mallet and chisel; and in both cases had hot irons at hand with which to sear the raw surfaces, boiling oil in which to dip the stump, and various resins, mosses, and fungi, supposed to possess the power of arresting hemorrhage. Some tightly bandaged the limbs they wished to remove, so that they mortified and dropped off; and others amputated with red-hot knives, or knives made of wood or horn dipped in vitriol. The desired power of controling the hemorrhage was obtained by the invention of the tourniquet in 1674 by a French Surgeon, Morell. The ancient Surgeons endeavored to save a covering of skin for the stump by having the skin drawn upwards by an assistant, previously to using the knife. In 1679 Lowdham of Exeter suggested cutting semicircular flaps on one or both sides of a limb, so as to preserve a fleshy cushion to cover the end of the bone. Both these methods are now in use, and are known as the "circular" and the "flap" operations: the latter is more frequently used in this country. A flap amputation is performed thus: The patient being placed in the most convenient position, an assistant compresses the main artery of the limb with his thumb, or a tourniquet is adjusted over it. Another assistant supports the limb. The Surgeon with one hand lifts the tissues from the bone, and, transfixing them with a long narrow knife, cuts rapidly downwards and towards the surface of the skin, forming a flap; he then repeats this on the other side of the limb. An assistant now draws up these flaps, and the knife is carried round the bone, dividing any flesh still adhering to it. The Surgeon now saws the bone. He then, with a small forceps, seizes the end of the main artery, and drawing it slightly from the tissues, an assistant ties it with a thread. All the vessels being secured, the flaps are stitched together with a needle and thread, and a piece of wet lint is laid over the wound. An expert Surgeon can remove a limb thus in from thirty to sixty seconds.

AMUSETTE.—A stocked gun mounted on a swivel, and carrying a ball or charge of buck-shot of from 8 to 32 ounces' weight. The *amusette* invented by the celebrated Marshal Saxe carried a half-pound leaden ball.

ANABASH.—Expeditious couriers, in antiquity, who carried dispatches of great importance in the Roman Wars.

ANACARA.—A sort of drum much used by the Oriental cavalry and mounted troops.

ANACLETICUM.—A particular blast of the trumpet, in the ancient art of war, whereby the fearful and flying soldiers were rallied to the combat.

ANALYSIS OF POWDER.—In the inspection of gunpowder, the following is the usual process of analyzing: Pulverize 75 grains, place in a glass beaker with eight ounces of distilled water; stir rapidly with a glass rod; when clear, test with litmus-paper for acids and with turmeric for alkalies. Wash repeatedly to remove all the sulphur and charcoal, and examine the residuum with a microscope for coarse particles of either or foreign substances. Determine the amount of moisture by placing 45 grains of powder, ground fine, in a watch-crystal, dry thoroughly, and cover the crystal with another. The weight of dish and cover being known, the loss of weight due to moisture contained in them is found.

Put the 45 grains of dry powder in a pipette, having a wad of heated asbestos in the narrow part; verify the weight of the pipette and wad; insert the pipette into a hole in the cork of a small weighed flask; treat the powder with 50 c.c. of rectified bisulphide of carbon, remove the pipette and cork, recork the flask, and distil off the bisulphide of carbon for future use. A sand-bath is used during distillation, which must proceed very slowly, the flask being raised above the sand, which must not become too warm. The percentage of sulphur is calculated from the weight thus obtained. One tenth per cent is added to the amount of sulphur, as that quantity generally remains in the powder after the treatment with the bisulphide of carbon.

The pipette containing the residue is fixed in a small weighed flask, the portion above the crook being wrapped in muslin. The tube of the flask is connected with an air-pump by a rubber tube, and the contents of the pipette treated with 40 c.c. of distilled water; work the pump carefully to allow the water to enter the flask by drops; to prevent crystallization of the dissolved niter in the narrow part of the pipette, cold water is first used, then warm, and lastly hot. Drench the muslin on the pipette with water of the same temperature as that for dissolving the niter. When the flask contains 40 c.c. of the niter solution, remove the pipette and evaporate the water on a sand-bath, removing the flask occasionally, and cool as the solution becomes saturated. When the niter is crystallized, it is heated until it and the flask are quite dry; the weight of the niter is then taken.

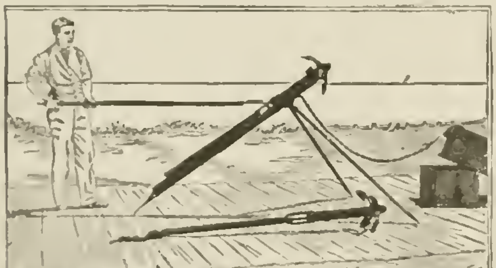
The asbestos wad and a large part of the charcoal are pushed out of the pipette by a wire into a watch-glass; the pipette and watch-glass and contents dried and weighed; the weight of the pipette, watch-glass, and asbestos being known, that of the charcoal is obtained. The weight added to the sulphur is of course deducted. See *Gunpowder* and *Inspection of Powder*.

ANARCHY.—The state of society without any regular government, when a country is torn by the strife of parties, and no law or authority remains. Complete anarchy is necessarily rare and of short duration; but conditions approaching to it often arise after revolutions and gross abuses in government; and in such cases it is apt to become, as in the South American States, a chronic or permanent evil, attended with constant national decay.

ANCHOR.—An iron instrument composed of a long shank, having a ring at one end to which the cable is fastened, and at the other branching out into two arms or flukes tending upwards with hooks or edges on each side; its use in an army equipment is to moor transports, boats, pontoons, and rafts. It is also a good hold for a capstan. The weights of anchors vary according to the particular use they are put to.

ANCHOR-BALL.—A contrivance for saving life in cases of shipwreck. It consists of a ball having several hinged prongs fitting in slots, which are intended to catch in the rigging of a stranded vessel. The ball is fired from a mortar, and carries a light line by which a stout rope may be carried ashore from the vessel. The French use a ball for this purpose having a harpoon passing through it, on the rear end of which a line is wound. The term *anchor-ball* is also applied to a carcass or incendiary ball affixed to a grapnel by which it is intended to adhere to and fire a vessel.

ANCHOR-ROCKET.—An 8-centimeter rocket (8^{cm} Ankerrakete), used by the Germans for life-saving purposes, composed of a body, anchor-head, base, rocket-stick, and chain. The case, or rocket-body, is made of sheet-metal, .06 inch in thickness. The anchor-head is made of iron. The front end is sub-spherical in form, connected with the convex curves of the arms



by re-entrant tangent-curved surfaces. The short shank in rear of the head forms a cylindrical tenon that fits the front end of the rocket-case, to which it is secured by screws. The arms and flukes are four in number. The former are triangular-prismoidal in outline, and are placed at right angles to each other. The arms are furnished with the usual palmate flukes, which are well adapted for "holding." The rear end of the rocket-case is reinforced on the inside for 1.5 inch of its length by a cylindrical iron ring. The latter furnishes a seat into which the screws that attach the base are turned. The base is tripodal in form, the legs joining a cylindrical ring at the front end. The conjunction of the legs, or ribs, at the rear end forms a seat into which is screwed the rocket-stick.

When prepared for use and ready for packing the rocket-case is filled with composition and the rear end of the case closed with a water-proof cap to protect the contents from the effects of moisture. This cap is placed 1.3 inch towards the front from the rear edge of the basal ring. A fuse, 2.7 inches in length and .5 inch in diameter, passes through the cap and connects with the rocket composition. The projecting fuse is liable to be broken off in handling if great care is not exercised, as the operator will involuntarily thrust his hand between the ribs to grasp the rocket in picking it up or carrying it. The fuse is steadied in its position by a strap of laboratory paper attached to one of the ribs in the same manner as in the 5^{cm} rocket. The fuse is coated with shell-lac varnish.

The rocket-*stick*, technically so called, is a hollow cylindrical tube of sheet-metal, with a diameter about equal to that of the wooden stick for the 8^{cm} life-saving rocket. It is constructed by taking a strip of sheet-metal of the necessary length and width, curving it and fastening the edges together with twenty-three iron rivets. The front end is filled with an iron plug extended to the front as a frustum of a cone, 1.125 inch in altitude, from which projects the male screw, 2.25 inches long, that enters the base of the rocket when assembled for use. The rear end is furnished with an iron loop having flattened arms that are riveted to the tube. This loop serves as the point of attachment for the rocket-chain. The rocket-chain is made of the best wrought-iron. The rocket-case, base, and "stick" form the *shank* of the quadripalmate anchor. The usual anchor *stock* is absent in this combination. The anchor-rocket, rocket-stick, and chain are all painted black.

The following are the principal dimensions and weights:

	Inches.	Centimeters.
Total length of 8^{cm} anchor-rocket	33.15	84.19
Rocket case:		
Length	20.15	51.17
Exterior diameter	3.22	8.17
Interior diameter	3.1	7.87
Anchor-head:		
Total length	6.5	16.51
Diameter, excluding arms	3.35	8.50
Length of tenon-shank	1.85	4.69
Diameter of tenon-shank	3.1	7.87
Arms:		
Depth near shank	1.4	3.55
Width under side near shank	1.2	3.04
Depth near fluke	0.8	2.03
Width under side near fluke	0.8	2.03
Spread of flukes	15.5	39.36
Length of palms	3.75	9.51
Width of palms	3.75	9.51
Base-ring:		
Length	1.5	3.81
Exterior diameter	3.1	7.87
Interior diameter	2.87	7.28
Base:		
Total length	9.4	23.87
Diameter, front end	3.75	9.51
Diameter, rear end	1.8	4.57
Length of, embracing case	1.4	3.55
Depth of ribs, front end	0.75	1.90
Depth of ribs, rear end	0.80	2.03
Width of ribs	0.40	1.01
Rocket-stick:		
Total length	39.375	99.98
Length of screw	2.25	5.71
Diameter of screw	0.875	2.21
Rocket-chain:		
Total length	123.0	312.41
Ring:		
Exterior diameter	1.5	3.81
Interior diameter	0.7	1.77
Links:		
Length	1.5	3.81
Width	0.75	1.90
Thickness	0.20	0.50
Total length of rocket and stick	70.275	178.47
	Lbs	Kilos.
Average weight of anchor-rocket	37.375	16 95
Average weight of rocket-stick and chain	9.0	4.08

The German Anchor and Life-saving Rockets are packed securely in tin-lined boxes. The boxes are made of hard pine, planed smooth on both sides, with the corners dovetailed. The bottom, sides, and ends are lined with tin. The top is not lined and is screwed to the sides and ends. A label on the inside of the cover of the box bears printed on its face a list of the contents of the box in the German language. A similar label is pasted on the end of the box. The rocket-boxes are oiled but not painted. Bottom, middle, and top clamps at each end hold the rockets in place. A strip of felt separates the rockets from the clamps. See *Chandler Anchor-shot*, *German Life-saving Rocket*, *Life-saving Rockets*, *Lyle-Emery Grapple-shot*, and *Rockets*.

ANCIENT.—A term formerly used to express the grand ensign or standard of an army.

ANCIENT AND HONORABLE ARTILLERY COMPANY.—The first regularly organized military company in America, formed in 1637, and copied from the Honorable Artillery Company of London, dating from 1537. The Boston Company was chartered June, 1638, has always been vigorously sustained, and is noted for the eminent citizens in its membership. It has an annual parade, sermon, and dinner, formal and dignified. A third and elaborately illustrated history of the Company has been recently published. See *Artillery Corps* and *Honorable Artillery Company*.

ANCILE.—A kind of shield, in antiquity, which fell, as pretended, from heaven, in the reign of Numa Pompilius; at which time, likewise, a voice was heard declaring that Rome would be mistress of the world as long as she should preserve this holy buckler.

ANCONY.—A foundry term for a piece of partially wrought bar-iron, partly finished in the middle, but unwrought at the ends.

ANDABATÆ.—In military antiquity a kind of gladiators who fought hoodwinked, wearing a style of helmet that covered the eyes and face. They fought mounted on horseback, or on chariots.

ANDREW.—The Order of St. Andrew, or The Thistle, is a Scottish order of knighthood, named after the Patron Saint of Scotland. Nisbet, with pardonable partiality, prefers it to all other orders, purely military, "chiefly for the antiquity of it, which gives it a place and precedency over all other orders now in being." He then proceeds, after Bishop Lesley, to recount the story of the St. Andrew's cross having appeared in heaven to Achaius, king of Scots, and Hungus, king of the Picts, as a sign of the victory which they should gain the following day over Athelstane, king of England; and their subsequent vow, when the prophecy was fulfilled, to bear it on their ensigns and banners. It is frequently said to have been recognized as an order of knighthood in the reign of James V., and, after a period of abeyance, to have been revived by James II. of Great Britain in 1687. For the actual facts of the case see, however, the article *Thistle*. The Star of the Order of the Thistle is worn on the left side. It consists of a St. Andrew's Cross of silver embroidery, with rays emanating from between the points of the cross, in the center of which is a thistle of gold and green upon a field of green, surrounded by a circle of green, bearing the motto of the order in golden characters. The badge or jewel is worn pendent to the collar, or to a dark-green ribbon over the left shoulder, and tied under the arm. It consists of a figure of St. Andrew with the cross enamelled and chased on rays of gold; the cross and feet resting upon the ground of enamelled green. The collar is of thistles, intermingled with sprigs of rue. By a statute passed in May, 1827, the order is to consist of the Sovereign and sixteen Knights. The letters K. T. are placed after the names of knights of the order. The motto is *Nemo me impune lacesset*. Nisbet, differing from Sir George Mackenzie, prefers *lacesset*, as "having more of daring and gallantry." See *Thistle*.

Star of the Order of the Thistle.

ANELACE.—A short sword of the fifteenth century, so called because it was worn fastened to a ring. It had a blade very broad at the top, but gradually tapering towards the end till it came into a point like a tongue, which form seems to have been copied from the ancient *parazonium*.

ANEMOGRAPH.—An instrument used in target-practice for measuring and recording the direction and force of the wind. See *Anemometer*.

ANEMOMETER.—An instrument for measuring the strength and velocity of the wind. A simple anemometer and one much used in ballistics is the Robinson hemispherical-cup instrument, shown in Fig. 1. It consists of four hollow hemispheres or cups fixed to the ends of two horizontal iron rods crossing each other at right angles, and supported on a vertical axis which turns freely. The cups revolve with a third of the wind's velocity, and the instrument is so constructed that five hundred revolutions are made whilst a mile of wind passes over it. The revolutions are registered by a system of wheels similar to those of an ordinary gas-meter. The difference between two readings gives the number of revolutions passed over during the intervening time, from which the miles can be calculated, and the rate per hour.

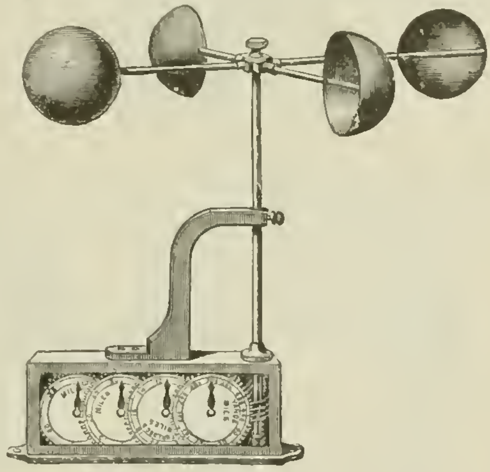


Fig. 1.

Dr. Robinson entertained the theory that the cups (measuring from their center) revolved with one third of the wind's velocity, and this theory having been supported by experiment, allowance has been made in graduating the wheels so that the true velocity is obtained by direct observation.

The first dial indicates hundreds of thousands of revolutions or miles, according to mode of division; the second, tens of thousands; the third, thousands; the fourth, hundreds; and the fifth, tens. Should the index point *between* two figures, the lesser of the two is to be taken. Whenever the index of the first dial is found to have passed zero (0), a cross or star is to be prefixed to the next reading. The number of *thousands* of revolutions made during a month is ascertained by subtracting the first reading from the last, and prefixing to the figures thus obtained a figure corresponding to the number of stars in the column. Every thousand revolutions represent two miles of wind, and the number of miles which have passed in a month is ascertained, therefore, by multiplying by 2.

To ascertain the velocity of the wind for a short period: Take two readings of all the dials with an interval of twelve minutes. The difference of these readings, divided by ten, is the velocity of the wind in miles per hour. Pressure-anemometers are of very

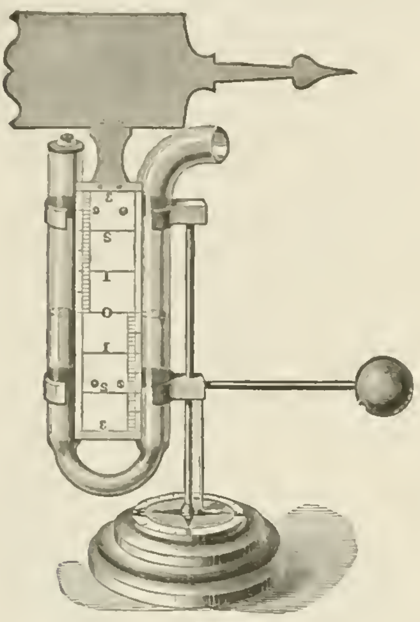

FIG. 2.

great importance in meteorological observatories. Of these, the most complete is that invented by Osler. In this instrument, the force of the wind is ascertained in a different way from the hemispherical-cup anemo-

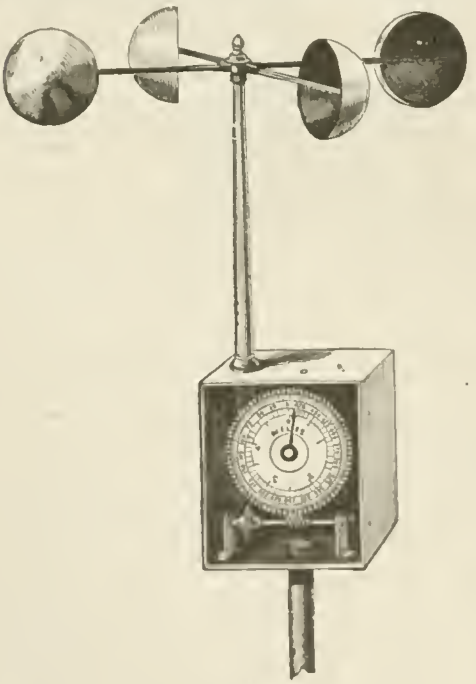

FIG. 3.

meter. A brass plate one foot square is suspended by means of springs, and being attached to the vane of the instrument, is maintained at right angles to the direction of the wind. This plate, by the action of the wind, is beaten back upon the springs, and in so doing causes a pencil to move backwards and forwards on a sheet of paper placed below it. This sheet of paper is made to pass under the pencil in a direction at right angles to its oscillation, and by means of clock-work moves at a uniform rate, so that the force of the wind at any particular time of the day is recorded with perfect accuracy. A pencil in connection with the vane, and moving in the same transverse line as the former, records the changes in the direction of the wind; and a third pencil, guided by a rain-gauge, registers the quantity of rain that has fallen. The Lind anemometer, shown in Fig. 2, is very convenient for rough purposes. It consists of a glass siphon, with parallel limbs, mounted upon a vertical rod, on which it moves freely by the action of the vane which surmounts it. The upper part of one of the limbs is bent outward to the wind. Between the limbs is a scale, graduated from 0 to 3 in tenths, the zero being in the center of the scale. In use, the tube is filled with water to the zero of the scale, and exposed to the action of the wind, by which the water is depressed in the one limb and raised in the other. The sum of the elevation and depression is the height of the column which the wind is capable of sustaining. The Beckley anemometer, shown in Fig. 3, is a modification of that of Robinson. The hemispherical cups act by a vertical axis upon two graduated concentric circles, the inner one representing five miles, divided into tenths, and the outer one having one hundred divisions, each of which is equivalent to five miles. At the top of the dial is a fixed index, which, as the toothed wheel revolves, marks on the inner circle the miles (up to five) and the hundredths of miles the wind has traveled, while a movable index, which revolves with the wheel, indicates on the outer circle the passage of every five miles. If, when placing the instrument, the hands stand at 0, the next reading will show the number of miles the wind has traveled; but should they stand otherwise the reading may be noted and deducted from the second reading, thus: Suppose the fixed index points to 2.5 and the movable index to 125, the reading after twelve hours may be 200 on the outer circle and 3.0 on the inner circle; these added together give 203. By deducting the previous reading, 127.5, we have the true reading, viz., 75.5 miles as the distance traveled by the wind.

ANEMOSCOPE.—An instrument for showing the course or direction of the wind. It is related that Andronicus Cyrrhestes built an octagonal tower at Athens, having at each side a statue of the god to whom the wind blowing from that quarter was dedicated; and in the middle of the tower was a small spire having a copper Triton, which, being put in motion by the wind, pointed to the deity from whom it proceeded. The custom of putting vanes on church-steeples is at least as old as the middle of the ninth century; and as these vanes were frequently made to resemble a cock, the emblem of clerical vigilance, they received the name of weather-cocks. The anemoscope may be combined with the anemometer, thus indicating both the direction and the force of the wind. Latterly the anemoscope has been made self-recording, and now in most observatories needs no watching, every movement of the wind being written down; the force or pressure and the velocity in miles per hour being also recorded. This is done by pencils which press lightly upon a cylinder covered with a sheet of paper divided into horizontal hour-lines, the lines moving at the rate of half an inch an hour, a complete revolution of the cylinder occupying twenty-four hours. Lines marked by the pencils show by their relation to the graduated lines the direction of the wind at any moment of the day.

ANEROID BAROMETER.—An instrument for indicating atmospheric pressure. Invented about the beginning of the present century, it was not until about 1848 that the difficulties involved in the construction of such an instrument were overcome, and the present serviceable form devised by M. Vidie. Since that time the aneroid has continued substantially the same; improvements being rather in the direction of more perfect workmanship in its parts, and in the more perfect adaptation of its metals, than in any change of form.

As shown in Fig. 1, the aneroid consists of a flat cylindrical vacuum-box, the upper surface of which is corrugated in order that it may yield more readily to external pressure. The lower surface of the vacuum-chamber is firmly fixed at the center to a strong foundation-plate, whilst at the center of the upper surface is a metallic pillar, M, which acts upon a powerful steel spring, R. The varying atmospheric pressure causes the surface of the vacuum-chamber to rise and fall; these movements are transmitted to the spring, and thence by two levers, *l* and *m*, to a metallic axis, *r*. From the latter rises a lever, *t*, to whose extremity a chain, *s*, is attached, which turns a drum the axis of which bears the index-needle. A firm spiral spring keeps the chain constantly in proper tension. By this arrangement of multiplying levers, a very small movement of the surface of the vacuum-chamber causes a large deviation of the needle; $\frac{1}{200}$ of an inch causing it to move through a space of three inches. Compensation for temperature is effected, as in chronometers, by an adjustment of brass and steel in the main lever, by whose unequal expansion and contraction the liability to error from change of temperature is overcome. The dial is graduated arbitrarily to correspond with the mercurial barometer, after the instrument is tested under the air-pump to find the range. It is apparent, therefore, that the aneroid can never be used as an independent standard, but must be frequently compared with the mercurial barometer. When so compared, however, and adjusted by a mercurial standard, the aneroid possesses several advantages over the former. It is extremely portable and can be carried in any way, or subjected to any motion without danger of disturbance of its indications. It is not at all liable to get out of order; is not easily broken; and lastly, *it is very much more sensitive* than the mercurial barometer. The late Admiral Fitzroy, Mr. Glaisher the aeronaut, and many other authorities, testify to the extreme sensibility of the aneroid; the former particularly noting "its quickness in showing the variations of atmospheric pressure." Even in observatories, therefore, where mercurial standards are in use, the aneroid is most valuable in its capacity of giving earlier indications than can be obtained from the more sluggish mercurial column. To the seaman, who has often extreme difficulty in using the barometer from the pumping of the mercury caused by the vessel's motion, the aneroid is indispensable; and from its greater delicacy, he can often prepare for a change in weather a considerable time before the mercurial barometer gives evidence of an impending storm.

Fig. 2 represents the mining and surveying aneroid, designed for the purpose of readily ascertaining slight variations in gradients, levels, etc. Besides extreme sensitiveness, the specialty claimed for this instrument is an arrangement of the scale of altitudes which admits of subdivision by a vernier, hitherto impracticable, owing to the altitude scale in ordinary use being a gradually diminishing one, to which a vernier cannot be applied. In the present instrument the action has been so adjusted as to give accurate readings upon a regular scale of altitudes, the barometrical scale of inches having been made progressive so as to afford the correct relative readings with the scale of altitudes. For mining purposes the entire circle of the dial is graduated to represent 6 inches of the mercurial column, i.e., from 27 inches to 33. This scale will register about 2000 feet *below* sea-level to 4000 feet *above;* the finest divisions, hundredths of the altitude scale, represent 10-feet measurements, which can be again subdivided by the vernier scale to *single feet.* The vernier scale is moved by a rack-work adjustment, and a magnifying-lens which rotates on the outer circumference of the instrument facilitates the reading of minute quantities. For surface-surveying purposes, where it is not required to be used *below* sea-level, the instrument is made with the scale divided from 25 to 31 inches, thus giving an altitude scale of 5000 feet above sea-level only, and with this open scale and the assistance of the vernier the same minute readings can be easily taken.

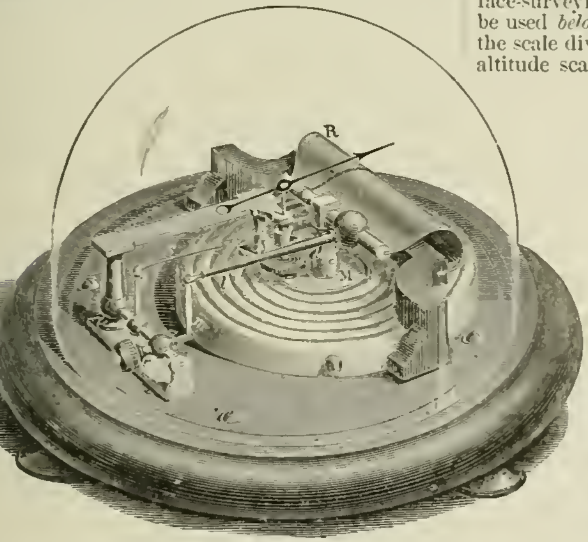

Fig. 1.

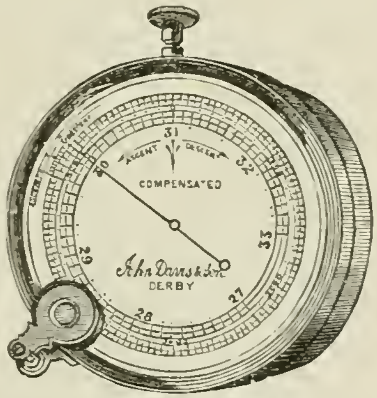

Fig. 2.

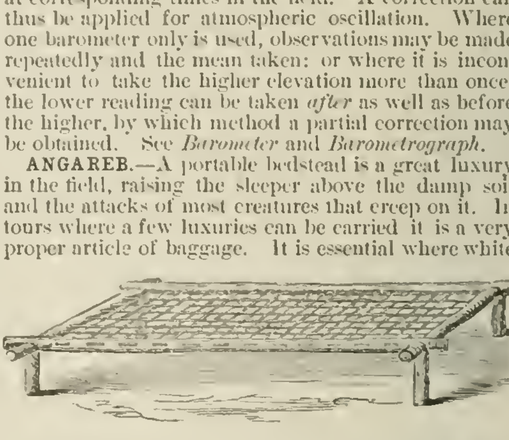
From its portability, sensitiveness, and the ease with which approximate altitudes may be ascertained, the aneroid barometer is very valuable to the engineer. In preliminary surveys and reconnoissances it has been found extremely useful, and for these purposes it is largely employed. Carrying one of these little instruments, the size of which need not exceed two or three inches in diameter, the engineer, riding rapidly over a country, can speedily and with ease procure the data for the determination of the line of a survey. Holding an aneroid in his hand, the traveler seated in the railroad-car can mark the changes of elevation as his train moves; the mountain-climber can note, step by step, his gain in altitude; and the miner, with the new mining aneroid, can measure his descent in single feet. For hypsometrical work it is especially important that the aneroid should be absolutely accurate; that its compensation for effect of temperature on the metallic works be perfect, and that its indications should be identical with those of the mercurial column. The importance of compensation, particularly for pocket-aneroids, is evident when it is remembered that the change from a room to the external atmosphere may frequently involve a difference in temperature of from 30° to 50° F., a difference which, without proper compensation, may move the needle through a space equal to one hundred or more feet. It is also necessary that the aneroid be tested for correspondence with the mercurial column. For this purpose there is an apparatus specially arranged, by which the aneroid and a standard mercurial barometer are subjected to identical changes of atmospheric pressure. Side by side the two barometers are moved through the entire range from normal pressure to complete vacuum. If the scale of the aneroid be accurately divided and in accord with the instrument itself, the needle will move tenth by tenth with the mercurial column, in perfect coincidence. The best results, in all problems of altitude, with the aneroid barometer are obtained by the use of the following table prepared by Sir G. Airy, late Astronomer Royal of England. To use this table (arranged for temperature of 50° F.), take the reading in inches of the barometer scale at the lower and upper stations. Find in the table the heights in feet corresponding to the barometer readings; subtract them, and the remainder will be the height required. When the mean temperature is above or below 50° F., the following correction must be applied: add together the temperature of the upper and lower stations. If the sum is greater than 100° F., *increase* the height by $\frac{1}{1000}$ part for every degree of the excess above 100°; if the sum is less than 100°, *diminish* the height by $\frac{1}{1000}$ part for every degree less than 100°. The complete formula is

$$D = (H - h)\left(\frac{1 + T + t - 100}{1000}\right).$$

T and t are the observed temperatures; H and h are the heights in feet taken from the table.

of time elapses between two observations, engineers are now accustomed to use two matched barometers, one of which is kept in camp, where observations are taken at stated intervals, whilst the other is observed at corresponding times in the field. A correction can thus be applied for atmospheric oscillation. Where one barometer only is used, observations may be made repeatedly and the mean taken: or where it is inconvenient to take the higher elevation more than once, the lower reading can be taken *after* as well as before the higher, by which method a partial correction may be obtained. See *Barometer* and *Barometrograph*.

ANGAREB.—A portable bedstead is a great luxury in the field, raising the sleeper above the damp soil and the attacks of most creatures that creep on it. In tours where a few luxuries can be carried it is a very proper article of baggage. It is essential where white



ants are numerous. A very comfortable bed, shown in the drawing, is made on the principle of a tennis-player's racquet; being a framework of wood, with strips of raw-hide lashed across it from side to side and from end to end. It is the *Angareb* of Upper Egypt, and may be readily constructed in the field. See *Camp-bedstead*.

ANGARIA.—According to ancient military writers, a guard of soldiers posted in any place for the security of it. Angaria, in civil law, implies a service by compulsion; as, furnishing horses and wagons for conveying corn and other stores for the army.

It should be borne in mind that all aneroids vary in their readings with the position in which they are held, reading somewhat higher in a horizontal position with face up than when vertical. As they are tested and adjusted in a horizontal position, it is better that they should be uniformly read from the horizontal dial. Before a reading is taken, the face should be tapped slightly with the finger to bring the needle fairly into equilibrium. As there may be considerable atmospheric variation if any great interval

ANGELIAPHORI.—An ancient name for the reconnoitring parties of the Grecian army.

ANGEL-SHOT.—A shot formed of two hemispheres or spheres connected by a chain. It was invented by Admiral DeWitt, in 1666, and was formerly much employed for carrying away rigging in naval actions. It was sometimes fired from a cannon with two slightly diverging barrels united at the breech, forming a single chamber, and discharged through a single vent.

ANGLE.—The opening or inclination of two lines that cut or meet one another. If the lines are straight the angle is *rectilinear.* The magnitude of an angle depends, not upon the length of the lines or legs, but upon the degree of their opening. If the legs are supposed closed, like a pair of compasses, and then gradually opened till they come into one straight line, they form a series of gradually increasing angles; when half way between shut and straight they contain a *right angle.* Any angle less than a right angle is called *acute,* and one greater is called *obtuse.* Angles are measured by degrees, of which a right angle contains 90. The angle made by two curved lines (*curvilinear*) is the same as the angle made by the tangents to the two curves at the point of intersection. Angles made by planes with one another can also be reduced to rectilinear angles. When three or more planes meet at the same point, the angular space included between them is called a *solid angle.* The angles most frequently referred to in fortification, gunnery, etc., are: *angle of arrival, angle of clearance, angle of defense, angle of departure, angle of depression, angle of descent, angle of dish, angle of dispart, angle of elevation, angle of fall, angle of fire, angle of incidence, angle of inclination, angle of lock, angle of projection, angle of reflection, angle of sight, angle of spiral, dead angle, diminished angle, flanked angle, interior flanking angle, re-entering angle, salient angle,* and *terminal angle.*

ANGLE OF ARRIVAL.—The angle included between a tangent to the trajectory at the crest of the parapet and a horizontal line. Supposing *small* angles proportional to their tangents, we have these simple relations: 1. *At the same distance from the crest, the fall of the projectile is proportional to the angle of arrival;* 2. *For the same angle of arrival, the fall of the projectile is proportional to the distance from the crest.*

ANGLE OF CLEARANCE.—In gunnery, the angle of elevation obtained when the top of the tangent scale and dispart sight and the notch on the muzzle are in line.

ANGLE OF DEFENSE.—In fortification, the angle formed by a line of defense and a flank. The angles of defense should never be less than 90° and never more than 120°.

ANGLE OF DEPARTURE.—In gunnery, the actual angle which the shot's path on leaving the muzzle of a gun makes with the true horizon. This, when there is windage, may differ sensibly from the *angle of inclination,* and appears also to do so in the lighter rifled guns, where the shots are observed to rise, from the muzzle being slightly thrown up. This rise is caused from the "jump" of the gun.

ANGLE OF DEPRESSION.—In gunnery, the angle given to a piece of ordnance when laid under metal, or at an angle below the horizon.

ANGLE OF DESCENT.—In gunnery, the angle which the tangent to the trajectory makes with the horizon at the height of the crest of the parapet or other object to be cleared. It is rather less than the terminal angle.

ANGLE OF DISH.—The measure of the dish of a wheel, being the angle made by the spokes of the wheel with the plane of its face.

ANGLE OF DISPART.—The number of degrees the axis of the bore would point above the object aimed at when laid by the surface of the gun.

ANGLE OF ELEVATION.—In gunnery, the angle between the axis of the gun and the visual line from the sight on the tangent scale to the object. It has no reference to the horizon or to any natural level.

ANGLE OF FALL.—The angle which the tangent makes at the *point of fall* with the terre-plein. The size of this angle will determine the kind of ricochet. It will be grazing if the angle is 4° or less, and plunging when it is comprised between 6° and 10°.

ANGLE OF FIRE.—In gunnery, the angle which the axis of the barrel makes with the horizontal line; on account of the balloting of the projectile, the angle of fire is not always equal to the angle of departure, or projection.

ANGLE OF INCIDENCE.—In gunnery, the angle which the tangent to the trajectory makes with the actual surface struck at the point of descent.

ANGLE OF INCLINATION.—In gunnery, the angle which the axis of the gun forms with the true horizon, or the angle shown by a correct spirit-level. This is, consequently, the angle recorded when guns are laid by the quadrant.

ANGLE OF LOCK.—The angle included between the stock and the plane of the wheel, when the wheel touches the lock-plate in turning. The *angle of lock* with the 5' track is a little more than 50°.

ANGLE OF PROJECTION.—In gunnery, the angle which the tangent makes with the horizontal at the muzzle. See *Angle of Departure.*

ANGLE OF REFLECTION.—The angle intercepted between the line of direction of a body rebounding after it has struck against another body, and a perpendicular erected at the point of contact.

ANGLE OF SIGHT.—In gunnery, the angle included between the line of sight and line of fire. Angles of sight are divided into natural and artificial angles of sight, corresponding to the natural and artificial lines of sight which enclose them. See *Pointing.*

ANGLE OF SPIRAL.—This angle, sometimes called the *angle of rifling,* differs in different guns, depending principally on the length, weight, and muzzle-velocities of the projectiles fired from them. It is measured at any point of the groove, in guns rifled with *increasing twist,* by the angle which a tangent to the groove at that point makes with a line in the bore parallel to its axis; and in guns rifled with *uniform twist,* by the angle which the groove itself makes with a line in the bore parallel to its axis. In guns rifled with increasing twist, the angle of spiral at the muzzle is called the *final angle of rifling,* and that at the breech end of the rifling is called the *initial angle of rifling.*

ANGLE OF THE CENTER.—In fortification, the angle formed at the center of the polygon by lines drawn thence to the points of two adjacent bastions.

ANGLE OF THE EPAULE.—In fortification, the angle formed by one face and one flank of the bastion.

ANGLE OF THE FLANK.—In fortification, the angle formed by the flank and curtain.

ANGLE OF THE LINE OF DEFENSE.—In fortification, that angle made by the flank and the line of defense.

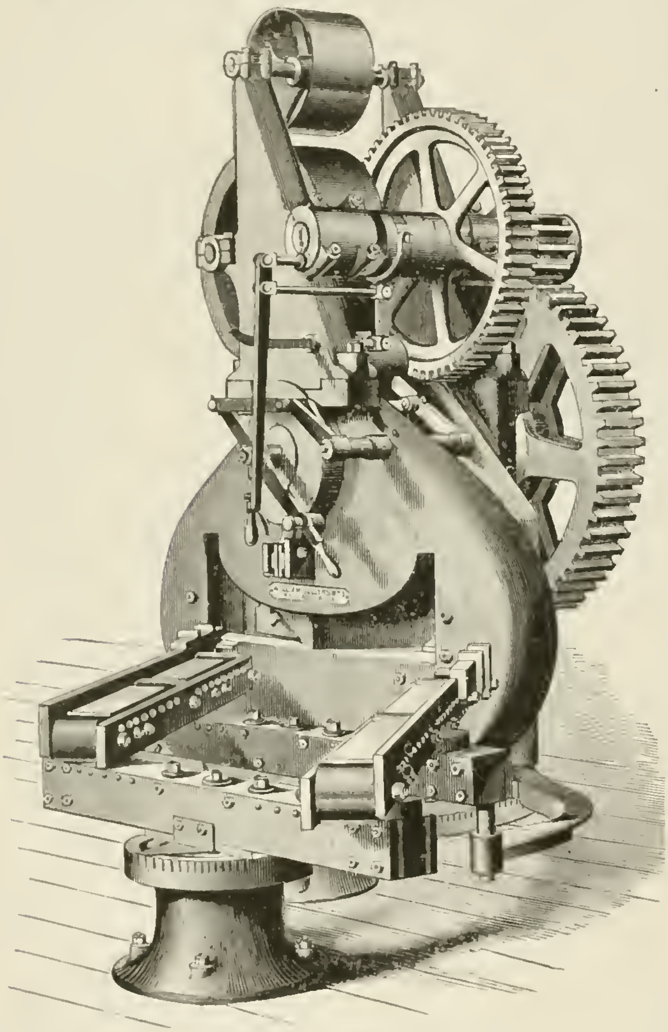
ANGLE OF THE POLYGON.—In fortification, the angle formed by the meeting of two sides of the polygon; it is likewise called the *polygon angle.*

ANGLE OF THE TENAILLE.—In fortification, the angle made by two lines fichant,—that is, the faces of the two bastions extended until they meet in an angle towards the curtain,—and is that which always carries its point towards the outworks.

ANGLE OF TRACTION.—In draught, the angle which the plane of the traces makes with the road on which the carriage is moving. Artillery carriages having sometimes to move over the worst description of roads, the angle of traction must be slightly inclined upwards, as the vertical component of the pull will then assist the wheels to surmount obstacles; the weight being transferred to the shoulders of the horse increasing the pressure of his feet upon the ground, thus giving him a firmer hold, and enabling him to exert with ease a stronger pull, while the resistance against which he contends is at the same time diminished.

ANGLE SHEARING-MACHINE.—A machine of frequent use in the Armory and Foundry. The same principle involved in lever shearing and punching machines obtains in this useful tool. Angles which have been curved or bent before shearing and while resting on trestles may be readily trimmed. The blades have no shear given to their edges; but by punching the angle off with a cut extending over all parts of the iron with a uniform pressure, the piece cut off is not bent out of shape. This is an important feature in the machine, as it enables it to be used in cutting up angles to length without distorting the ends cut off. Very much more rapid work can be done when the plates are moved by a spacing device than when laid out with a template and passed through the machine by hand; accordingly, dividing-machines can be adapted to the shearers and punchers to enable the sheets to be spaced mechanically, making proper allowance for the difference of diameter or circumference of outer or inner sheets in cylindrical work.

The drawing shows a Duplex Angle Shear, as made by William Sellers & Co. This is a most perfectly



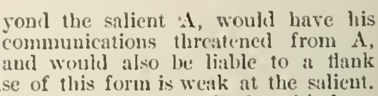
Angle Shearing-Machine.

contrived machine, and very effective in operation. The great weight of the machine is carried on a set of anti-friction rollers. This enables the machine to be turned to the required angle of cut, thus setting the blades to the angle, and not swinging the bars to be sheared to the same angle. This is a very important matter, as involving great economy in armory-room. There are two shearing slides to carry the movable or upper blades, and these are at an angle of 90° to each other, so as to cut the angles as they lie on their flat with one leg vertical, and to make the cut at any required angle of oblique division, from 30° angle to 90°. The machine, as represented, is operated by a heavy crank, which works either one of two diagonal slides carrying the cutting blades for right- or left-hand cutting. The bars are punched off at one stroke, so as not to distort the crop ends by any shearing motion of the blades, and the machine is powerful enough to cut 6 inches by 6 inches by 1 inch angles, and to make the cut at any angle required in bridge structures from 30° included angle to square. The machine is provided with guiding tables for the angles to rest on, and the entire machine, carrying its guiding tables with it, is made to swing on a center, so that the presentation to the machine of the angle to be cut is always in the same right line. This arrangement is very economical of room, as the irons taken from the pile are presented in line with the pile, the machine being turned to the required angle of cut, either to the right or the left hand. Pulley on the machine is 36 inches diameter, 12 inches face, and should make 300 revolutions per minute. The machine must be placed under the driving pulley of the line, and the belt is so carried by guiding pulleys on the machine and near to the line driver as will permit the vibration of the machine to its required angle of cut. See *Lever Shearing-machine, Power Shears,* and *Shearing-machine.*

ANGON.—A barbed spear used by many early nations. The Franks, in the seventh century, employed angons both for thrusting and hurling. The staves were armed with iron, so as to leave but little of the wood uncovered; the head had two barbs. When hurled or thrust at an opponent, the head of the angon became fixed in the flesh by means of the barbs. This form of spear was much adopted by the Anglo-Saxon and other Teutonic nations.

ANGUIS.—A flag adopted by the Romans, which was carried at the head of a cohort (the tenth part of a Roman legion, consisting of 600 men); this flag resembled a serpent in shape, and was more commonly called *draco.*

ANGULAR BASE OF OPERATIONS.—If the base is angular, the angle may be towards the enemy or away from him. If it is salient, as in the drawing, it is plain an enemy, EE, moving be-



yond the salient A, would have his communications threatened from A, and would also be liable to a flank attack. A base of this form is weak at the salient. The smaller the angle at A, or the farther this front is advanced beyond B and C, the weaker will the base be. The salient must therefore be strengthened, and made perfectly safe. A base of this form is, however, more favorable for an army acting on the defensive than for one acting offensively. For an army acting within the angle BAC can move from one part of the line to another, to reinforce any part of the line, more quickly than one on the exterior can. If the base instead of being salient is drawn back behind B and C, that is, forms a re-entrant, it will be more favorable for an army acting offensively than for an enemy acting defensively. For an army proceeding from a base of this form can threaten or seize the communications of its opponent without exposing its own.

ANGULAR VELOCITY.—The velocity of a body rotating round a fixed point, which is measured by the circular arc described by any point of the body at some unit of radial distance, usually one foot from the axis of rotation. The velocity of any particular point of a rotatory body may be found by multiplying its angular velocity by the radial distance of the point from the axis of rotation; and *vice versâ*, the angular velocity may be found by dividing the velocity of any known point by its radial distance.

ANGUSTICLAVE.—A robe or tunic embroidered with purple studs or knobs, and with narrow purple stripes, worn by Roman knights, to distinguish them from members of the Senatorian order, who wore a garment with *broad* stripes, called *latus clavus*.

ANIME.—A sort of ancient cuirass, also called *brigandine*. It was used in Italy until the seventeenth century, under the name of *anima* or *animetta*.

ANIOCRATER.—The highest military rank of the Lacedæmonians; one who commanded the whole army during the absence of the king.

ANIPPUS.—A name commonly applied to the light cavalry of the Grecians.

ANISOCYCLE.—An ancient machine of a spiral form, like the spring of a watch, used for throwing arrows to a great distance.

ANJON.—An ancient battle-axe frequently employed for missile purposes.

ANNALS.—A species of military history, wherein events are related in the chronological order in which they happened. They differ from a perfect history in being merely a relation of what passes every year, as a journal is of what passes every day.

ANNAMALLY.—The name of a forest in the southern part of India, which yields good teak timber; the wood is made use of for ordnance purposes in the Madras Presidency.

ANNATINÆ.—Transport-ships (so called by Julius Cæsar) in which were transported provisions, etc., to armies and fleets. Also called *Corbitæ*.

ANNE.—The Order of St. Anne was originally established in Holstein, and carried with the Princes of that country into Russia. It was made a Russian Order in 1796, and is now widely diffused.

ANNEALING.—When steel, after having been raised to a very high temperature, is suddenly cooled by immersing it in pure water, brine, or mercury, it becomes excessively hard and brittle, and while in this condition cannot be worked in any way. To remedy this difficulty, the steel is reheated, and allowed to cool very gradually, by which process it regains the properties of softness and malleability. This process of heating and slow cooling is called *Annealing*. Care must be taken not to overheat the steel, as that injures the metal by burning out some of the carbon. The steel is cooled in various substances, such as powdered lime, sand, cast-iron borings, dry saw-dust, or warm ashes; the sole object being to make the cooling as slow as possible, and also to protect the steel from the air. In the annealing of cast-iron the heat requires to be kept up much longer than with steel, and the iron must be well supported to prevent its warping or breaking. When annealed it is much more uniform in temper, and less liable to alter its figure by any subsequent exposure to a moderate heat.

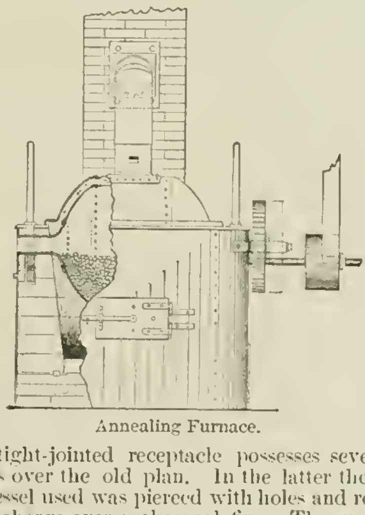
This property of becoming soft and malleable on being heated and slowly cooled is common to nearly all metals, *Copper* being the most marked exception. In working this metal the opposite course has to be pursued; that is, it is made softer and more flexible by plunging it when red-hot into cold water. When it is required *very* soft and the surface clean, a small quantity of sulphuric acid is mixed with the water.

The tempering of steel is really a process of annealing. The steel is placed in an oil-bath, or surrounded by a metallic mixture which has a low fusing-point; and according to the temperature to which it is subjected, a steel with various degrees of softness and strength is obtained. Parke's table of metallic mixtures capable of being used in the tempering or annealing of instruments made from steel is as follows:

	Alloy. Lead.	Alloy. Tin.	Fusing-point ° F.
Lancets	7 parts	4 parts	420
Razors	8 "	4 "	442
Penknives	8¼ "	4 "	450
" large	10 "	4 "	470
Scissors, shears	14 "	4 "	490
Axes, plane-irons	19 "	4 "	590
Table-knives	30 "	4 "	530
Watch-springs, swords	48 "	4 "	550
Large springs, augers	100 "	4 "	558

The theory of annealing is very imperfectly understood. A certain rearrangement of the atoms of the glass or metal no doubt takes place, and an absorption of heat occurs. It is possible that as the crystalline structure is indicative of brittleness, and the fibrous texture characteristic of strength, that the passage of glass or metal from a brittle to a non-brittle material may be due to the development of a fibrous structure, where a crystalline one was originally present. See *Steel* and *Tempering*.

ANNEALING FURNACE.—A furnace employed at Arsenals for annealing copper or brass shells, cannon-primer tubes, etc. The Annealing Furnace in use at Frankford Arsenal consists of the furnace proper, constructed of boiler-iron, lined with fire-brick, and arranged with flue and cold blast for draught and heat; of an annealing retort, cylindrical in shape, with closed ends of hemispherical form. From these ends project trunnions which revolve on friction rolls attached to the furnace. The left trunnion, looking toward the furnace, is hollow, and subserves several useful purposes. It is a peep-hole for observing the degree of heat to which the charge is being raised, an outlet for the smoke into which the oil on the shells is converted, a means of obtaining samples for test, and of emptying the charge when sufficiently annealed. The annealing accomplished



Annealing Furnace.

in this tight-jointed receptacle possesses several advantages over the old plan. In the latter the cylindrical vessel used was pierced with holes and revolved with its charge over a charcoal fire. The surface of the shells became considerably oxidized from exposure to the atmosphere and took up some dirt, as ashes from exterior surroundings, during the process. By the new plan the charge is protected from the direct action of the fire, and the gases and smoke generated and expanded inside the retort flow out through the hollow trunnion. By the old method charcoal was necessary as a fuel to guard against the sulphur and other gases which would be generated from burning anthracite coal. Anthracite coal is used with the new retort, and the shells are annealed with less oxidation of their surfaces, and consequently require less pickling and cause less wear upon machinery and tools in the continued process of drawing. Ten thousand shells or thirty thousand cannon-primer tubes is a full charge for the retort. A crane takes the retort from the furnace and deposits it upon a cradle from which it is readily emptied. The retort with full charge weighs about 600 pounds. The furnace has a hinged wrought-iron cover, which is lowered over the retort during the operation of annealing and raised when the retort is removed; also a hinged flue, which fits into an opening in the cover connecting it with the draft. The drawing on the preceding page shows the general construction and operation of the furnace.

ANNEAU D'OR.—A gold ring. In accordance with the example of the ancients, Francis I. of France instituted a military recompense in the shape of an *anneau* for all who distinguished themselves in any military enterprise.

ANNULAR-BIT.—A boring-bit which cuts a circular channel, but does not *rout* the central portion. Wads and other articles in the armory are made by a tool of this kind.

ANNUNCIADA.—1. The Religious Order of the Heavenly Annunciation, or of the Nuns of the Annunciation of Mary, was instituted by Victoria Fornare at Genoa in 1682, after the rule of St. Augustine. All the convents of the order in France, Germany, and the Netherlands have disappeared since the French Revolution. Some still exist in Italy. 2. Another Order of the Annunciation, or of Nuns of Mary's announcement or the ten virtues, was endowed by John of Valois at Bourges in 1501, after its separation from Louis XII. In 1514 it was placed under the authority of the Franciscans. This order, which extended to fifty convents for the reception of poor gentlewomen, was broken up at the Revolution. 3. The Order of Knights of the Annunciation in Savoy, *ordine suprema dell' annunciata*, known originally as the order of the neck-chain, or collar, was instituted in 1360 by Amadeus VI., Duke of Savoy. It received statutes from Amadeus VIII. in 1409; was renewed in 1518 under the name of the Holy Annunciation; and in 1720 was raised by Victor Amadeus to be the first order of the kingdom of Savoy. The King is always Grand Master. The knights, who, since 1720, are not limited in number, must be of high rank, and already admitted to the Orders of St. Mauritius and St. Lazarus. They compose only one class. The decoration is a gold medal, on which is represented the Annunciation, surrounded by love-knots. It is usually worn suspended by a simple gold chain; but the proper collar or chain of the order is composed alternately of love-knots and roses. On the roses are engraved the letters F E R T, which some interpret *Fortitudo ejus Rhodum tenuit*, in allusion to the defense of Rhodes by Amadeus I., and which others hold to signify *Frappes, entres, rompes tous.* Since 1680 the knights wear on the left breast a star embroidered in gold. The four supreme officers of the order—the Chancellor (always a Bishop or Archbishop), the Secretary (usually the Minister of Foreign Affairs), the Almoner (usually the King's First Almoner), and the Treasurer—wear the decoration round the neck, suspended by a sky-blue ribbon, accompanied by a star on the left breast.

Star of the Order of the Annunciation.

ANSÆ—ANSE.—The handles of certain kinds of ancient ordnance. Small pieces of light weight intended to be moved from place to place by hand, such as life-saving guns, are provided with *ansæ*. These handles, especially in some foreign cannon, are cast in the form of dolphins and serpents.

ANSPESSADE.—A term originally used to denote dismounted horsemen who were obliged to serve temporarily in the infantry, and who broke off the tops of their lances so as to reduce their length to that of the halberds of the sergeants. Also, a non-commissioned officer who acts subordinate to a corporal; a lance-corporal.

ANTECESSORES—ANTECURSORES.—Light cavalry of the Romans, which formed the advanced-guard of an army while on the march.

ANTE-MURAL.—In fortification, an outwork consisting of a high strong wall with turrets, for the defense of a gate.

ANTEPILANI.—Soldiers of a Roman legion who composed the first and second ranks in line of battle, and who were accordingly placed in front of the third rank. The first rank was called *hastati*, the second *principes*, and the third *pilani* or *triarii*.

ANTESIGNANI.—A name given to the soldiers of the Roman army who protected the colors, etc.; according to some authorities they were the *hastati* or *principes*, and according to others they were a select detachment consisting of picked soldiers.

ANTESTATURE.—A small intrenchment or work formed of palisades or sacks of earth.

ANTHONY.—The military order of the Knights of St. Anthony was instituted by Albert, Duke of Bavaria, Holland, and Zealand, when he designed to make war against the Turks in 1382. The knights wore a collar of gold made in the form of a hermit's girdle, from which hung a stick like a crutch, with a little bell, as they are represented in St. Anthony's pictures.

ANTHRACITE.—A mineral substance of the nature of coal, but consisting of carbon with a minimum amount of hydrogen. It is of a black color, conchoidal fracture, and imperfectly metallic luster (hence called *glance*-coal). It burns slowly and without flame, and hence is sometimes called *blind*-coal. Its vegetable origin cannot be doubted. Where strata of common coal have been broken through by trap-dikes, the coal next the trap is found to be anthracite, with a gradual transition into the ordinary state; hence geologists look upon anthracite as natural coke, formed by heat or other process from ordinary coal. Anthracite is used as fuel like coke. It is applied in many places to the burning of lime and bricks, the reduction of iron, etc. It occurs extensively in Ireland, and in some of the coal-fields of England, Scotland, and the Continent of Europe; but on the largest scale in the United States.

In 1776, anthracite from near Wilkesbarre, Penn., was floated down the Susquehanna to Carlisle, and was used in the Government Arsenal. In 1803, 100 tons were brought from Summit Hill to Philadelphia, and were sold to the City Government for use in the pumping-works, but the engineers did not know how to burn it, and it was broken up to gravel the walks in the yards. In 1812 two ark-loads were sold at the falls of the Schuylkill at $21 per ton. A morning was wasted in futile attempts to burn this coal, and at noon the workmen and their employer, discouraged at their ill-luck, shut up the furnace and went to dinner. On their return they were astonished to find a roaring fire, the furnace-doors red-hot, and the furnace itself in danger of melting. From that day dates the successful use of anthracite in America. The development of this interest is shown in the following table:

Anthracite is the purest form of natural carbon except the diamond. The carbon varies from 95 per cent, in specimens picked from the best veins, to 80 or 85 per cent. Coal containing less than 80 per cent of carbon is not classed as anthracite. The volatile matter present is water, oxygen, hydrogen, and nitrogen; the ash contains oxide of iron, iron pyrites, silica, alumina, lime, etc. Pennsylvania anthracites have usually 86 to 94 per cent of carbon, 1½ to 7 per cent of volatile matter, and 1½ to 7 per cent of ash; the

density varies from 1.4 to 1.63. Anthracite was derived from bituminous coal by heat acting under great pressure, and probably caused by pressure in the geological changes which threw the anthracite regions, as in eastern Pennsylvania, into great mountain-waves. The heat drove off all volatile matters which it would develop from the bituminous coal, and left the more stable material behind as a natural coke, differing from artificial coke only in its superior density. The loss of vegetable matter by decomposition in the formation of bituminous coal is estimated at about three fifths of the material, and in the production of anthracite at about three fourths; the added compression leaves the resulting bulk about one fifth or one eighth the original mass. It follows, then, that to produce a vein of anthracite 30 feet thick, 240 feet of vegetable matter must have existed. The coal-deposits, as found in the anthracite formation near Pottsville in the Schuylkill valley, include 15 groups, with 30 beds or veins more than 2 feet thick, and 20 seams less than 2 feet. The thickest, or mammoth vein, is a single bed from 20 to 70 feet thick, in some places divided into three layers by seams of slate. About four fifths of the present production of anthracite comes from this vein. The aggregate thickness of the coal-veins at this point is 113 feet, of which 80 feet may be profitably mined.

The possibilities of the production of anthracite in America may be gathered from the following table:

See *Coal* and *Coke*.

ANTI-CORROSION.—A lacker formerly applied to iron traversing-platforms, gun-carriages, and the outside of guns. It has been superseded by Pulford's magnetic paint.

ANTIMONY.—A metal of a gray or leaden color, and very brittle. It is found in mines with *galena*, or the sulphuret of lead, from which it is easily distinguished, the antimony occurring in fine streaky fibrous crystalline masses of a radiated texture, whereas sulphuret of lead is of a smooth, shiny, laminated nature. Antimony is found in Cornwall, France, Spain, Borneo, Nepal, the Straits, and Siam, and is commonly associated with iron, zinc, quartz, silver, sulphate of baryta, and carbonate of zinc. It fuses at about 800 Fahr., and volatilizes very perceptibly at a somewhat higher temperature. It is one of the ingredients used in the detonating composition of friction-tubes, and stars for signal-rockets. When mixed with lead, it has the property of hardening bullets. Sulphide of antimony enters into those compositions employed to give a strong light. It is particularly well suited for that purpose, for being decomposed at a comparatively low temperature, the metal is set free and disseminated through the flame in a state of incandescence, causing the intensity of the light to be considerable; moreover, the heated particles, coming in contact with the atmosphere, are thereby oxidized, forming a white smoke which is very favorable to the reflection of light.

ANTUSTRIONES.—A body-guard of the Kings or Chiefs of the ancient Germans, which was composed of volunteers.

ANVIL.—1. An iron block, with a smooth, flat steel face, on which malleable metals are hammered and shaped. Anvils are of all sizes, from the tiny articles used by watchmakers to the immense masses for trip-hammer work in great iron-foundries. The common anvil of blacksmiths has a cone or horn at one end, and a socket for a chisel in the other. The best anvils are made of cast-iron, faced with steel, the steel being placed at the bottom of the mould and the iron poured upon it. 2. The resisting cone, plate, or bar against which the fulminate in a metallic cartridge is exploded. 3. An archaism for the handle or hilt of a sword. Also, a small pennon on the end of a lance.

APAREJO.—The pack-saddle used in the American military service. It consists of a strong leather sack, about two feet wide and from 55 to 60 inches long, according to the girth of the animal. A seam running from the front to the rear of the aparejo divides it into two equal parts, each of which is composed of a double layer of hide, with sufficient space between to introduce a suitable stuffing of hay, grass, moss, fiber, etc. These side flaps, when fastened together at the top, form a ridge within which the back-bone of the animal rests free from friction or pressure. On the inside of each flap is left a circular hole through which the stuffing material can at any time be reached.

The careful packer should keep the stuffing evenly distributed, or so as to vary with the conformation of the back of the particular animal, as portions of it are constantly shifting and working up into lumps, in consequence of the travel. The drawings show the interior and exterior of the aparejo. To *set up* the aparejo, or to give it evenness and stiffness, small ash, rose, or willow sprouts from ½ to ⅜ of an inch in

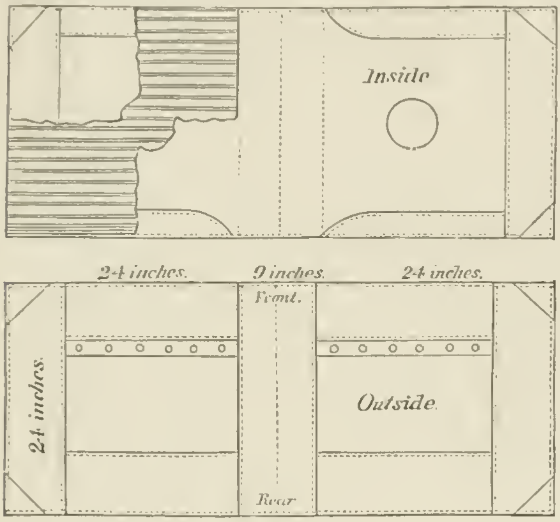

Fig. 1.

diameter, and as long as possible without springing (any tough and elastic wood will answer), are placed inside of it and at equal distances apart—about 2 inches. On the inside of these, and towards the animal, coarse grass or hay (such as is light and tough and will not break up) is placed layer after layer until the sides are as full as possible. The corners should be stuffed as hard as possible by means of a sharp stick. Serious trouble is often experienced on

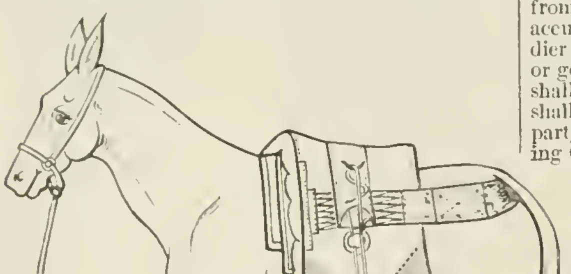

Fig. 2.

long and toilsome marches from loss of flesh, causing the aparejo to fit badly and cause a sore back. Great care must be taken to make good all deficiencies in the stuffing, and when the aparejo is too large to be adapted to a thin animal by stuffing, a portion should be cut out of the center. Straw pads are useful for protecting the hips and withers when placed under the cinches of those animals carrying rough loads. When the aparejo is stuffed it should be put on the animal for which it is intended, and the crupper adjusted. Fig. 2 represents the animal saddled with the crupper in proper position. The shape of the aparejo enables all loads to be nicely balanced. One hundred pounds on one side may be made to ride with fifty pounds on the other without straining the animal. It presents much more surface for pressure to the animal than any other form of pack-saddle. The lower corners secure the lash-rope and prevent it slipping when on the road. By removing the hay or stuffing from the sides a sore back may be easily remedied, and by properly adjusting the filling, the aparejo may be made to perfectly fit a badly shaped back. These may be cited as some of its advantages. See *Packing.*

APAREJO-CINCHA.—A girth made of hide or strong canvas, about six feet long and twenty inches wide, and folded so as to bring the edges in the centre of the cincha. A semicircle of strong leather pierced with several holes is stitched on one end, and two loops of strong leather on the other. See *Hammer-cloth* and *Packing.*

APEX.—The tip, point, or summit of anything. The Romans so named the crest of a helmet, or the part whereon the horse-hair plume was attached.

APHRACTI.—In the ancient military art, open vessels, without decks or hatches, furnished only at head and stern with cross-planks, whereon the men stood to fight.

APOBATES.—A name given by the ancients to warriors who fought mounted on chariots; they were also called *Andabatæ* or *Parabates;* they were generally leaders who fought in this manner. Their armor and arms consisted of helmet, breast-armor, lance, javelin, sword, and shield. These warriors occasionally alighted from the chariots to attack their adversaries on foot.

APOLOGY.—In a military point of view, an apology made and accepted debars the officer who accepts from bringing forward the matter as a substantive accusation. The law declares that no officer or soldier shall use any reproachful or provoking speeches or gestures to another. Any officer who so offends shall be put in arrest. Any soldier who so offends shall be confined, and required to ask pardon of the party offended, in the presence of his Commanding Officer.

APOMAQUE.—A word, among the Grecians, signifying those soldiers who were disqualified for military service from physical disability or other causes.

APOMECOMETER.—An instrument used for measuring heights, constructed in accordance with the principles which govern the sextant, viz.: As the angles of incidence and reflection are always equal, the rays of an object being thrown on the plane of one mirror are from that reflected to the plane of another mirror, thereby making both extremes of the vertical height coincide exactly at the same point on the horizon-glass, so that by measuring the base-line we obtain a result equal to the altitude. The eye of the observer when in position will be at the lower end of the hypothenuse, and the summit of the object at the other. Keeping the line of vision, which forms the base, exactly horizontal, the observer approaches the object till the images coincide, when the base will agree in length with the perpendicular, and the measured length of the former will give the height of the latter.

APPAREILLES.—In fortification, those slopes that lead to the platform of the bastion.

APPASTIS.—A war tax which was levied in ancient times upon the inhabitants of conquered countries. Also known as *Pactis*.

APPEAL.—Any officer or soldier who may think himself wronged by his Colonel or the Commanding Officer of his regiment, and after due application to him is refused redress, may appeal to the next higher commander, who is to examine into said complaint and take proper measures for redressing the wrong complained of, and transmit, as soon as possible, to the Department of War a true statement of such complaint, with the proceedings had thereon. If any inferior officer or soldier shall think himself wronged by his Captain, or other officer, he is to complain thereof to the Commanding Officer of the regiment, who is required to summon a Regimental Court-Martial for doing justice to the complainant; from which Regimental Court-Martial either party may, if he thinks himself still aggrieved, appeal to a General Court-Martial. But if upon a second hearing the appeal shall appear vexatious and groundless, the person so appealing shall be punished at the discretion of the said Court-Martial.

The wrongs here alluded to have reference chiefly to matters of accounts between the Captain, or Commander of the company, and the soldier, relating to clothing and other supplies, as well as to pay; and the Regimental Court, in examining into such transactions, may be considered more as a Court of Inquiry than a Court-Martial, or it may be viewed as an Arbitration Board, called on to adjust and settle differences arising in the settlements of accounts between the Captain and his men. One reason why a power of appeal is declared to be a matter of absolute right to inferior officers or soldiers complaining of being wronged by their officers doubtless is, that a Regimental or Garrison Court-Martial has not the power of inflicting any punishment on Commissioned Officers. It can do no more than express its opinion that the complaint is just, or the contrary, and, where it is practicable and proper, relieve the sufferer as to any existing grievance; but the injury complained of, however flagrant, must still have remained unredressed, as far as punishment is concerned, if an appeal to a General Court-Martial had not been declared to be a matter of right to the party aggrieved.

APPEL.—A smart stroke with the blade by a fencer, on the sword of his antagonist on the opposite side to that which he engaged, generally accompanied with a stamp of the foot, and used for the purpose of procuring an opening.

APPOINT.—To fix by a decree, order, command, resolve, decision, or mutual agreement. In the United States the President, by and with the advice and consent of the Senate, appoints and commissions all Commissioned Officers of the Army. Appointments to the rank of General Officer are made by selection from the Army. All vacancies in the grade of Second Lieutenant are filled by appointment from the graduates of the Military Academy, so long as any such remain in service unassigned; and any vacancies thereafter remaining are filled by promotion of meritorious Non commissioned Officers of the Army. Vacancies remaining after exhausting the two classes named are filled by appointment of persons in civil life. But appointments of civilians, except such as are regular graduates of the Military Academy who have been honorably discharged from the service, are made in time of peace only when more vacancies exist in the Army than will be required in the assignment of the next graduating class. To insure the selection of proper *Candidates for Promotion* from the grades of Non commissioned Officer, Company Commanders report to their Regimental Commanders, by the first of February in each year, such as, in their opinion, by education, conduct, and services, seem to merit advancement, and who have served not less than two years in the Army. The reports set forth a description of the candidate, his length of service as Non-commissioned Officer and as Private Soldier, his character as to fidelity and sobriety; his age, physical qualifications, and mental abilities; the extent to which his talents have been cultivated, and his fitness generally to discharge the duties of a Commissioned Officer. If recommended on account of meritorious services, the particular services referred to are stated in detail. A qualified Board is annually assembled to make a preliminary examination into the claims and qualifications of such Non-commissioned Officers, and the report of this Board is forwarded to the Secretary of War.

Whenever the public service may require the appointment of a civilian to the Army, a Board of Officers is instituted, before which the candidate is authorized by the Secretary of War to appear for examination into his physical ability, moral character, attainments, and general fitness for the service. As a rule, promotions of Non-commissioned Officers to the rank of Second Lieutenant will not be made if the candidate is under twenty-one or over thirty years of age, nor if the candidate at the time of his appointment is married. The limits of age in cases of civilian candidates are twenty and thirty years. Meritorious Non-commissioned Officers of the Army recommended for appointment receive a certificate to that effect from the Adjutant-General of the Army, and are known in the service as "Candidates for Promotion," and have the title of "Candidate" prefixed to that of their rank on all rolls, returns, orders, and correspondence. They are entitled to wear on each sleeve of their coat a single stripe of gilt lace, but are entitled to this privilege so long only as they maintain the specially honorable position of "Candidate." The privileges of a candidate terminate with the calendar year next succeeding that in which he receives his "Certificate," unless his recommendation is continued by the succeeding Boards of Examination. Candidates who become ineligible by reason of over-age are entitled to wear the candidates' stripe on the *left* sleeve only, so long as they maintain the same standing and good conduct as Non-commissioned Officers in the service as at their examination. "Candidates" who think themselves wronged in the loss of that position have a right to trial by General Court-Martial on appeal, within two months, to the Department Commander; and no Non-commissioned Officer, while holding the privileges of a "Candidate," can be brought before a Field-officers' Court, or a Garrison or Regimental Court-Martial. All vacancies in established regiments and corps to the rank of Colonel are filled by promotion according to seniority, except in case of disability or other incompetency. Promotions to the rank of Captain are made regimentally; to Major and Lieutenant-Colonel and Colonel, according to the arm, as Infantry, Artillery, etc.; and in the Staff Departments, and in the Engineers and Ordnance, according to Corps. Suspension from rank prevents an officer's promotion to a higher grade, but will not otherwise prejudice his relative advancement by seniority in the grade occupied for the time being. See *Promotion*.

APPOINTE.—This word was applicable to French soldiers only during the old monarchy of France, and meant a man who for his service and extraordinary bravery received more than common pay. There were likewise instances in which officers were distinguished by being styled *Officers Appointes*.

APPOINTING POWER.—It has been contended by advocates of executive discretion that army appointments are embraced in the power granted to the President in the second section of the Constitution, to nominate and, by and with the advice and consent of the Senate, appoint "all other officers of the United States whose appointments are not herein otherwise provided for and which may be established by law. But the Congress may, by law, vest the appointment of such inferior officers as they think proper in the President alone, in the Courts of Law, or in the Heads of Departments." If due regard, however, be paid to the words, "*whose appointments are not herein otherwise provided for*," the pretension set up in favor of executive power will receive no support from the terms of the Constitution. The powers granted to Congress to *raise* and support armies, and to make all *rules* for the *government* and *regulation* of the land and naval forces, are necessarily so comprehensive in character as to embrace all means which Congress, according to circumstances, may deem proper and necessary in order to raise armies, or to govern them when raised. Rules of appointment to office, rules of promotion—another form of appointment—and all rules whatever in relation to the land and naval forces, save the appointment of the Commander-in-Chief of those united forces, who is designated by the Constitution, are hence within the competency of Congress.

It is true that this great power vested in Congress has been exercised by them, in most cases, by giving to the President a large discretion in appointments and other matters connected with the army. But the principle itself—that supreme command is vested in Congress—has been often asserted in our military legislation. Contemporaneously with the foundation of the government laws have been passed giving to general and other officers the right of appointment to certain offices; in other cases the President has been confined in his selection to classes designated by law; again, rules have been made by Congress for the promotion of officers, and in 1846 an army of volunteers was raised by Congress, the officers of which Congress directed should be appointed according to the laws of the States in which the troops were raised, excepting the General Officers, who were to be appointed by the President and the Senate—a clear recognition that the troops thus raised were United States troops and not militia. See *Appoint*.

APPOINTMENT.—Office, rank, or employment. Also, the equipment, ordnance, furniture, and necessary articles of an army.

APPOINTMENTS.—The military accouterments of officers or soldiers, such as belts, sashes, swords, etc. In the English service the *appointments* in the mounted branch consist of accouterments, saddle, etc., making, with the Non-commissioned Officer, a total weight for the horse to carry of about 18 stone.

APPOINTON.—A sort of poniard which was extensively used in ancient times.

APPREHEND.—In a military sense, the seizing or confining of any person; as, to apprehend a deserter, etc.

APPRENTI.—Formerly in the French service there were *apprenti* or soldiers among the artillery, who served for less pay than the regular artillerymen, until they became perfect in their profession, when they were admitted to such vacancies as occurred in their respective branches.

APPROACH.—The route by which a fortified place or military position can be approached by an attacking force.

APPROACHES.—The successors of Vauban followed up, as far as practicable, the methodical stages in conducting the attack founded upon his long experience, and which consisted in a single or a double connected attack; approaching the points assailed by as many lines of communication, directed upon them, as circumstances seemed to demand, and protecting these approaches by three continuous main lines of trenches, termed the parallels, and several portions of parallels, termed demi parallels, placed between the second and third parallels, all of them so placed as to be in good tactical relations to each other.

The approaches were usually run in zigzag directions towards the salients of the defences, crossing the lines of the capitals of these salients; the front of each approach gradually contracting as it was advanced towards the salient; and each boyau of the approach receiving such a direction as not to expose it to an enfilading fire from any point of the defences within cannon-range. The drawing shows the profile of the approach. In addition to the communications between the parallels, two or more lines of approaches were run, from the positions selected for the depots of the trenches, to points of the first parallel convenient for the supplies for this and the other lines of works. These were also usually run in the direction of the capitals of some two or more of the salients.

Besides giving the boyaux directions unfavorable to an enfilading fire from the defences, each one is extended some ten or twelve yards back, to the rear of the one behind it, so that should the besieged endeavor to take up a temporary position, exterior to his main defences, each boyau would still be covered by the portion of the one in advance of it run to the rear, not only from an enfilading but from any slant reverse views, except from points so far beyond the defences as to make their temporary occupation very perilous to the besieged, from their exposure to open assaults.

The positions given to the approaches along the capitals are not obligatory; but will generally be found to offer more advantages than any other that

The Profile of the Approach.

could be given them on ground entirely unobstructed. In the first place, the capitals are the shortest lines from the parallels to the salients of the defences. In the second, by running the boyaux across the capitals, and gradually diminishing the extent of their front, the entire approach will be better flanked by the fire of the parallel in its rear; will be in a position to receive but little if any of the fire which is delivered from the two faces of the salient upon which it is run; will be out of the line of fire of the batteries enfilading these two faces; and will usually be in the most favorable position to defile each boyau from the fire of the besieged.

The front occupied by each approach will depend upon the length given to each boyau. As a general rule, the boyaux should not receive a greater length than 100 yards, in order not to expose too long a line to tempt the besieged to enfilade it, and the approach may be started at the first parallel with a front of 60 yards, which should be gradually narrowed, so as to have a front of about 30 yards at the position of the third parallel.

APPROPRIATIONS.—Annual appropriations, originating in the Lower House of Congress, are made for the support of the United States army. The English army is raised by the Queen, and maintained by annual appropriations by Parliament; the system for the support of armies is much the same throughout Europe. In the United States the term *appropriation* is also used by Post and Regimental Councils of Administration in the expenditure of funds.

APPUI.—A stay or support. In military tactics, the *points d'appui* are such parts of the field of battle as are suited to give support or shelter. As the wings of an army (like the extreme sides of a chess-board) are the weakest points of resistance to attack, they especially require support or protection, and are placed, when it is possible, in localities which serve to obstruct the attacking forces. Lakes, morasses, woods, streams, and steep declivities may thus serve as *points d'appui*.

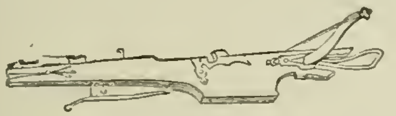
APRON.—This word is employed both in military and in shipping affairs. The apron of a cannon is a piece of sheet-lead which covers the touch-hole, tied by two pieces of white rope. In ship-building, the apron is a piece of curved timber fixed behind the lower part of the stem and just above the foremost end of the keel; its chief use is to fortify the stem and connect it more firmly with the keel. The name of apron is also given to the plank-flooring raised at the en trance of a dock, a little higher than the bottom, to form an abutment against which the gates may shut.

AQUEDUCT.—An artificial course or channel by which water is conveyed along an inclined plain. When an aqueduct is carried across a valley it is usually raised on arches, and where elevated ground or hills intervene a passage is cut, or, if necessary, a tunnel bored for it. Aqueducts were not unknown to the Greeks; but there are no remains of those which they constructed, and the brief notices of them by Pausanias, Herodotus, and others do not enable us to form any distinct notion of their character. The aqueducts of the Romans were amongst the most magnificent of their works, and the noble supply of water which modern Rome derives from the three now in use, of which two are ancient, gives the stranger a very vivid conception of the vast scale on which the ancient city must have been provided with one of the most important appliances of civilization and refinement, when nine were employed to pour water into its baths and fountains.

AQUILA.—The principal standard of a Roman legion. The standard of Romulus is said to have consisted of a handful of hay, straw, or fern, affixed to a pole or spear; whence the company of soldiers who served under it was called *Manipulus*. This primitive standard was soon superseded by the figures of animals. In 104 B.C. the Eagle was permanently adopted: it was made of silver or bronze, and was represented with expanded wings.

AQUILIFER.—A name given by the Romans to the officers who carried the Eagles of the legions.

ARBALEST—ARBLAST—ARCUBALEST.—A weapon much in use during the feudal times. Its recognized position among military arms may be dated from about the period of Richard I. The smaller kinds of arbalest were bent by pressing the hand on a small steel lever called the "goat's foot;" but the larger kinds were bent by placing the foot in a loop or stirrup at the end of the central shaft, and drawing the cord upwards with the hand. At a later period the bow was made very strong, often of steel; in this form it required a mechanical contrivance, called a "moulinet," to bend it. Sometimes ordinary arrows were used with the arbalest, but more usually arrows of a shorter and stouter kind, called "carrials" or "quarrels," were employed; these had a four-sided



Arbalest.

pyramidal form of head. Occasionally stones and leaden balls were shot from the larger arbalests. The Arbalestiers, or Cross-bowmen, carried a quiver with fifty arrows as an armament in some of the battles of the thirteenth century. They were an essential component of armies of that period, taking up their position in the van of the battle array; some were mounted, some on foot, and they occasionally wore armor. The supply of arrows or quarrels was carried after them to the battle-field in carts. The arbalest continued to be a favorite weapon in England throughout the thirteenth century; but in the fourteenth it gave way to the long-bow, which was found to be a more convenient weapon in battle.

ARBALESTINA.—In the military system of the Middle Ages, the arbalestina was a small window or wicket through which the Cross-bowmen shot their quarrels or arrows at an enemy besieging a fortified place.

ARBALETRIER D'UNE GALERE.—That part of a galley where the Cross-bowmen were placed during an engagement.

ARBRIER.—A short bow adjusted to a staff, and fixed at right angles to it, near one extremity. It was the *Arblast* in its elementary form.

ARC.—Any part of a curved line. The straight line joining the ends of an arc is its *chord*, which is always less than the arc itself. Arcs of circles are *similar* when they subtend equal angles at the centers of their respective circles; and if similar arcs belong to equal circles, the arcs themselves are *equal*. The length of an arc is readily found if the angle which it subtends at the center of the circle is known, and also the length of the whole circumference. Let the whole circumference be 100, and the angle of an arc 50°, the length of the arc is

$$360^\circ : 50^\circ : : 100 : \frac{100 \times 50}{360} = 14 \text{ nearly.}$$

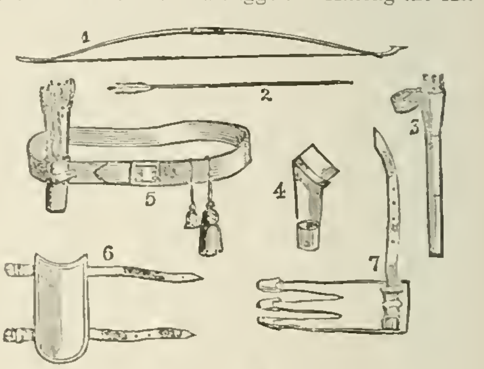
ARC À JALET.—A small cross-bow, used in ancient times to throw bullets, etc.

ARCH.—An arrangement of bricks, stones, or other materials over an open space, by which they are made not only to support each other by mutual pressure, but to sustain a superincumbent weight. We have the excellent authority of Sir G. Wilkinson for stating that the arch was known to, and used by, the ancient Egyptians; and that the Assyrians were acquainted with its principles is placed beyond doubt by the arched gateways so frequently represented in their bass-reliefs. The arch is generally supposed to have been unknown to the Greeks—a supposition which becomes very improbable if we hold it to be proved that it was used by nations with whose works they must have been familiar. But that the Greeks did not employ it generally in their architectural structures is certain; and as it is not less certain that the Romans did, it is to the latter people that the nations of modern Europe are indebted for their acquaintance with its great utility. The introduction of the arch by the Romans gradually effected a complete revolution in the architectural forms which they borrowed from the Greeks. The predominance of horizontal lines gave way by degrees, till, as the Romanesque passed into the Gothic style, it was superseded by the segments of a circle, placed generally more or less in a perpendicular direction. In its earliest application by the Romans, the arch did not spring from the

Triumphal Arch of Constantine at Rome.

entablature of the columns, but was generally placed behind them, and rested upon separate imposts. Subsequently this arrangement was departed from, and the arch assumed the position which it has since retained above the columns; sometimes having an entablature interposed, and sometimes rising directly from the capital of the column or pier, as in the Romanesque. Before mentioning very briefly the different forms of the arch, it seems natural to refer to a very simple structure, frequently met with in those early edifices in our own country which we are in the habit of designating as Saxon. It consists of two stones, their lower ends resting on rude piers, their tops leaning against each other, and thus forming two sides of a triangle, which is capable of supporting a moderate superincumbent weight. The mechanical principles on which the arch depends, though here very imperfectly employed, seem sufficiently called into play to suggest their more extensive application; and it is not impossible that out of this rude construction the arch, in its later and more elaborate forms, might have developed itself amongst ourselves without hints from foreign sources. Of the arch itself, the following variations of form may be enumerated: the semicircle, the segment, the ellipse, which were the only forms employed by the ancients, and which alone were known in mediaeval architecture up to the time at which the pointed arch was introduced. Of these, the stilted arch and the horseshoe-arch are modifications, in both of which the center or point from which the arch is described is above the line of the impost, but in the former of which the mouldings are continued downwards vertically; whilst in the latter they are slightly inclined inwards, or the curve is prolonged till it meets the impost. The horseshoe-arch belongs peculiarly to Arabian architecture, not only from its having originated simultaneously with the faith of the Prophet, but from its continuing to be used exclusively by his followers. Next in point of time, though far surpassing all the others in beauty and variety, is the pointed arch, the origin of which is still a subject of antiquarian controversy. The greater or less acuteness of the pointed arch depends on the position of the two center points from which its curved sides are described. Of the foil-arches, or arches in which the forms of a leaf are imitated, may be mentioned the trefoil, the cinquefoil, and the polyfoil, the latter being met with in Arabian and Romanesque buildings. At a later period of Gothic architecture, with the decorated style, the ogee arch was introduced, and the Tudor or four-cornered arch appeared about the commencement of the perpendicular style. When first introduced, the proportions of this arch were bold and effective; but it was gradually depressed till the principle of the arch was lost, and its very form was again merged first in two and then in one flat stone or lintel over an opening. With the last form of the Tudor arch we thus reach almost the point of departure in the construction of the arch, and complete our enumeration of its forms. The sides of an arch are termed *haunches* or *flanks*, and its highest part is called the *crown*. The wedge-shaped stones, bricks, or other materials of which an arch is constructed are called *voussoirs*; the uppermost one of all is called the *keystone*; the lowest, which is placed immediately over the impost, the *springer*, or springing-stone; the under or lower side of the voussoirs, the *intrados*; the upper side, the *extrados* or *back*. Arches are variously constructed and employed in military architecture.

ARCHERS.—Archers are soldiers whose weapons are the bow and arrow. Among the ancients specially eminent in this mode of warfare, we may particularize the Thracians, Cretans, Parthians, and Numidians; among the moderns, the Arabians, Germans, and Saracens. The Emperor Frederick II. employed Saracenic archers with great effect in his Lombard campaign; and to them is ascribed the victory at Cortenuova in 1237. The archers belonged to the light troops, and their province was to open the battle. The Emperor Leo especially lauded the dexterity of the Arabian archers. In later ages the bow came to be employed in England, where the archers wore light armor, a short sword, and a quiver with twenty or more arrows. At first these archers fought in small groups; in later years, in large masses. At the battle of Cressy they formed in divisions of 4000 men, 200 in line and 400 deep. The archers decided the fate of the day in several battles—such as Cressy and Poitiers (1356), Agincourt (1415), Crévaut (1423), Verneuil (1424), and Rovernay (1429). The French archers never equalled the English, in spite of the pains Charles VI. and Charles VII. took with them. The latter organized in 1448 the *Franc-archers*, to which corps every parish had to contribute one man; but this measure was attended with so little success that the king was induced to take Scottish archers into his pay, to make any head against the English. The French archers wore a coat of buffalo-hide lined with strong linen, and were accompanied by shield-bearers. In this manner 2000 bowmen with their shield-bearers fought under the Count de Foix at the siege of Bayonne in 1451. The archers universally belonged to the *élite* of the troops, and received higher pay than the rest. At one period the arbalest, or cross-bow, was more in favor than the long-bow. Long after the discovery of gunpowder we find the bow and arrow still used; as, for example, at the siege of Capua in 1500, and the siege of Peineburg in 1502. Nay, even in 1572 Queen Elizabeth promised to place at the disposal of Charles IX. 6000 men, of whom the half were archers. In a treatise on martial discipline, by Ralph Smithe, written in the time of Queen Elizabeth, we have a picture of the English archer two centuries after Chaucer's time: "Captens and officers should be skilful of that most noble weapon the long-bow; and to see that their soldiers, according to their draught and strength, have good bowes, well nocked, well strynged, everie strynge whippe in their nocke, and in the middes rubbed with wax braser, and shutting-glove, some spare strynges trymed as aforesaid; every man one shefe of arrows, with a case of leather defensible against the rayne, and in the same four-and-twenty arrowes, whereof eight of them should be lighter than the residue, to gall or astonye the enemye with the hailshot of light arrowes before they shall come within the danger of their harquebus shot. Let every man have a brigandine or a little coat of plate, a skull or hufkyn, a maule of leade of five foote in lengthe, and a pike, and the same hanging by his girdle with a hook and a dagger." Among the Asi-



Archery Apparatus.

atic Turks, the Persians, the Tartars, and other nations of the East, as well as the American Indians, the bow and arrow are still used as weapons of war. In Europe they are nearly abandoned for military purposes.

Although archers are still included among the fighting-men of barbarous and semi-barbarous nations, archery is now nothing more than a pastime, encouraged by Archery Clubs or Societies. In this sense, however, archery is experiencing a revival, being healthful as an out-door exercise, even if no further useful. During the reign of Charles II., archery was much patronized by the Court, Tothill Fields being the chief scene of exercise. After his reign archery fell into desuetude for about a century. In 1776, a Mr. Aston revived archery in the neighborhood of London; and very shortly there were several Toxopholite or Archery Societies formed. The system survived till 1793, when another period of inactivity supervened, lasting till 1844. In this last-named year archery was revived in Yorkshire, and has since gone on extending every year. A recommendation to the sport is that ladies can take part in it—one of the few open-air pastimes of which this can be said. In the modern exercise of archery there are several varieties of contests between the antagonistic parties; but the usual variety is target-shooting. In archery-matches a number of prizes are generally awarded, the principal being for the greatest number of arrows shot into any part of the target, and for the nearest approach to the exact center. The target has a gold spot in the center, a red ring around this, then a blue ring, then a black, and outside of all a white ring bordered with green. The merit of the shooting consists in a near approach to the exact center, or "gold." Two targets are generally used in a match, on opposite sides of the field, each by one party. The apparatus mostly used at these archery-meetings is: 1, the bow, varying in weight according to the strength of the person who is to use it; 2, the arrow; 3, the quiver, a tin case for holding arrows not immediately in use; 4, the pouch; 5, the belt for holding the arrows actually in use. The tassel of the belt serves to clean the arrows when dusty. 6, the brace, buckled round the left arm, to protect it from being hurt by the string when shooting; 7, the shooting-glove, formed to protect the three fingers used in drawing the string. Besides these articles and the target, archers are sometimes provided with a large case called an "ascham," fitted up with the necessary drawers and compartments for the reception of the bow, arrows, string, and other necessary accouterments. In archery-competition the total number and value of each person's hits are registered on a scoring-card. The shots are usually punctured on a card with a pin, as being preferable to pencil or ink-marks; and the mode of ascertaining the value of the hits, which is increased in proportion as they reach the center, will be seen by the following example:

Names.	Gold.	Red.	Blue.	Black.	White.	Total.	Value.
A...	. .	. . . . .	. . . . . .	. . . . . .	. . . . . .	35	119
				. . . . . .	. . . . . .		
					. . .		
B.........	.	. .	. . . . .	. . . . . .	. . . . . .	26	90
			. . .	.	. . . . .		

It appears by the card that A has 2 in the gold, 4 in the red, 6 in the inner white, 10 in the black, and 13 in the outer white, making a total of 35. The real value of these is ascertained by multiplying the hits in the gold by 9; in the red by 7; in the blue by 5; in the black by 3; and by leaving without alteration the number in the white or outer. By this process it will appear that A's numbers, according to the *value* of each circle, amount to 119, and B's to 90; hence A is the winner by 29. But A's *total* might have been less than B's, and still he might have been the winner, providing the shots had lain more towards the gold than B's. As an instance of the skill which long and careful practice may insure, Mr. Horace A. Ford, who has written an excellent work on archery, on one occasion, out of 144 shots, made 143 hits—765 score; on another, 144 shots, 137 hits—809 score; and on another, 75 shots, 75 hits—555 score.

ARCH-GAYE.—A lance used by the Gauls and Franks, which consisted of a sharp-pointed piece of iron attached to a light wooden handle. Also known as *Lance-gaye.*

ARCHIBALD WHEEL.—An iron-hubbed wheel used on the wagons and gun-carriages of the United States army. The wheel is noted for its strength, endurance, and independence of climatic changes. Fig. 1 represents a lateral section of the hub of this wheel, exposing the axle, bolts, and the method of construction. A is the axle; B, the back of the hub, which is also the axle-box; C, the front or loose flange; DD, the bolts through spokes and flanges; EE, the spokes; F, the brass cap; G, the axle-nut; a small screw at the outer extremity, is removed when oiling the axle. Fig. 2 shows the construction at the center and rim, and clearly exhibits the joints and the position of bolts. The size of the

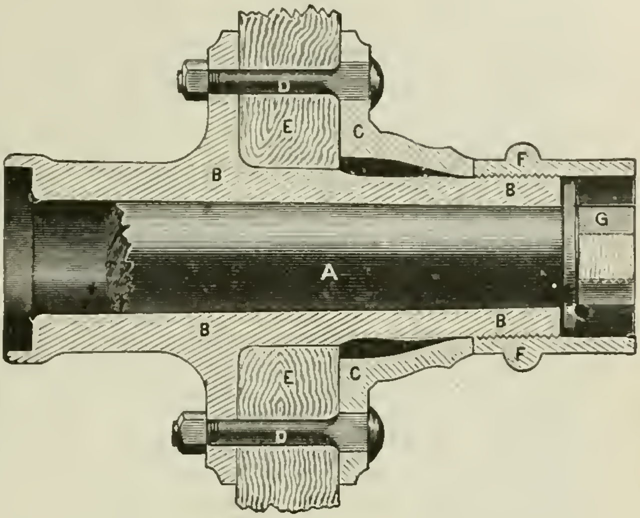


Fig. 1.

spokes in these wheels is, as a rule, the same as the diameter of the axle. In case of accident, the wheel may be readily repaired, its construction being so

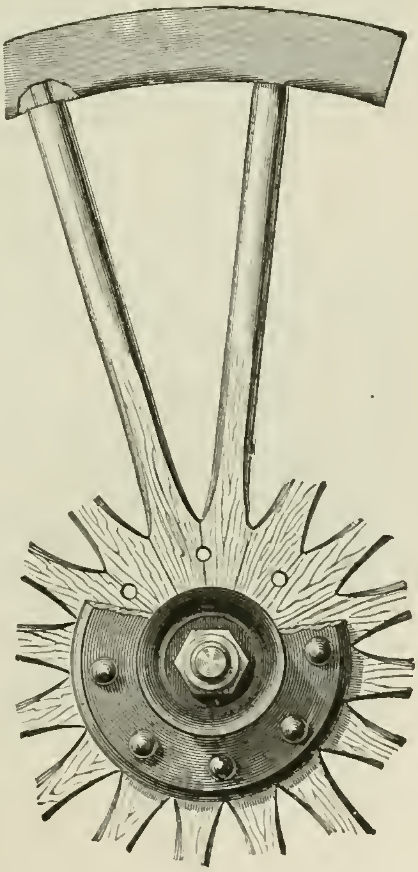

Fig. 2.

simple. Duplicate spokes, hubs or boxes, and axles should, if practicable, be kept on hand for the purposes of repair.

To replace a box and that portion of the hub at-

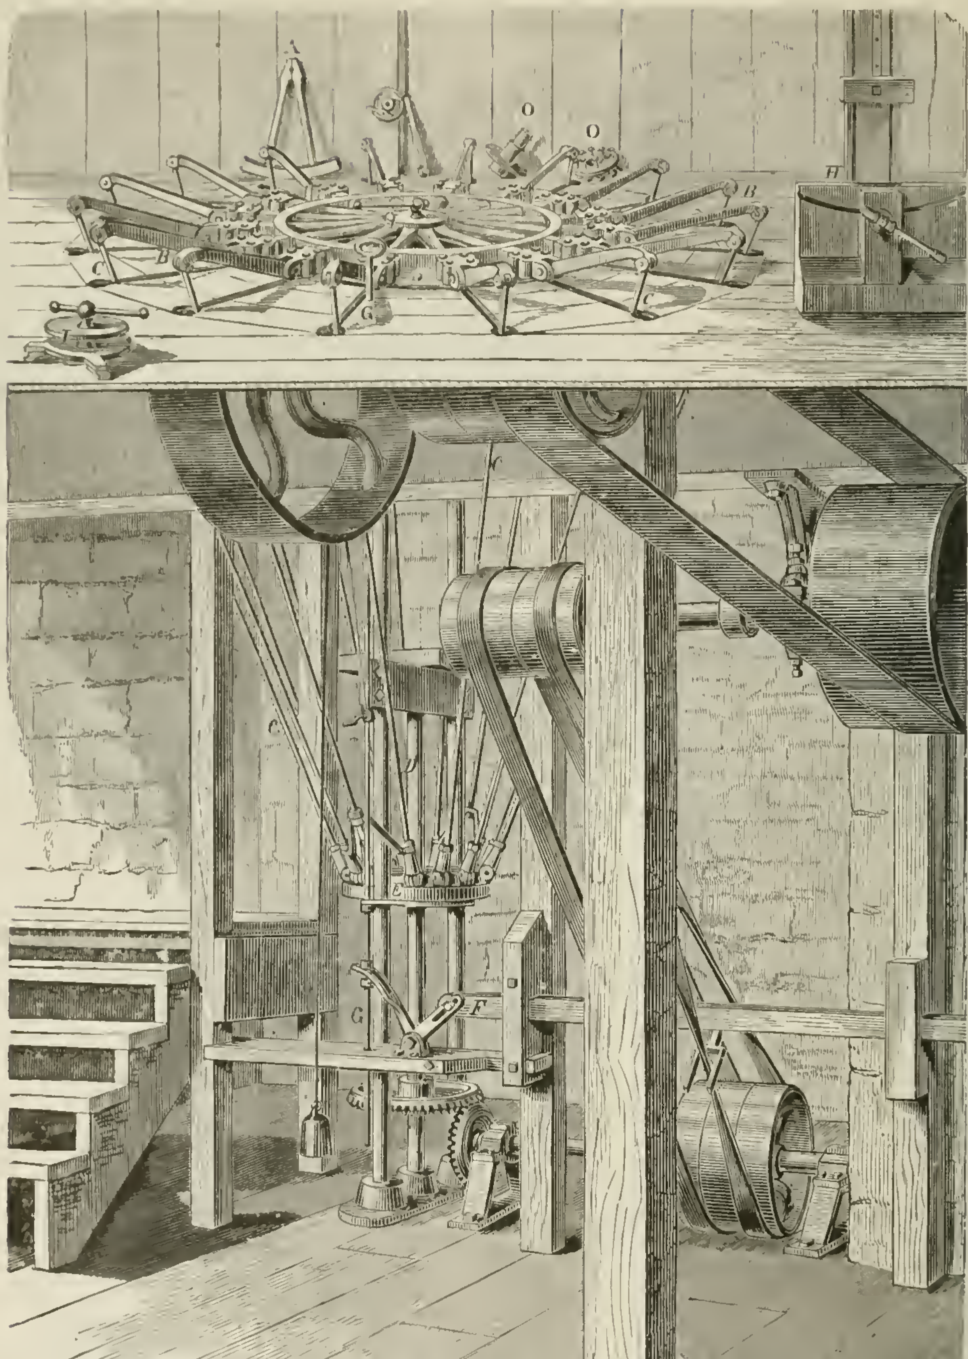

FIG. 3.

tached: Unscrew and remove the front hub-band, take off the hub-nuts, and the box will easily drive out. The new box is as easily put on again, after which screw on the front hub-band. The tire being on will hold the wood part so that it cannot move while the hub is being taken off. This hub or box is as firm and true on the wheel as was the first one. The change can be made by anybody, and in a few moments.

To repair a spoke: Take off the tire and felloe on the injured spoke (and in taking off this felloe it is not necessary on account of the peculiar dowel used to start off any other felloe), take out only the bolt that passes through the injured spoke, saw off this spoke as close to the hub as possible, and bore or dig out the spoke, drive in the duplicate spoke as far as possible, and arrange the tenon at the felloe so that the tire may press the spoke about ⅛ inch farther into the hub, and after the tire is on put in the hub-bolt.

The following is the approximate weight per set of each size and style of bed of axles fitted for Archibald Wheels, with beds long enough to weld up 4 feet 6 between axle-collars (shorter beds will weigh less, and longer beds more):

SIZE.	DRAWN.	PLATFORM.	SQUARE.
1½ inch.	65 lbs.	82 lbs.	90 lbs.
1⅝ "	80 "	95 "	105 "
1¾ "	95 "	115 "	125 "
1⅞ "	112 "	135 "	145 "
2 "	135 "	150 "	165 "
2⅛ "	155 "	185 "	190 "
2¼ "	175 "	205 "	210 "
2½ "	215 "	255 "	260 "
2¾ "	255 "	310 "	315 "
3 "	320 "	375 "	390 "

It is noticeable how much less these weigh than the same style of axles *with boxes* for wood-hub wheels.

The drawing on the opposite page shows the machine with which this wheel is manufactured, and a reference to same will assist in a perfect understanding of the structure and endurance of the wheel. The machine acts to force into close contact the flat surfaces of the spokes at their inner ends, and thus compact them, so that their faces form true circular planes, upon which the inner faces of the hub-flanges rest. It will be seen from the cut here printed, representing the machine, that it occupies two consecutive floors. A strong circular plate of cast-iron, about seven feet in diameter, having its upper surface faced off true, is placed horizontally level with the floor of the shop. Arranged at equal distances around its outer edge are a number of levers, B, equal to the number of spokes to be set in the wheel,—sixteen in this case,—having their fulcrums securely bolted to the plate. The long arms of the lever radiate from the plate about three feet all around; the short arms are formed into cams or rolling inclines, acting upon sliding pins of cast-iron, which move freely in a radial direction, in guides formed in the fulcrum-blocks. When the long arms of the levers are raised, the sliding pins are pressed outward by a spring, until they bear upon the cam-shaped short arms of the levers at the point nearest the fulcrum or center of motion of the lever. When the long arms of the levers are lowered, their sliding-pins are forced inward by the cams, and unite in pressing inward the wheel properly placed in their embrace. The levers are all actuated with rapidity, uniformity, and certainty, by means of wrought-iron rods, C, extending downward from the ends of the levers, converging to a vertical column, D, under the center of the plate, much as the braces of an umbrella extend downward from the ribs to the stick. A screw is cut upon the central column, D; and a nut, E, answering to the slide upon an umbrella-stick, raises or lowers all the levers at once with great facility and with any required power. Motion is given to the nut by means of beveled gears, and open and cross belts with fast and loose pulleys, so arranged that, at the upward and downward limits, the belts are thrown automatically upon the loose pulleys, and the motion of the nut and levers stopped. Any required motion, either up or down within the range of the screw, can be obtained with great delicacy and convenience by a shipper, F, actuated by a shipping-rod, G. The felloes and spokes, having been perfectly shaped and completely finished by machinery, are first put together by driving the spokes into the felloe or rim, one at a time; the felloe being held firmly by a vise, H, specially constructed to prevent splitting of the felloe or twisting of the spoke, so that an exact fit is obtained at this important point. The felloes with their spokes are then placed in the press, when the perfection of the fitting is shown by the perfect joint made by the spokes when they meet in the circle, to be curved and embraced by the hub, and by the coincidence of the half-holes in the contiguous sides of the spokes, A, which together form the holes for the eight bolts that are finally to hold the hub-plates together. Temporary hub-plates, I,—one above and one below,—with a powerful screw in their center, hold the ends of all the spokes truly in the plane of the circular plate while undergoing the pressure of the levers. The extent of this pressure is ascertained by marking carefully with a sharp pencil around the circumference of the upper temporary hub-plate after the spokes have been brought to a close, firm joint; and then the pressure is put on till the joint of the felloes closes up firmly. Another similar mark being made, upon removal of the temporary hub-plate, it is found that a space of a quarter of an inch is made between the two pencil-marks—a reduction in diameter of half an inch. Now, as the difference in circumference corresponding to a difference in diameter of half an inch is 1.5708 inches, this divided by 16 (the number of spokes) gives .098 of an inch, *or substantially one tenth of an inch, as the lateral compression of each spoke.* This is by no means the limit, but is regarded sufficient to secure the spokes against being loosened by shrinkage in any climate, and this pressure is what gives this wheel its enormous strength and durability. The hub, OO, is firmly bolted together while the wheel is in the press, and holds the spokes securely, the bolts fitting snugly in both spoke and hub. The felloes spring apart a little when taken from the press, but only a little; and the tire easily makes that all firm again.

So great is the facility with which this machine is operated, that one man with an assistant easily puts together a set per hour, including the time of adjusting machinery for the difference in diameter of the wheels.

The great point in this wheel, made in this manner, is the thorough compactness of the hub-ends of the spokes, though the other ends of the spokes and the joints in the felloes receive scarcely less benefit. By observing an old wheel it will be seen that the spokes are bedded into the felloes and hub. This is done by degrees, and is unavoidable in wheels made in the usual way. The only way to keep such a wheel together is to reset the tire, so as to take up the looseness caused by the slow crushing and grinding process. This is all prevented in the Archibald process of manufacture, by putting on a pressure at every joint of more than ten times the amount the wheel will ever be called upon to sustain in actual use, and at a time when the wheel is so held as to receive this pressure without possible injury to it. One tenth of this pressure from a tire would ruin the wheel, but the tire when properly put on will hold all this pressure and remain on tight until worn out. The hub holds all the pressure of the spokes within it independently of the tire. Wheels made by this method are perfectly round and true. The pressure distributed about the rim can be varied from zero to one hundred tons, if required. There are reasons why iron-hubbed wheels made in this manner should be far superior to wheels with wooden hubs. The spokes cannot crush into the hub, as they will do into wooden-hubs whether driven full size into a very large hub, as was the practice fifty years since, or, as at present, into a smaller hub, the spokes having tenons and shoulders. With wooden hubs the spokes are weakened just where they need the greatest strength; while in the iron-hubbed wheel the spokes are more than twice as large at the hub as a wooden-hub wheel of corresponding size. A wheel made on this plan will not shrink, and as the bases of the spokes are as firmly compressed against each other as it is possible for wood to be, and held by metallic flanges firmly bolted together, it is apparent that such a wheel possesses the advantage of the most perfect method of construction yet devised. See *Wheel*.

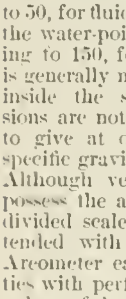
ARCHITONNERRE.—A machine made of copper, which threw iron bullets with great force and noise; it was used in ancient times, and was the invention of Archimedes.

ARCHITRAVE.—The master-beam, or chief supporter, in any part of a subterraneous fortification.

ARCO.—A metal composed of 70 parts of pure copper, 27 parts of zinc, and 3 parts of lead. It is used for the brass-work of small-arms.

AREA.—A term in mathematics meaning *quantity of surface*. The calculation of areas, or mensuration of surfaces, is one of the ultimate objects of geometry. The measuring unit is a square inch, a square foot, etc., according to the unit of length. As a figure is thus measured by finding an equivalent for its surface in *squares*, the process is sometimes called the *quadrature* of the figure. In a military sense, *area* is the superficial contents of any rampart or other work of a fortification.

AREOMETER.—An instrument, called also Hydrometer, which is allowed to float freely in liquids to determine their specific gravity or that of solid bodies. The delicacy of the instrument depends on the distance of the divisions on the scale, or on the thinness of the stem compared with the bulbs. An instrument possessing this advantage cannot be made to serve both for liquids heavier and lighter than water, for the stem would be of an inconvenient length; and it is usual to construct two Areometers—one marked with the water-point at the top and the scale descending to 50, for fluids heavier than water; and the other with the water-point at the bottom and the scale ascending to 150, for fluids lighter than water. The scale is generally marked on a slip of paper, which is fixed inside the stem. On some Areometers the divisions are not at equal distances, but are so drawn as to give at once, without table or calculation, the specific gravity of the fluid in which they are placed. Although very desirable, in practice they do not possess the accuracy of the Areometer with equally-divided scales, because the graduation of them is attended with considerable difficulty. No form of Areometer can be made to determine specific gravities with perfect accuracy, and such instruments are only useful where a ready and good approximation is all that is needed. They are, in consequence, employed chiefly to ascertain the specific gravity of the various liquors and solutions which occur in the arts and manufactures, and very frequently they are graduated with reference to special liquids, as spirits, wine, milk, brine, etc. The alcoholometer or Lydrometer of Sikes is an instrument of this latter description, and is in general use in the excise for estimating the strength of spirits. The peculiar feature of Areometers with weights is that, instead of a scale, they have only one mark on the stem, to which the Areometer is in all cases sunk. One of the best-known instruments of this kind is the Areometer of Nicholson. It consists of a brass tube, BC, about 1 inch in diameter, closed above and below by conical ends, to the upper of which a wire is fixed, carrying on the top of it a cup, A, capable of containing the weights; and to the lower a hook is attached, from which hangs the cup, D. The lower part of the cup, D, is also provided with a hook, and the whole instrument is kept vertical, partly by the weight of the cup and partly by the weight of the ball, E, suspended from it. On the wire, a notch, W, is made, to serve as the mark or fixed point to which the Areometer is sunk. The specific gravities of liquids are determined by Nicholson's Areometer in the following way: The weight of the Areometer itself is first ascertained—let it be in a given case 2000 grains; it is then put into water at the temperature of 60° F., and weights (say 500 grains) put in, till it is sunk to W. It is now removed to the liquid under examination; and if the weight required to sink the instrument now to the standard-point be only 100 grains, we have the specific gravity of the liquid equal to $\frac{2100}{2500}$, or $\frac{21}{25}$. In both fluids the same volume has been displaced, and that is in each case equal to the weight of the Areometer; but the weight of the Areometer in the second case was 2000 + 100, and in the former 2000 + 500; hence the above result. Nicholson's Areometer is seldom used for finding the specific gravity of fluids; its use is almost entirely restricted to ascertaining that of small solid substances. The following example will show how this is done: If in the cup of the Areometer already mentioned, when placed in water, the solid be put, and only 440 grains be then necessary to bring the instrument to W, 60 grains is manifestly the weight of the solid, because 500 grains were needed without it to do the same thing. The solid is next placed in the lower cup, D, and if 460 grains are now needed to sink to the standard-point, the solid has thus lost 20 grains of its weight by being immersed in the water. According to the principles of Archimedes, these 20 grains are also the weight of a volume of water equal to that of the solid; so the specific gravity of the solid is $\frac{60}{20}$, or 3. By reversing the cup, D, which is furnished with perforations, to allow free passage to the air, and attaching the weight, E, to the handle of it, the specific gravity of substances lighter than water may also be determined by this instrument. The other forms of weight-areometers are those of Fahrenheit, Tralles, and Charles. See *Hydrometer* and *Specific Gravity*.



AREOSCOPE.—An instrument used for analyzing the air of barracks, hospitals, etc. It is principally employed by the English Medical Corps.

ARES.—The god of war in Greek mythology, and corresponding to the Roman Mars.

ARGENT.—The French word for silver; always used in English Heraldry to signify that metal. In engraving shields it is left white.

ARGOULET.—An ancient dragoon. Also an inferior sort of musket made at Liege for trading with the negroes.

ARIES.—The battering-ram, so called because the metallic head was sometimes fashioned like the head of a ram. As a means of battering walls it is said to have been invented by Artemanes of Calzomene, a Greek architect, about 441 B.C. It is described by Josephus, who states that it was sometimes supported on the shoulders of men who advanced on a run; at other times it was slung from a frame, and operated by ropes. Philip of Macedon is said to have been the first to place the frame on wheels, at the siege of Byzantium. Plutarch informs us that Mark Antony, in the Parthian war, made use of an aries 80 feet long. Vitruvius says they were sometimes 106 to 120 feet in length.

ARM.—1. An instrument of warfare; a weapon of offence or defence. 2. Any particular description or class of troops. The Artillery, the Cavalry, the Infantry, and the Engineers are each an arm of the service. The word used figuratively denotes power. 3. That portion of an axletree about which the wheel revolves. See *Axletree-arm*.

ARMAMENT.—All arrangements made for the defence, with musketry and artillery, belong to what is termed the *armament*. The armament with musketry is complete when the banquette and the interior and superior slopes are properly arranged to enable the soldier to deliver his fire with effect, and to mount on the parapet to meet the enemy with the bayonet. For this last purpose stout pickets may be driven into the interior slope, about midway from the bottom and three feet apart, or a narrow plank may be laid along this slope. The armament with artillery is, in like manner, complete when suitable means are taken to allow the guns to fire over the parapet or through openings made in it, and when all the required accessories are provided for the service of the guns. The armament with artillery is a subject of great importance, because it is not equally adapted to all classes of works. Experience has demonstrated that the most efficient way of employing artillery is in protecting the collateral salients by a well-directed flank- and cross-fire which shall not leave untouched a single foot of ground within its range over which the enemy must approach. It has, moreover, shown that a work with a weak profile affords but little security to artillery within it; for artillery cannot defend itself, and such a work can be too easily carried by assault to offer any hope of keeping the enemy at a distance long enough to allow the artillery to produce its full effect. The proper positions for artillery are on the flanks and salients of a work, because from these points the salients are best protected and the approaches best swept; and the guns should be collected at these points in batteries of several pieces, for experience has shown that it is only by opening a heavy, well-sustained fire on the enemy's columns that an efficient check can be given to them. If only a few files are taken off, or the shot passes over the men, it rather inspires the enemy with confidence in his safety, and with contempt for the defences.

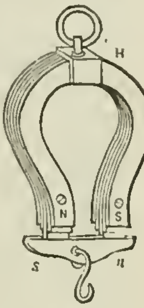
When, in the defence of a work, from the indications without there is no longer any doubt respecting the real point of attack selected, all the disposable artillery will be brought forward and placed in barbette, in the best positions on this point and the collateral works for sweeping the ground over which the trenches must be pushed. In the mean time embrasures, platforms, and traverses should be prepared on the most suitable positions, to place the artillery under shelter from the enfilading batteries so soon as they are ready to open fire. Every disposable gun, except the reserve pieces, should, both at this time and whilst the besiegers' batteries are still incomplete, be placed in positions to bear upon the points occupied by them, with mortars of long range placed wherever they will be well masked and can throw their shells with the most effect against these points. The traverses, to cover from enfilade views, should be shot-proof gabionades, and be placed so far apart only as to allow the least room for two guns between them. The terre-pleins of the barbettes should be cut down and their parapets somewhat raised, to admit of embrasures for the guns along them. The fire of the defences should be concentrated on a few of the principal batteries rather than scattered over all, because, by delaying the progress of these, the others, if the besiegers act prudently, will not open their fire until all are ready.

ARMAMENTARY.—A term sometimes employed to denote an armory, magazine, or arsenal.

ARMA SHOT.—An expression meaning to roll rope-yarns about a cross-bar shot in order to facilitate ramming it home, and also to prevent the ends catching any accidental inequalities in the bore.

ARMATURA.—In ancient military history, the fixed and established military exercises of the Romans. Under this heading is understood the throwing of the spear, javelin, shooting with bows and arrows, etc. Armatura was also an appellation given to the soldiers who were light-armed; as, also, a name given to the soldiers in the Emperor's retinue.

ARMATURE.—1. Armor worn or used for the protection and defence of the body. 2. The term armature is applied to the pieces of soft iron that are placed at the extremities or poles of magnets to preserve their magnetic power. When magnets are allowed to remain any length of time without such appendages, in consequence of the disturbing influence of terrestrial magnetism they lose considerably in strength; but when they are provided with them their magnetism is kept in a state of constant activity, and thereby shielded from this disturbance. The reason of this is found in two facts well known in the science of magnetism; viz., that when a piece of soft iron is brought into contact with the extremity of a magnet it is itself induced to become magnetic, and that the unlike poles of two different magnets powerfully attract each other. Referring to the figure, the north pole, N, of the horseshoe-magnet, NHS, acting on the armature, *sn*, induces it to become a magnet, having its south pole, *s*, next to N, and its north pole, *n*, at the opposite extremity. The pole, S, by virtue of its magnetic affinity powerfully attracts the north pole, *n*, thus formed, and adds its own inducing influence to heighten the magnetic condition previously induced in the armature by the pole, N. The armature, from the combined action of both poles of the horseshoe-magnet, is thus converted into a powerful magnet, with its poles lying in an opposite direction to that of the primary poles. The original magnet is, in consequence, brought into contact with one of its own making, the exact counterpart of itself—a condition highly favorable to the maintenance of its strength. It is due to the same mutual attractions that a much larger weight can be suspended from the armature thus placed than what the single poles can together sustain. Bar-magnets may be armed in the same way by laying them at some distance parallel to each other, with their unlike poles towards the same parts, and then connecting their extremities by two pieces of soft iron. When a magnet, such as a compass-needle, is free to take up the position required by the magnetism of the earth, the earth itself plays the part of an armature.



ARM-CHEST.—A portable locker for holding arms, and affording a ready supply of pistols, muskets, or other weapons. Also used in the military service for the transportation of rifles, revolvers, etc.

ARME BLANCHE.—Literally, white arm. Arms used in hand-to-hand conflicts, such as swords, bayonets, foils, etc.

ARME COURTOISE.—An arm used in tilts or tournaments during the Middle Ages. It was a kind of sword with a ring or knot placed at the tip of the blade to prevent it causing a dangerous wound.

ARMED RECONNOISSANCE. — Reconnoissances made in the neighborhood of an enemy require to be done under the protection of a proper detachment, the strength and composition of which will depend on the object to be attained. If the object be to gain secretly a knowledge of the enemy's whereabouts and strength, then a detachment of light cavalry, conducted by a trusty guide through circuitous by-ways, and moving with celerity, but with proper precautions against falling into an ambush or having its retreat cut off, is usually resorted to. The details for this will be found under the head *Patrols*. When an enemy's position is to be reconnoitred with a view to force him to show his hand, by causing him to call out all his troops, then a large detachment of all arms, adequate to the task of pressing the enemy vigorously, and also of withdrawing with safety when pressed in turn, must be thrown forward. Under the shelter of either of these forces, the officer charged with the reconnoissance takes the best moment and best point of view for carefully ascertaining the dispositions made by the enemy. A good time will be at early dawn, when troops, in most services, are all made to stand to their arms. The points which the officer must exhibit most attention in finding out are those occupied by the batteries, and all those in any way intrenched. See *Field-service* and *Reconnoissance*.

ARMED WHIP.—A kind of hand-flail or knout, with three, four, or six chains. This weapon is frequently called *Scorpion*.

ARMES DE JET.—Missive weapons; offensive arms or instruments which act by propulsion, whether by the force of powder, steam, wind, or mechanism.

ARMET.—A helmet or head-piece consisting of a globular iron cap, which spreads out with a large hollowed projection over the back of the neck, and in front has a piece formed like part of a bowl, so as to cover the mouth and chin.

ARMGAUNT.—That which is worn out by military service; as, an armgaunt steed, etc.

ARM-GUARDS.—Hollow plates of metal to be buckled over the mail, and adjusted to the outer surface of the upper arm and to the front of the lower arm, which bore the appropriate name of *arm-guards* or gardes-bras.

ARMIGER.—Formerly an armor-bearer, as of a knight; an esquire who bore his shield and rendered other services. In later use, one next in degree to a knight, and entitled to a coat of arms.

ARMILAUSA.—A military uniform coat worn by the Romans over their armor.

ARMILUDIA.—A name given by the Romans to the exercises of arms, and also applied to the day on which these exercises took place.

ARMILUSTRIUM.—The name given by the Romans to a military festival which took place on the 19th of October annually. After review, the soldiers offered up sacrifices for the success of the Roman arms.

ARMISTICE.—A cessation of active hostilities for a period agreed upon between belligerents. It must be agreed upon in writing, and duly ratified by the highest authorities of the contending parties. If an armistice be declared, without conditions, it extends no further than to require a total cessation of hostilities along the front of both belligerents. If conditions be agreed upon, they should be clearly expressed, and must be rigidly adhered to by both parties. If either party violates any express condition, the armistice may be declared null and void by the other. An armistice may be general, and valid for all points and lines of the belligerents; or special, that is, referring to certain troops or certain localities only. An armistice may be concluded for a definite time; or for an indefinite time, during which either belligerent may resume hostilities on giving the notice agreed upon to the other. The motives which induce the one or the other belligerent to conclude an armistice, whether it be expected to be preliminary to a treaty of peace, or to prepare during the armistice for a more vigorous prosecution of the war, does in no way affect the character of the armistice itself. An armistice is binding upon the belligerents from the day of the agreed commencement; but the officers of the armies are responsible from the day only when they receive official information of its existence. Commanding Officers have the right to conclude armistices binding on the district over which their command extends, but such armistice is subject to the ratification of the superior authority, and ceases so soon as it is made known to the enemy that the armistice is not ratified, even if a certain time for the elapsing between giving notice of cessation and the resumption of hostilities should have been stipulated for. It is incumbent upon the contracting parties of an armistice to stipulate what intercourse of persons or traffic between the inhabitants of the territories occupied by the hostile armies shall be allowed, if any. If nothing is stipulated, the intercourse remains suspended, as during actual hostilities. An armistice is not a partial or a temporary peace; it is only the suspension of military operations to the extent agreed upon by the parties. When an armistice is concluded between a fortified place and the army besieging it, it is agreed by all the authorities on this subject that the besieger must cease all extension, perfection, or advance of his attacking works, as much so as from attacks by main force. But as there is a difference of opinion among martial jurists whether the besieged have the right to repair breaches or to erect new works of defence within the place during an armistice, this point should be determined by express agreement between the parties. So soon as a capitulation is signed, the capitulator has no right to demolish, destroy, or injure the works, arms, stores, or ammunition in his possession, during the time which elapses between the signing and the execution of the capitulation, unless otherwise stipulated in the same. When an armistice is clearly broken by one of the parties, the other party is released from all obligation to observe it. Prisoners taken in the act of breaking an armistice must be treated as prisoners of war, the officer alone being responsible who gives the order for such a violation of an armistice. The highest authority of the belligerent aggrieved may demand redress for the infraction of an armistice. Belligerents sometimes conclude an armistice while their plenipotentiaries are met to discuss the conditions of a treaty of peace; but plenipotentiaries may meet without a preliminary armistice; in the latter case, the war is carried on without any abatement. See *Capitulation* and *Truce*.

ARMLET.—A protecting sleeve of leather or metal worn on the forearm, and used as a shield for the arm or as a covering for that portion of the coat-sleeve.

ARMOR—ARMOUR.—A general name for the apparatus for personal defence, as contradistinguished from arms or weapons of offence. Little of it is worn by soldiers at the present day, seeing that hand-to-hand conflicts, in which it is especially serviceable, are rather exceptional in modern warfare. It was before the invention of gunpowder that armor—often called in England by the name of *harness*—was especially used. All the ancient nations who occupy a place in history were accustomed to adopt one or other of the defensive clothing or implements which collectively come under the denomination of armor. Leather armor was sometimes worn; but brass, iron, and other metals were preferred. Some of the more luxurious leaders had much silver and gold in their armor. In the Bible, shields, helmets, breastplates, and greaves are mentioned among the articles of armor borne or worn by the Israelites and their opponents. The classical writers—Homer, Xenophon, Herodotus, Livy, Tacitus, Varro, etc.—supply abundant evidence of the use of armor among the nations concerning whom they wrote. It is believed that the early Britons bore little or no other armor than shields. The Anglo-Saxons were more fully provided. At different times before the Norman Conquest they appear to have had four-cornered helmets; loricæ made of leather; scale-armor; leathern helmets; wooden shields covered with leather; sheep-skin shields; conical caps or helmets of metal; pectorals or neck-guards; breast-guards of undressed hide; flat-ringed armor; byrnes or tunics of overlapping pieces of leather; close-fitting cuirasses of leather, and sometimes of strong linen; leg-guards of twisted woollen cloth; shields of various sizes, from half a yard to a yard and a half in length; and casques having more or less resemblance to the ancient helmets. When the Danes were in Britain they had at first no other armor than leathern neck-pieces, which descended some way over the shoulders and chest; and greaves or shin-pieces for the legs. In the time of Canute or Knute, however, they adopted a kind of armor which Sir Samuel Meyrick supposes them to have borrowed from the Norsemen or Norwegians. It comprised a tunic, with a hood and long sleeves; pantaloons which covered feet as well as legs; and sugar-loaf-shaped helmets or skull-caps, with attached pieces which hid nearly the whole face except the eyes. All these were probably made of leather; but most of the surfaces were strengthened by macles or mascles, a perforated network of steel.

With William the Conqueror came in the kinds of armor which were at that time prevalent among the knights and soldiers of the Continent of Europe, and which became afterwards more or less combined with the armor previously known in England. William himself occasionally wore a hauberk of ring-armor. This kind of armor was much worn during his reign, the rings being usually attached to a foundation of leather. One curious variety of ring-armor, called the haubergeon, had the tunic and breeches all in one piece. The helmets were generally conical, with a nasal or nose-guard descending from the front. A distinct ring-armor, called *hose*, was often worn on the legs. The shield was generally kite-shaped, unlike the oval shield carried by the Anglo-Saxons. Gradual changes in these various portions of armor were made between the reigns of William, Rufus and John. Under Henry III., we find stitched and padded hauberks and chaussés, called "ouvrages de pourpointerie"; suits of ring-armor; greaves or shin-pieces of steel; poleyns or knee-guards; vambraces or arm-guards; jacks, jaques, or jackets, made of leather,

Suit of Armor,
presented by the Emperor Maximilian to Henry VIII.

and worn over the ring-armor; interlaced ring-armor of oriental invention, not requiring to be stitched to any garment or foundation; helmets, visors, and skull-caps of various forms; and chanfrons, or armor for the head and face of horses. During Edward III.'s reign iron plate-armor was much used by troopers, in the various forms of helmet, breastplate, gauntlet, and greaves. In the fourteenth century chain-mail fell into disuse, and was succeeded by plate-armor; this last-named kind became more and more complicated, and reached its greatest pitch of elaboration in the reign of Richard III. During the times of Henry VII. and VIII. the armor was sometimes fluted, often elaborately engraved, and even damascened or inlaid with gold. Under James I. the knightly ideas of the feudal times gave way, and the use of armor declined; a knight armed *cap-à-pie* was a rarity. Charles I. tried to revive its use, but he had few followers; and the days of Cromwell may be regarded as the last in which armor was worn to any considerable extent by the regular soldiers. Helmets and cuirasses are still worn by the three regiments of Household Cavalry (Life-Guards and Horse-Guards), but more for show than for service.

ARMOR-BEARER.—One who carries the armor of another; an Armiger; an Esquire.

ARMORED DEFENSES.—The first time that a rifled gun was fired at armor for land-works was in 1860, when an 80-pdr. Armstrong gun fired wrought-iron flat-headed shot, and a 40-pdr. fired cast-iron shot, at two iron embrasures (8 inches and 10 inches thick) fixed in a masonry-work at Shoeburyness. This trial brought out the advantages arising from the use of iron for strengthening works, and the disadvantage of having splayed sides in an iron embrasure. From that time experiments against armor followed each other rapidly. In 1861 comparative trials were made between wrought-iron armor-plates backed with rigid materials, such as cast-iron and granite, and similar plates backed with timber, cork, India-rubber, layers of wire, and other substances. From these it was gathered that while the hard materials improved the resisting power of the armor, they led to its being more injured by cracking and to the giving way of fastenings. Other trials were made with wrought-iron plates inclined to the horizon at various angles, from which it was concluded that a mass of armor placed upright will offer as much resistance as the same mass disposed at any inclination so as to cover the same vertical area. Even *wool* was experimented upon as to its power of resisting cannon-shot. Next, some shields, 6 inches and 10 inches thick, composed mainly of boiler-plates ⅝ inch thick, riveted and screwed together, gave very indifferent results, and two other heavier casemate-shields, of very opposite construction, made of massive slabs of rolled iron, laid one in front of the other, and crossing at right angles, with lead between them, were tried, in 1862–3, with good results. In the Warrior target, composed of 4½ inches of rolled-iron plates on 17 inches of wood, backed by a thin iron skin, we see the advantage of timber backing, the weakness of joints in armor, and the disadvantage of joining armor-plates to each other by means of tongues and grooves on their edges. In other of these ship's targets the question of providing a compound backing of wood and iron instead of wood alone is practically solved in favor of the former, and the disadvantage of doing away with all wood in the backing is also proved. Up to 1863, the heaviest gun used in experiment was a 10½-inch rifled gun, throwing a cylindrical shot of about 300 lbs., with a muzzle-velocity of about 1320 f.-s. There were also a 7-inch Whitworth (130-pdr.) and a large 13-inch smooth-bore Horsfall gun. But shortly afterwards a 23-ton gun of 13.3 inches' caliber, capable of piercing a ship's side stronger than that of the Warrior at two miles' range with a shot of 600 lbs., called for a corresponding advance in the strength of armored structures. Consequently H.M.S. Hercules was protected with 9-inch armor at her water-line; and a target representing her at this part, with a very massive backing of teak and iron stringers, ribs, and skin, afforded effective resistance to the gun above referred to at 700 yards range, and would have done so at much shorter ranges. This trial showed the advantage of giving depth or thickness to shot-resisting structures. A method of holding on armor-plates by continuous irons turned over their edges instead of by bolts was also tried, but there were objections to it.

Turning again more particularly to the protection of land-works, the following experience was gained about this time—that is, in 1865. Two complete masonry casemates, with ports in iron shields, were built at Shoeburyness. The masonry was 14 feet thick, consisting, generally, of a face of 6 to 8 feet of stone, with brick-work behind it, and the side walls and vaulting of the casemates were of brick. The shield of one was a compound structure 12 feet long, 8 feet high, and, altogether, 21 inches thick (including 7 inches of wood); that of the other was made out of a solid rolled-iron plate 7 feet high, 6 feet wide, and 13½ inches thick. After the mounting, working, and firing of a 23-ton and a 12-ton gun in the casemates, as well as on the roofs, had proved the work to be suitable in arrangement for such guns, the front of the work was attacked by a battery of 7-inch, 8-inch, 9.22-inch, and 10-inch guns, at ranges of 600 and 1000 yards, firing steel and cast-iron shot, some with hemispherical and some with elliptical heads. The general result of this trial was that after 33 hits the work began to become untenable, after 54 hits its fire would have been virtually silenced, and after 86 hits, of which 22 were on iron, the masonry front was destroyed, but the shields still afforded a fair amount of protection. The aggregate of all the blows delivered came to 200,000 foot-tons, of which 52,000 were on iron. Among many other trials that took place about this time were those which brought out the excellent qualities of chilled cast-iron for battering projectiles, as proposed by Captain (now Sir W.) Palliser, and also the advantages of the pointed (ogival) over the blunt (hemispherical) head. For these experiments iron armor, placed both directly and obliquely to the line of fire, was used; chilled iron, in consequence of these results, almost entirely superseded steel for battering projectiles, for a time at 'east. Next in order came a series of trials of plates of steel, and of steel and iron combined; some were of thin layers of steel and iron welded together, others of sandwiches of steel between rolled iron, others of faces of steel welded to iron, and others of steel and iron in reverse order to this; but none of these competed successfully with a simple soft rolled-iron plate in resisting chilled-iron shot. Some plates made entirely of steel were tried about this time, as they had been also years before, but none of them stood at all well. The difficulty of treating steel in large masses, and especially of welding these masses of steel and iron together, had evidently not been mastered up to this time. In consequence of the growing powers of battering-ordnance, it now became evident that land-works would require walls of considerable thicknesses of armor; but there were two main reasons why very thick armor-plates should not be used in them. In the first place, the manufacture of a very thick plate is not so complete as that of one of moderate thickness, or at least to make it as complete would involve an enormous increase of cost in plant and manufacture; and next, the thicker the plates the deeper the joints must be, and therefore the more points of undue weakness will the armor present. It therefore became important to see whether the required protection could not be gained without the use of very thick plates. Against doing this was the prevailing opinion, based chiefly on theoretical considerations, that a single plate of given thickness would offer something like twice the combined resistance of two plates each of half that thickness, or about three times the resistance of three plates, making up the same total thickness, and so on. This view was entirely disputed by those who had to deal with these questions officially.

In 1871 two targets representing portions of the walls of ships' turrets were tried at Shoeburyness. The one was protected by single 14-inch plates, the other by two thicknesses of armor, 8-inch and 6-inch respectively, with 9 inches of timber between them. In other respects the targets were similar. After receiving the same amount of battering the armor of both was taken off, and the effect upon the inner skin of the two-plate target was unmistakably less than that on the single-plate structure. It may also be mentioned that, more recently still, a structure composed of three thicknesses of 6½ inches of iron proved rather superior to a solid 16½-inch plate in stopping the 818-lb. shot of the service 38-ton gun, striking with a velocity of about 1415 f.-s. To settle the best proportions, quantity, and best nature of material to be interposed between armor-plates, a series of careful experiments was set on foot, and the result was that a uniform spacing of about 5 inches (to be slightly modified under certain circumstances) between the different plates in all structures was decided upon; and also, although an iron concrete, made by working up together cast-iron borings, asphalt, bitumen, and pitch, gave the best result, mainly on account of its great weight, yet brick-work in asphalt, Portland-cement concrete, and hard wood proved so satisfactory that these materials have been adopted, as circumstances required, in all armored walls. It may be well to mention here a very remarkable result that was obtained in the course of the early trials with plate-upon-plate structures. When void spaces were left between the plates of these structures it was found that the heads of the Palliser shells collapsed completely under the work they had to do in penetrating them, and, naturally, the effect produced upon the target was thereby very much reduced. In one case a chilled shot from the 38-ton gun, which was capable of piercing 19½ inches of armor, was found sticking in a finely divided state against a 10-inch plate after having passed through only a 4-inch plate a few feet in front of it; and on another occasion, a 4½-inch plate, set up 18 inches in front of a masonry wall, with a void space between them, so far reduced the effect of a chilled cast-iron projectile from the 38-ton gun, at 50 yards, that it broke up on first striking the granite, and was afterwards dug out in pieces at a depth of only about 3 feet 6 inches from the original front of the masonry. Repeated and well-pronounced instances of this utter destruction of chilled projectiles from this cause have been gained and carefully investigated, with a view to turning the principle to some account in defence-works; but partly on account of certain difficulties of detail, and mainly on account of the action not being produced on steel projectiles, the idea of using void spacing in practice has been nearly given up. The next trials on a large scale were those of 1868, at Shoeburyness. In these, a casemate having a front of 22 feet by 14 feet, representing a portion of the iron fort which was then in course of construction for the position behind Plymouth breakwater fort, stood 37 rounds from the 12-inch gun of 25 tons, charge 76 lbs. pellet-powder, the 10-inch gun of 18 tons, charge 60 lbs. R. L. G., and the 15-inch Rodman gun of 19 tons, charge 100 lbs. American (equivalent to 83¼ lbs. English) powder, at 200 yards' range; and although it was of course considerably damaged by this fire, it was, at the end of it, pronounced to be defensible. This trial led to some important additions being made to the front wall of the fort itself as it went on. The roof also of this casemate was tested by the fire of 13-inch mortars at 1000 yards, but they proved quite powerless against it. Only a few shells, however, struck it out of nearly 300 rounds. Adjoining this casemate was another embodying several kinds of cellular construction in its iron front, with the object of comparing the resistance of moderately thick solid plates with that of thinner front plates supported by cellular compound backing; but in no instance did the latter construction prove itself superior to the other. This result was borne out by the trial of another shield in 1868. The support given to armor by massive piers of masonry and concrete, cased in thick boiler-plate, proved very satisfactory.

It may be well here to notice briefly the matter of holding on armor-plates, on which so much of course depends, and we may begin by saying that of the innumerable contrivances for this object nothing has been found equal to that of a simple screwed wrought-iron bolt fitted with nuts. The steps by which the present pattern of armor-bolt for fortifications has been arrived at may be thus described: At first a bolt with a deep V-shaped screw-thread was used, but in the early stages of the trials a shallow round-cut thread was substituted for this with great advantage. Also a gradual and slight cone was adopted in lieu of the abrupt and spreading cone used at first in the heads of these bolts. Next, Sir W. Palliser's valuable suggestion that part of the shank or stem of an armor-bolt should be reduced to the lesser diameter of the thread led to an immense improvement, and this has been since extended to the whole length of the stem, leaving the thread a plus or raised thread, thus facilitating the extension of the material of the bolt throughout its whole length instead of locally in short lengths. Then Captain English proposed, first, the rounding of the bearing surface of a common hexagon nut, and afterward the use of a spherical nut seated in a cup-shaped hole in the armor or in a special cupped washer; with these improvements and that of the enlargement of the holes through which the bolt has to pass (all of which have for their object the relief of the bolt from cross-strains, and the insertion of a due proportion of elastic material to be squeezed when the bolt is put under tension) all difficulties with bolts have disappeared, and instead of their being sources of weakness they really, in most cases, give assistance to the armor. The special washers are of the following make: First, a circular washer is made by coiling and welding a bar 1¼ inch by ½ inch, and this is cupped to suit the spherical nut of the bolt. To strengthen this part an outer coil of unwelded bar of about the same section is screwed around it; as this outer coil has to expand after the inner coil may have given way, and as in doing so it would naturally unwind itself and open out, this tendency to separation has been met by making the thread by which this outer coil is screwed on to the inner of quicker pitch than that of its own coils, and thus as it unwinds it actually becomes more and more tightly squeezed together.

All other trials of this period may now be passed over until we come to that of the casemate-shield set up at Shoeburyness in 1870, which embodied all the experience gained from the previous twelve years of experiment. The guns used were the 12-inch of 25 tons, the 10-inch of 18 tons, the 9-inch Whitworth gun of 14½ tons, and the 15-inch Rodman of 19 tons, at 200 yards. Some rounds were fired obliquely, but most of them were fired direct at the face of the shield. The shield, which presented a front of 12 feet by 8 feet, received 17 blows, equivalent to 90,000 foot-tons, and, except in one or two matters of detail which were susceptible of easy improvement, it stood the trial remarkably well, and proved that it possessed a great margin of strength for these and even more powerful guns. In 1872 a plate-upon-plate target, representing 17 inches of armor altogether, stopped a Palliser shot fired direct at it from the 35-ton 12-inch gun with 110 lbs. of P. powder; and a similar target with 13 inches of armor stopped a shot from the same gun, striking it at an angle of 60° with its face. In 1861 the cupola of the Trusty was tried off Sheerness. It was in the form of a truncated cone, covered with 4½ inches of armor, and resisted fairly well the guns of those days. The cupola was not damaged in its machinery throughout the trial. Next, in 1866, one of the turrets of the Royal Sovereign, carrying armor in thickness 5½ to 10 inches, was tried at Spithead with the 12½-ton guns of H.M.S. Bellerophon. The turret was a good deal injured, but the turning machinery remained in working order. In 1872 the turret of the Glatton was tried at Portland with the fire of a 12-inch 25-ton gun of H.M.S. Hotspur, at 200 yards' range. The armor was 14 inches thick, and it received two Palliser shots, fired with 85-lb. charges, one of which grazed first on the glacis. There was some damage done inside the turret, but the goat, rabbit, and fowl which had been placed inside were unharmed, and the turret turned freely after the trial. In 1870–1–2 some lengthened trials were made with shot and shell impinging upon ship's decks, which gave some decided results, namely, that a 13-inch mortar shell at 4200 yards' range would go easily through a strong ship's deck covered with 1½-inch plating and 4½-inch wood planking, and that at 2800 yards it would go through it if covered with 1-inch plating; that 9-inch *live shell* from the 12-ton gun striking at an angle of 8° is too much for a similar deck covered with 1½-inch plating at short range, but the same deck will just turn a 9-inch *shot* at the same angle. Also, that a strong deck covered with 3-inch plating and 4 inches of oak was only just proof against 10-inch shells fired with battering charges from the 18-ton gun and striking at an angle of 10°. The rule that roughly held good a few years back, that battering guns could not at the shortest range do more than pierce iron armor-plates equal in thickness to their own caliber, has been quite upset in the last year or two by practice from the new long guns, with bores of 23 and more calibers in length. Thus a 6-inch gun of less than 4 tons' weight, and an 8-inch gun of less than 12 tons, have pierced within an inch of double their caliber in thickness of solid iron plate; and calculations tend to show that the long B. L. guns of 9.2-inch of 18 tons, the 10.4-inch of 26 tons, and the 12-inch of 43 tons' weight achieve fully as much as this.

Speaking generally, the service-guns were always capable of doing somewhat more than is indicated by the old rule above mentioned, and if with the improved powders of the present day their charges can with safety be increased to the extent which we believe has been proposed for them—as, for instance, 90 lbs. P^2 for the 10-inch 18-ton gun, 110 lbs. P^2 for the 11-inch 25-ton gun, and 160 lbs. P^2 for the 12½-inch 38-ton gun—then these guns will be nearly if not quite able to pierce at short range a thickness of solid iron equal to 1½ times their caliber. While upon this subject, we may say that no great advance has been made in late years toward determining a *law* for the resistance of armor, nor do we think that for practical purposes—whatever may be the case from a scientific point of view—much good will come of inquiry in this direction. The conditions and effects are altogether too variable and uncertain for the construction of mathematical formulæ. For instance, in recent practice, under apparently similar conditions of projectiles and plates, there has been an unaccounted-for variation of effect of something like 5 per cent plus or minus. But we can, by building upon results obtained with one gun, say within a little what another gun will do, and so construct tables of penetrations for all velocities, or, in other words, for all ranges. Thus, with the average service conditions of weight and length of battering projectiles, a shell of good quality with a velocity between 1050 to 1150 f.-s. will pierce solid iron equal in thickness to its own caliber; with a velocity between 1500 and 1650 it will pierce iron of a thickness equal to one and a half times its caliber; and with a velocity between 2000 and 2200 it will pierce solid iron equal in thickness to double its caliber. To obtain the latter degree of perforation at the muzzles of the latest guns the powder-charges must, we believe, be equal to at least one half the weight of the shot. At Gâvre, in 1876, a Whitworth 35-ton gun of 12-inch (maximum) caliber, fired with 120 lbs. P. powder, is reported to have sent a flat-headed steel shell of 808 lbs. through two 8-inch plates; but the experience with flat heads would not lead us to expect so much effect upon a well-constructed two-plate target of this thickness. In 1877 a target composed of four 8-inch rolled-iron plates, with layers of 5 inches of teak between them, was set up at Shoeburyness for the trial of the 80-ton gun of the pattern made for H.M.S. Inflexible and for the turret on Dover Pier. Two rounds were fired—one before and one after the gun had been chambered. The Palliser projectiles weighed 1700 lbs. The range was 120 yards. In the one case the shot was fired with 370 lbs. P^2 powder, and struck with a velocity of 1495 f.-s. and total energy of 26,400 foot-tons; in the other, 425 lbs. P^2 powder gave a striking velocity of 1585 f.-s., and an energy of nearly 30,000 foot-tons. In neither case was the target perforated, though as the shot had got their noses an inch or two into the back plate, it was a good deal cracked and bulged behind. Had the plates been 7 inches instead of 8 inches thick, probably the last shot, at any rate, would have got through.

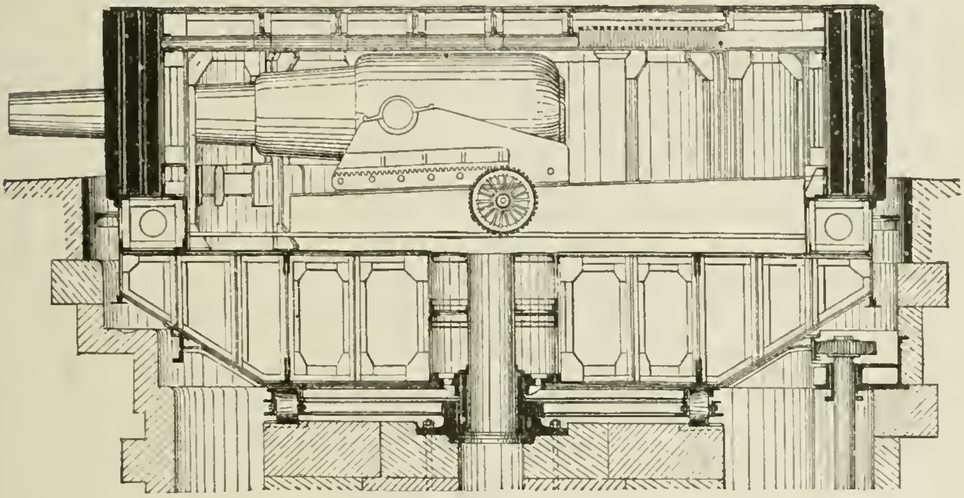
In 1869 a chilled cast-iron casemate front, egg-shaped (thickness of metal about the port 27 inches), underwent a considerable trial, at Tegel, with 72-pdrs. and 96-pdrs., and it stood fairly well. The indents were very slight, but the material, as usual, was extremely brittle, and, to adopt the expressive language of a report quoted in the professional papers of the Corps of Engineers, U.S. Army, it was "pretty well cracked up." The next trial of chilled cast-iron armor was at Magdeburg, in 1874, against a very massive rounded target made by Grüson, and although, both from the form of the structure and the hardness of the material, individual shot were very effectually turned off it, yet repeated blows caused serious injury. Still, the Germans and Belgians have adopted this mode of construction for both shields and turrets—especially for a number of 21^cm^ and 28^cm^ breech-loading muzzle-pivoting guns for the defense of the mouths of rivers. Some of the other European Powers also are using it, to a greater or less extent, for both inland and coast fortresses. The chief advantage of this material is that it can be made of any shape, and therefore rounded and sloping surfaces can be presented to the shot; and it affords also a certain facility for varying at will the thickness of the metal in the different parts of a wall.

As early as in 1859 armor-plates of mild steel and steely iron, and iron and steel combined, and various kinds of steel plates tempered in oil and water, had been tried, and all failed in a greater or less degree when they came to stand the test of shot-blows. So the matter of steel armor rested until the Italians, in 1876, boldly re-opened the question by setting up two armor-plates (made by M. Schneider, of Creusot) of soft forged steel 21¾ inches thick, for trial at Spezia. The plates were about 11 feet long and 4 feet 7 inches wide, and they were backed with massive oak, covering a strong iron skin well supported in rear. For comparison with these, three iron plates of nearly the same dimensions as the steel plates, and similarly supported, were tried at the same time, as well as two plate-upon-plate targets, each consisting of iron plates 11.8 inches and 9.8 inches thick, with 12 inches of wood between them and backing of timber and iron behind them. We must also mention two targets composed of 8-inch wrought-iron plates backed by blocks of chilled cast-iron of "Gregorini" metal, 14 inches thick. In one of these the chilled blocks touched the front armor, in the other 12 inches of wood were interposed. In all the targets there was the same total thickness of 4 feet 4 inches, made up of about 22 inches of armor and 30 inches of timber and skin. The general result of the trial was this: One steel plate was a good deal cracked, and had its end knocked away by two blows from a 10-inch and one from an 11-inch gun, throwing chilled cast-iron projectiles; and the fourth round from the 100-ton gun with a 2000-lb. chilled cast-iron projectile, striking with a velocity of 1500 f.-s. and a muzzle-energy of 31,000 foot-tons, dashed the plate to pieces, though it apparently could not quite perforate it. The other thick steel plate was completely demolished by a single round from the same 100-ton gun. The thick wrought-iron plate made in England was much less injured generally by the lighter guns than was the steel plate, though the indents in it were deeper; but the 100-ton gun sent its shot through all the iron plates, and also broke them in two. The "plate-upon-plate" targets did not do so well as the solid plates, and the targets with the chilled-iron backings entirely succumbed to a single blow on each from the 100-ton gun. The results of the trial were seriously invalidated by the narrowness of the plates used,—a width of 4 feet 7 inches being altogether too little for a plate which is to receive a 17-inch shot, and on this account these costly and elaborate trials at Spezia have afforded much less useful information than they ought to have given. The brittleness of the steel, and its consequent incapacity for resistance to repeated blows, is a striking feature of these trials; the failure of the plate-upon-plate targets, through their being a bad imitation of our construction, is another; the utter collapse of the target with the chilled-iron blocks is a third; and the defective plan of holding armor by screwing bolts into the backs of plates is a fourth. It is to be regretted, also, that these trials did not give us a more exact measure of the armor-piercing power of the 100-ton gun, which was a counterpart of the four which were to be mounted at Gibraltar and Malta. In 1879 the Italians again experimented at Spezia upon thick steel plates. This time the plates were nearly 28 inches thick, and were entirely cased in 1-inch plate boxes, which dispensed with bolting. They were narrow plates, as before (4 feet 7 inches wide and 9 feet long), weight about 20 tons each; but these plates were so utterly destroyed by a single round each from chilled-iron or steel projectiles from the 100-ton gun firing 550 lbs. of Fossano powder, that the trials had to be discontinued without telling much more than was known before. The forged-steel projectile made by Whitworth seems to have penetrated the deepest (21.65 inches) and remained entire, but it was somewhat set up.

Perhaps the shortest way of giving an account of the manufacture of rolled-iron armor will be to say how some one plate in particular has been made, and we will select for this purpose one of the heaviest ever produced. This was one of the 8-inch plates made for the target to test the 80-ton gun at Shoeburyness. Its finished dimensions were: length, 16 feet; width, 10 feet; and its weight 23 tons. For its manufacture 1170 slabs, 30 inches long, 12 inches wide, and 1 inch thick, were made from the puddled ball and bar. These were piled, furnaced, and rolled into 65 plates about 5 feet square and from 1 inch to 1½ inch thick, called small molds. These, again, were piled and rolled into quarter-molds, and the quarter-molds into armor-plate molds, and the pile for the last rolling was made up of three molds about 10 feet square, two of 7-inch and one of 3-inch thickness. As they entered the furnace for this last heating they weighed about 35 tons; as they came out after about twelve hours they weighed 31½ tons. They were rolled down in the last rolling from 17 inches to 8 inches; so that in a certain sense this plate may be said to have been made by rolling a column of iron nearly 100 feet high down to one of only 8 inches high. The fibrous character of a plate depends largely upon the amount of reduction in the last rolling. The rolls are plain cast cylinders; those used in the present case are about 3 feet in diameter, 12 feet long, and each one of the pair weighs nearly 20 tons. They are driven by very powerful steam machinery, and made to reverse their running, so that the plates are sent through one way and then back again, and so on, the rolls being brought nearer together each time until the plate is brought down to the required thickness. The specific gravity of a good iron armor-plate is about 7.625. Armor-plate iron is not made for very high tensile strength, but it is essential that it should draw out well, and reduce in cross-section some 20 or 30 per cent before breaking. As regards chilled cast-iron there is not much to be said further than that Herr Grüson, the principal manufacturer of it, runs his blocks for fortifications direct from cupolas into sand-molds, chilling the faces which are to form the fronts of the blocks against masses of cast-iron. Some of the chills are twice the weight of the casting itself; the chill generally extends two or three inches into the metal. Single blocks have been used as heavy as 50 tons. The cost of these blocks may be taken as rather more than half the cost of wrought-iron armor-plates per ton, but then the cast-iron has to be used in masses more than twice the thickness of the wrought-iron which would give the same protection.

All the most successful compound plates have been made of ordinary armor-plate, iron faced with Bessemer steel. Of course an equally or even better face might be given by using crucible steel, but the cost and difficulty attending the use of this kind of steel would be enormous. In fact, it may be truly said that but for the Bessemer and Martin-Siemens processes it would have been practically out of the question to make compound plates at all. The most simple and effective process of manufacture of these plates is as follows: First, a rolled-iron armor-plate of the usual quality is made, and on it is laid round its edges a wrought-iron frame, the thickness of the armor-plate and the depth of the frame depending upon the thickness required in the finished plate. The plate and frame are then placed in an ordinary plate-heating furnace, and when at a welding heat they are brought out and molten steel made by the Bessemer process is poured out of large ladles on to the surface of the plate up to the brim of the frame. The mass is then allowed to cool, and is afterward re-heated and rolled down into an armor-plate of the desired thickness. The edge of wrought-iron is afterward planed off. Instead of having a simple frame round the edges of the plate it has been proposed to subdivide the surface into squares, as those of a chess-board, in order that by breaking the continuity of the steel the cracks caused by shot-blows may be stopped short, and with the same object it has been proposed to subdivide the steel by fine cuts across its face. The successful union of the steel and iron masses in these plates is very marked. A complete fusion seems to take place, and the natures of the two metals so far intermingle that it is sometimes hard to fix upon an exact line where the steel ends and the iron begins.

The drawing represents the turret for two 80-ton guns at the extremity of the Admiralty Pier at Dover. The work to carry this turret consists of an enlargement of the outer end of the pier. The foundations are laid at a depth of about 7 fathoms below low-water mark, and the guns are at a level of about 33 feet above high water. The structure, therefore, from the bed of the sea to the guns is about 95 feet high. Speaking in general terms, the turret consists first of a live ring and rollers of steel running on a path of steel laid on a massive cylinder of masonry. On this live ring runs a structure of iron framework of the form shown in the diagram, weighing about 240 tons. This framework contains the gun-chamber, which is protected by three thicknesses of 7-inch armor with two intermediate thicknesses of 2-inch plates, making together a weight of about 460 tons. If to these weights be added that of the guns, carriages, and the slides on which they stand, the total running weight will be about 895 tons. This will throw upon each of the 32 rollers of the live ring a pressure due to about 28 tons. The outside diameter of the turret is 37 feet, its internal diameter is 32 feet, the interior height of the gun-chamber is 8 feet 8 inches, the height of the turret-armor is 9 feet. It will be seen that a massive central casting is first held firmly down to the masonry, and that inside this there is a thick cylinder of hammered Bessemer steel surrounding the built-up wrought-iron cylinder which forms the center of the turret framework. We draw attention to this part because, of course, the shock of blows on the turret-walls, or, more strictly speaking, the unabsorbed part of it, ultimately comes to this part, and it has received special consideration on that account. The framework is generally of wrought-iron. The roof of the turret is of strong splinter-proof construction. Over each gun there is a part of it which is removable to admit of its being got in and out, and a part is made of open bars to allow a current of air to clear off any smoke that may enter the turret. The gun-ports admit of 7° of elevation and 2° of depression; the turret is capable of all-round fire. The glacis outside the turret is supported by a ring of armor-plates on edge, 5 inches and 3 inches thick, on a strong circle of 2-inch plating. The muzzles of the guns are brought inside the turret and depressed to an angle of 14° for loading, which is done under the glacis by steam gear. The turret is turned by a pinion, the vertical shaft shown working into a large ring with steel trundles secured to the framework, the power being given by a set of main engines capable of working up to 300 h.-p., and auxiliary engines of 45 or 50 h.-p. For the working and loading of the guns there will be another engine of about 30 h.-p. All the engines and the boilers are in the lower part of the battery, some 30 feet below the guns. The magazines are at nearly the same level as the engines, and the shell-stores at a higher level. There is a system of communication by signal and speaking from the gun-chamber to the engine-room, and throughout the battery.



Turret for two 80-ton Guns.

ARMORER.—The old meaning of this word has nearly passed away with the system to which it belonged. The armor-smiths, or makers of armor, were among the most skilful workers in metal during the feudal times; but their trade afterwards fell away. In the year 1690 the workmen-armorers of London, in a petition to Parliament, complained that their trade was well-nigh ruined. Armorers, in a somewhat different sense of the word, belong to the British army and navy at the present time. There are armorers to every regiment, not to make armor, but to repair arms. There is one to each troop of cavalry, and one to each company of infantry. The armorer is paid one penny per month for taking to pieces and cleaning the lock of each soldier's musket. There is also a regular tariff of prices for every minute detail of repair in the stock, lock, or barrel of muskets, pistols, carbines, and rifles, and in bayonets and ramrods. A school for training armorer-sergeants has recently been established in London to supply one such artificer to each battalion, who shall have a certain degree of control over the ten or twelve company-armorers in the battalion. On shipboard the armorer is a warrant-officer, who has charge of all the muskets, pistols, cutlasses, boarding-pikes, etc., which he is expected to keep clean and in ready order. He is assisted by a subordinate called the "armorer's mate;" and both are skilled in the general routine of smith's work.

ARMORER'S GAUGES.—For verifying the dimensions of the various parts of small-arms are templets of various sizes and shapes, rings, and cylindrical or conical gauges for interior dimensions. Two hundred are embraced in a complete set for the various arms made at the National Armory, of which about 78 are used for the Springfield rifle alone. Of these, the *caliber-gauge* measures the diameter of the bore. The *dimension-gauges* show the length of the barrel and its diameter at various distances, the value in inches and parts being measured by the *caliper-*

gauge. Other gauges measure the proper dimensions of the breech-screw and its thread, and those of the counter-bore of the barrel which receives it; others, again, the form, dimensions, and position of the sights. A separate gauge is required for the lock-plate, and for each separate part of which the lock is composed; as the *mainspring-gauge*, *sear-gauge*, *bridle-gauge*, *tumbler-gauge*, *hammer-gauge*, etc.; also, gauges for the various dimensions of the stock, of the bayonet, and of each of the appendages which accompany the gun. Including the gauges required for inspecting the various carbines and pistols made by different firms in the United States, the number will exceed 1000.

ARMORIAL.—Belonging to armor, or to the arms or escutcheon of a family.

ARMOR PIERCING PROJECTILES.—Projectiles intended for practice at objects composed of wood, masonry, or earth are made of cast-iron; but, since the introduction of iron for the defence of ships and fortifications, a material possessing greater hardness than ordinary cast-iron is required to overcome the resistance opposed by thick wrought-iron plates. Both elongated and spherical projectiles for use against armor should be of the hardest and toughest material possible. The power of a projectile to stand up to its work and deliver its full blow on the target depends on the *shape* as much as on the *quality* of the metal of which it is composed.

The resistance of the plate, neglecting friction, acts as a normal to each point of the surface of contact of a *spherical* projectile; thus, in Fig. 1 it will be seen that the portion of such a projectile included between A and B, which we may term the zone of compression, is subject to a crushing pressure towards the centre, O, but it may be said to be under no tensile strain. While the posterior portion of the projectile is suddenly checked by it in the form of a wedge, when a portion of the work stored up in it (the amount depending on the tensile strength of the material of the projectile) is impressed on the target through the front portion, AOB, while the remainder is carried off unprofitably in the fragments into which the posterior portion breaks. On examining the projectile after impact, a part very nearly corresponding to AOB in form will be found intact (Fig. 1) with the fractured surface scored and polished, while the remainder will be dispersed in small fragments. We know that any casting fractures most easily in the direction of a normal to its surface, the crystals settling themselves so as to form lines on this direction. Theoretically, the portion represented by Fig. 1

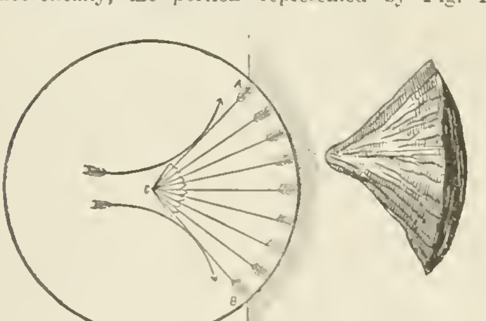


Fig. 1.

ought to be smaller as the penetration is less—except in the case of the entire blow being too small to overcome the tensile strength of the metal in the manner described: when the projectile would only split irregularly, or, in an extreme case, remain entire. In all instances obviously a great amount of the work stored up in the projectile is wasted; not that actually employed in breaking it, for such work is clearly the result of the reaction from the target, but whatever power remains stored up in the fragments after they sever themselves from the mass of the projectile. Since it is impossible to predict what part of a spherical projectile fired from a smooth-bore gun will come in contact with the target on impact, it is necessary that the material should be such as will offer the greatest union of hardness, crushing strength, and tenacity; therefore steel has been resorted to in some instances, and may be regarded as the culminating point of development of the smooth-bore projectiles.

The flat-ended form of *elongated* projectiles possesses a peculiar advantage as regards the projectile, and another as concerns the plate. As to the projectiles, it may be seen (Fig. 2) that in direct impact the whole of the resistance of the target acts in lines parallel to the projectile's axis, which direction is the most favorable to the projectile retaining its mass and delivering its full blow on the target; and, again, if the target is to be punched by actual shearing, the flat head is the form best adapted to effect it. The flat head would probably be best in the case of direct firing against plates composed of hard iron, for it is easy to conceive of a hard material offering very great resistance to the forcing open of a pointed head, which might

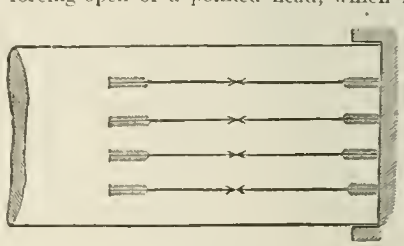

Fig. 2.

be punched by the clean shearing of a flat-headed projectile. The power given by rotation of keeping the same portion of a projectile presented to the front is of peculiar value in punching armor-plates; it enables the head of a projectile to be made of any desired form, while the power of reducing the calibre of a projectile in proportion to its weight, which is perhaps the principal advantage obtained by rifling, is also most important here, the depth of penetration being in inverse proportion to the circumference. In shells, however, this stability of the axis of rotation tells more fully, for it enables every part of the projectile to be made of such proportions as will give the maximum power at the moment of impact. The walls of an elongated shell being chiefly subjected to a longitudinal strain, an interior hollow may be made without entailing the great weakness existing in spherical shells as compared with solid shot. Hence it follows that while smooth-bore shells have seldom or never been fired at armor, rifled shells have proved very successful.

There are two causes which contribute to give shells peculiar power against iron plates. The *first* is that it is not necessary to weaken the head of a shell by making a fuse-hole in it; because no fuse is required, the heat generated on the impact of a projectile against the armor being sufficient to fire the bursting-charge. To such an extent is light as well as heat generated, that on firing at a target after dark a pale flash is seen to follow the impact. The *second* cause that operates to favor the action of shells is the fact that when the shell has penetrated to a depth of even a few inches before rupture occurs, the sides are supported by the armor around them, and the explosion, being confined at the sides, acts to the front with greatly increased force.

In a conical head the normal pressures throughout form a zone of compression acting as a wedge towards the body of the projectile, whose angle is the supplement of that of the cone of the head. This is better than that formed in the spherical head, because the angle is less acute, and because the apex of the wedge, instead of being a fixed point throughout (the center of the sphere), moves along the axis of the projectile as it enters deeper and deeper into the target. In the ogival head (Fig. 3) it will easily be seen how much superior is the action. In this the wedge is at the commencement slightly acute, but then the resistance acts on a small surface and is comparatively small, and the angle increases, till, at the junction of head and body, it becomes 180°, or a straight line, so that we then have the body of the projectile in much the same condition as the flat-headed bolt driving before it an ogival wedge, which opens the armor by

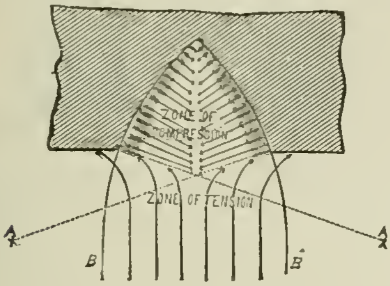

FIG. 3.

wedging rather than by clipping or punching. It is possible, no doubt, to conceive of a material that might be sheared by the flat projectile more easily than opened by the ogival; but it would be to contradict the results of experience to say that plate-iron was such a substance; and as the softer and more plastic natures of plate-iron have been found to hold their bolts the best, and stand the longest, and so have been universally adopted, the ogival has become obviously the correct form of head.

The effect of hardening projectiles is probably much greater than is generally supposed; that is, the amount of work gained is much greater than the increase of strength of the projectile. It is well known that a very small force may under certain circumstances determine the performance or non-performance of a very large amount of work. In like manner a very slight addition to the rigidity of a projectile, by hardening or otherwise, may determine whether a very large amount of work shall be wasted upon the projectile or expended upon the plate. Another means of increasing the work done upon the armor-plate in comparison with that done upon the projectile is by increasing the velocity of the latter. That is, a projectile moving at a low velocity may be smashed up or flattened against the plate, while the same projectile fired at a higher velocity may go through the same plate almost uninjured. On this principle a lead shot may be fired through an iron plate, or a tallow candle through a pine board.

Late trials have shown a superiority of steel projectiles over those made of chilled cast-iron; and although the former are somewhat more expensive than the latter, on the principle that the best is at the same time the cheapest, it would be misplaced economy to leave any means unavailed of to increase the penetrating power of projectiles. The quality of chilled projectiles, from the nature of their manufacture, is necessarily unreliable; whereas this is not the case with hammered cast-steel, or at least not to the same extent by far, even when large masses are produced, and the difficulty of manufacture increases with the calibre. The most essential difference in the behavior of steel and chilled projectiles on striking the target consists in the reaction on the projectile showing itself in the latter by breaking up, while the former are only set up. As the breaking up of the chilled shells may take place before the bursting-charge comes into operation, whereby the rending effect is considerably prejudiced, this material appears far less adapted for shells than steel. The superiority of steel in this respect is still further increased by the fact that the steel shell can have thinner walls, consequently a larger chamber, and can thus hold a larger bursting-charge than the chilled metal.—See *Armor-plates* and *Projectiles*.

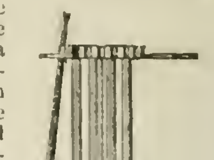
ARMOR-PLATES.—Armor-plates are made of wrought-iron, steel, wrought-iron and steel combined, and cast-iron. Wrought-iron has been found a suitable material for use as armor, owing to its strength, toughness, and malleability. Such plates have been so perfected that they do not break up, but are penetrated by displacement or crowding aside of the material in the path of the shot. Iron plates are either made of a single solid plate or of several iron plates, interlined with some more elastic material. The former are called solid plates, and the latter laminated plates. As the result of many experiments the following conclusions have been arrived at respecting armor-plates of wrought-iron: 1st. The plates should be of soft, tough iron, and, to secure these qualities, should be free from sulphur, phosphorus, and carbon. 2d. Plates made of boiler-iron riveted or screwed together do not give satisfactory results. 3d. Plates made up of several distinct plates bolted together are found to compare favorably with single solid plates of equal thickness. If the separate layers be well held together, each is forced against the one next behind it, and a continuous resistance is offered to the shot during its passage through the mass. If the plates are separated by layers of teak, such a shield stands the racking action of projectiles better than the solid plate, owing to its more elastic nature. 4th. The support given by a rigid backing, such as cast-iron or granite, improves the resisting power of the armor, but leads to its being injured in a greater degree by cracking, and the giving way of fastenings. 5th. The resistance of a plate to perforation is materially increased by a backing of oak or teak, or a compound backing of wood and iron. A backing of concrete has also been found suitable. Such an elastic backing strains the fastenings much less than a rigid one. 6th. A single solid plate has the disadvantage, when compared with the laminated, of deeper joints, causing points of undue weakness. Its manufacture is also more difficult, and will not be so complete as that of laminated plates without great increase of labor and expense. In laminated plates, the surfaces of the plates should not be in contact, but should be separated by some thickness of a softer and more elastic material, such as teak, to prevent their breaking under heavy blows. 7th. Rolled plates are superior to those made by hammering. 8th. The joints of armor are points of weakness, and it is disadvantageous to join plates by tongues and grooves on their edges. They are best held together by wrought-iron bolts, secured by spherical nuts seated in a cup-shaped hole in the armor. The stem of the bolt is of less diameter than the ends, leaving a plus thread. The bolt thus tends to stretch throughout its entire length, rather than pull out of the nut. The enlargement of the holes through which the bolt passes relieves it from cross-strains. Bolts of this kind rather add to the strength of armor. With steel or steel-faced armor, however, where it is essential that the outer surface should be unbroken, the bolts are screwed into the back of the plate and nutted up behind. 9th. An inner iron skin is of great advantage, adding solidity to the backing, and preventing the passage of many splinters.

Steel armor-plates possess some decided advantages over those of wrought-iron, viz., greater absolute tenacity, more perfect homogeneity of structure, and greater resistance to penetration. The disadvantage of steel is that, owing to its crystalline structure, it is liable to crack under repeated blows. Steel armor-plates have been constructed to successfully resist the heaviest gun yet made (1884). In the defensive armament of vessels the main object is to keep out projectiles; and since under ordinary conditions it would be improbable that the plates would be required to receive several blows in the same spot, it has been deemed advisable to substitute for wrought-iron either steel or a combination of steel and wrought-iron as a protection against the heaviest guns. Such a plate would arrest the projectile, although it might be racked to pieces by long-sustained fire. The advantage of wrought-iron over steel is that the effect of a blow is localized, the projectile causing simply a perforation or indentation, the plate as a whole remaining intact. With steel intense molecular action is set up by impact, cracks appear radiating from the point struck, and continue to develop for some time after impact. Thus, though a steel plate may not be perforated, it may be considerably shattered. To combine the greater toughness of wrought-iron with the greater hardness and resistance of steel, compound plates have been introduced. These consist of a wrought-iron foundation-plate with a steel face, the steel being run on the iron plate in a molten state; the whole is then rolled down to about half its original thickness. A modification of this is to have a rolled-steel face-plate attached to the foundation-plate by molten steel, the object being to secure a well-rolled face. The object of welding the steel on the iron is, not to prevent the steel from cracking, but to prevent the fissures from extending through the entire plate, and the iron is intended to hold the steel in its place after being broken, and prevent its falling off. Both chilled-iron and steel projectiles are broken up against these plates, and no experiments yet made have succeeded in destroying the cohesion of the steel face to the iron backing. By the employment of either steel or compound plates, instead of iron, there is a considerable saving of weight. In the more recent experiments (1882) the hammered steel plate of Schneider & Co. (said to contain about 0.45 per cent of carbon) has been found to compare most favorably with compound plates. The surface of this steel plate was chilled in oil to the depth of six inches, and it had been hammered down from a thickness of 7 feet to 18.9 inches. Chilled cast-iron has been extensively employed in land-batteries for the defense of harbors and mouths of rivers. Its advantages are comparative cheapness, great hardness, and the facility with which it can be made into any shape, thus presenting rounded or sloping surfaces to the shot. The main disadvantage of chilled cast-iron is its brittleness, and though, due to the form and hardness of the armor, it can successfully resist a single blow, repeated shocks crack it to pieces. The Grüson system of protecting sea-coast guns is an example of the application of this kind of armor. The turrets are egg-shaped to deflect the shot, the thickness of metal being 27 inches at the embrasures. Thick coverings of earth protect the armor to some extent. These turrets can be adapted to muzzle-pivoted breech-loading guns. See *Armored Defenses*, *Backing*, *Punching*, and *Racking*.

ARMORY.—A building specially provided in Arsenals for the deposit and preservation of small-arms. An Armory should be very dry and well ventilated. In a damp climate a "dry room" would be a desirable adjunct, for, with every care and attention, rust will make its appearance if the outer air is not excluded. The repair of the arms in Armories is usually carried out by civilian armorers. The name is also often applied to a collection of ancient armor and weapons—such as those in the Tower of London, in Sir Samuel Meyrick's Mansion at Goodrich Court on the Wye, and in Warwick Castle. See *Arsenal*.

ARM RACK.—A frame or fitting for the stowage of arms. It is usually vertical, out of harm's way, and in readiness for immediate use. In the conveyance of troops by sea, arm-racks form a part of the proper accommodation. They are also used in the barrack-rooms. Captain F. H. Phipps, of the United States Ordnance Department, has suggested the following description of Arm-rack holding twenty guns:

Top.—Made of two 1-inch white-pine boards, glued together, crossing grain of wood. Diameter of top, 13 inches. Top cut to receive twenty rifles. The guns are held in place and secured by a strap of iron 1 inch wide, leather-covered, hinged, and secured on opposite side by padlock; hinge and padlock-fastening secured by irons, as shown in the drawing.



Bottom.—Made of one 2-inch and one 1-inch white-pine boards, 22 inches in diameter, and one ¾-inch board of white-pine, 12½ inches in diameter, glued together, crossing grain. Twenty triangular-shaped partitions of poplar, 1⅞ inches wide at base by 4⅝ inches long, separate butts of rifles. A band of sheet-iron 1½ inches wide, secured by screws, whose heads are filed to prevent removal, surrounds the upper part of base, the top being flush with the top of partition. Four round pieces of white pine, 1½ inches in diameter and 3 feet 11 inches in length (total), connect top and bottom of frame. A rod of iron, ⅝-inch diameter, with square head at top and threaded for nut at bottom, binds the whole together. In lieu of the four wooden posts and iron rod a single one of gas-pipe might be substituted. The distance between the top and bottom is such that the upper band of rifle just touches the under side of top; and all is so arranged that, without removing the padlock and turning back the straps, no rifle can be removed. The three iron feet which support the whole can be screwed to the floor of the barracks.

Racks for carbines are similarly constructed, differing only in height and in the arrangement of top, which, instead of being cut entirely through to receive the barrel, is cut to the depth of only ⅝ inch to receive the muzzle of the carbine. This rack is almost identical with the one suggested by Major Comly; the principle is the same, but it is stronger, and its cost reduced about one fourth.

ARMS.—1. Instruments of different forms and natures, for attack and defense. The manufacture of arms is of very ancient date, coeval with the world. Necessity drove men to make them, either in defense of themselves against wild animals or against their enemies. The first arms of offense appear to have been made of wood, such as clubs. Arms of stone, bone, and brass succeeded clubs. Subsequently a variety of arms of iron and steel was introduced which comprised the spear, the lance, the hatchet, the battle-ax, the bow, and several others; and though these arms were in many instances rude and unwieldy, the treatment of iron seems to have been well known; in the manufacture of steel great skill was shown, as the blades of Damascus testify, and which were famed throughout the world. In India the tempering of steel was well known from a very early date. The arms of the present day in the British service vary according to the branch of the army in which they are used. In the infantry, the converted Enfield (Snider) rifle was for some time the general arm of the service, but has been superseded by the Martini-Henry rifle. In the cavalry, the sword, lance, carbine, and pistol form the arms of that branch, the dragoon guards, dragoons, and hussars being equipped with the carbine and sword, the lancers with the lance and pistol. In the artillery, in addition to the guns of a battery, the following arms are provided: for a battery of horse-artillery, a sword to each man of all ranks, and twelve carbines for sentry duties; for a battery of field-artillery, a sword to each non-commissioned officer, artificer, or trumpeter, and to all gunners a sword-bayonet, with the addition of twelve carbines for sentry duties. Heavy field-

ARMS OF VARIOUS NATIONS.

ARMS OF VARIOUS NATIONS.

batteries are similarly equipped. Garrison-batteries, all ranks, except trumpeters, are furnished with a complete stand of arms, the trumpeters (and artificers, if any) having a sword-bayonet.

Arms may be divided into two great classes—those that act by means of gunpowder, and those that do not. Of arms that act otherwise than by explosion, the greater part have been in use from the earliest times; they include the bow and arrow, sling, pike, spear, lance, dart, javelin, dagger, ax, mace, spiked or knotted club, scythe for chariots, dirk, bayonet, sword, cutlass, etc., together with such artillery as the ballista, catapulta, and battering-ram. Weapons depending on the use of gunpowder are of two kinds —those that can be held in the hand, and those that are too heavy to be portable. In the first class we find the names of the hand-cannon, hand-gun, arquebus, haquebuts, demi-haque, matchlock, wheel-lock, firelock, currier, snap-haunce, caliver, esclopette, petronel, dragon, hand-mortar, dag, tricker-lock, carbine, fusil, fowling-piece, blunderbuss, pistol, musket or musquet, musketoon, rifle, etc. In the second class, more usually included under the name of artillery, we find the springel, war-wolf, bombard, cart-of-war, culverin, demi-culverin, serpentine, falcon, saker, cannon, howitzer, petard, cannonade, mortar, rifled cannon, war-rockets, etc. The more important of these are briefly noticed under the proper headings. It is needless, perhaps, to add that nine tenths of these are utterly obsolete.

2. Arms, Armorial Bearings, or Ensigns, are the names given to such devices as when painted on a shield form a coat. These terms in popular speech include all the accompaniments of a shield, viz., the crest, helmet, and, where such exist, the supporters, etc. See *Heraldry*.

ARMS OF PRECISION.—Rifled arms of all natures. These arms have a longer range and a more accurate and rapid fire than that derived from the old smooth-bore weapons. The introduction of rifled small-arms of the present form, viz., breech-loaders, only dates back as far as 1864, when in the unequal struggle between Prussia and the Danes the former first used the needle-gun. This called the attention of the European Powers to the value of breech-loading rifles. The further value of such arms was again recognized

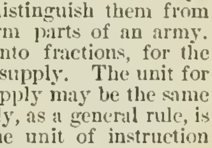
in the war of 1866 between Prussia and Austria, when the latter power met the former with only muzzle-loaders; the result is well known to history—the superiority and rapidity of the Prussian fire was marked. From this period the value of breech-loaders may be said to have been recognized. France produced her Chassepot, and England the converted Enfield, known as the Snider, ultimately the Martini-Henry; and now all the Continental Armies are armed with breech-loaders. Colonel Hamley, in his "Operations of War," describes the change rifles and rifled guns have brought about in the tactics of armies. No longer is the old formation of battalion-columns resorted to—deep columns offering too good a mark for the enemy. The Prussians, therefore, during the war of 1870, finding such formations no longer safe, diminished the size of their columns in order that the fire of the enemy might prove less destructive both in front and depth, besides giving a better opportunity of taking advantage of the natural cover which average ground affords to small bodies. The tables show the result of practice made with rifled field-guns and rifled small-arms; thus giving the reader an idea of the precision and disastrous effects of rifled arms.

ARMS OF SERVICE.—An arm of service may be defined to be "a union of combatants having the same mode of action." There are four of these arms in modern armies, viz., Infantry, Cavalry, Artillery, and Engineers. These four arms form the principal part of a mobilized army, and as they, or their representatives, are always formed into a line of battle to resist the attack of an enemy, or to make an attack, they are generally known as the "Line of the Army" or "Troops of the Line," to distinguish them from other bodies of men who form parts of an army. These *arms* are subdivided into fractions, for the purpose of instruction and of supply. The unit for instruction and the unit for supply may be the same or different. The unit of supply, as a general rule, is constant, and is also usually the unit of instruction in discipline. The unit of instruction in tactics will depend upon circumstances, and upon the kind of movements which the commander desires to make. The common unit for the four arms, for supplying the men's wants and for instruction in discipline, is the "*Company*." This unit receives, at other times, other names, depending upon circumstances. For instance, a *battery* of artillery is the same as company; the term *squadron* of cavalry frequently means a company, etc.

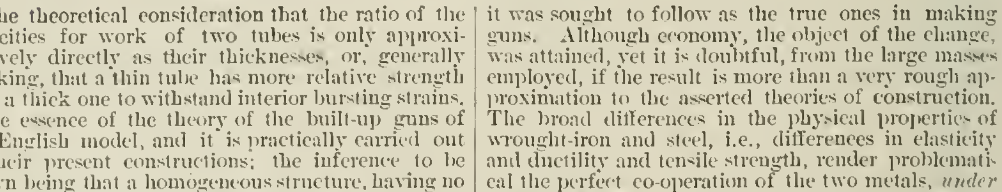
ARMS OF THE UNITED STATES.—Paleways of thirteen pieces, argent and gules; a chief, azure; the escutcheon on the breast of the American eagle displayed, proper, holding in his dexter talon an olive-branch, and in his sinister a bundle of thirteen arrows, all proper; and in his beak a scroll, inscribed with this motto: "E PLURIBUS UNUM."



For the *crest:* over the head of the eagle, which appears above the escutcheon, a glory breaking through a cloud, proper, and surrounding thirteen stars, forming a constellation, argent, and on an azure field.

ARMS PORT.—A position in the Manual of Arms, executed as follows: Being at a carry, the instructor commands: (1) *Arms*, (2) PORT. Throw the piece diagonally across the body, the lock to the front; grasp it smartly at the same instant with both hands, the right at the small of the stock, the left at the lower band, the barrel sloping upward and crossing opposite the point of the left shoulder, the butt proportionately lowered. The palm of the right hand is above, and that of the left under, the piece, the nails of both hands next the body, to which the elbows are closed. The position of *arms port* may be taken in advancing to an attack. It is likewise used by sentinels in receiving or holding communications. In challenging, and receiving the countersign, sentinels take the position of *charge bayonets.* (1) *Carry,* (2) ARMS. Resume the carry with the right hand. (Two). Drop the left hand by the side. See *Manual of Arms,* Fig 10.

ARMSTRONG GUNS.—The built-up gun construction of Great Britain, the germ of which is to be found in the coiled welded system of Sir William Armstrong, introduced to the artillery world in 1852 in the form of a breech-loading cannon, but passing from that date through numerous and important changes, especially the thickening of the coils and the introduction of tempered steel lining tubes, is the one which is still adhered to, in its general principles, by the ordnance constructors, both public and private, of the English nation The failure of the Armstrong breech-loading guns, and the subsequent introduction of muzzle-loading cannon in lieu thereof, in 1869, did not change, however, one of the essential features of the present construction—the employment of coiled welded wrought-iron sections—but led to the modified form of their production known as the Fraser system, and the introduction of comparatively thin oil-tempered steel tubes for the interior lining. The most prominent guns produced under this new system, which first attracted universal attention on account of their great comparative power, were the 25-, 35-, and 38-ton guns; but these, as is well known, were quickly superseded by the 16-inch 80-ton gun, and it, in its turn, by the largest of, as yet, constructed ordnance—the 100-ton guns of the Armstrong model, shown in section in the drawing.



Armstrong Gun.

The theoretical consideration that the ratio of the capacities for work of two tubes is only approximatively directly as their thicknesses, or, generally speaking, that a thin tube has more relative strength than a thick one to withstand interior bursting strains, is the essence of the theory of the built-up guns of the English model, and it is practically carried out in their present constructions; the inference to be drawn being that a homogeneous structure, having no subdivisions in its walls, does not bring into play the full strength of the entire thickness while under stress; and that guns constructed homogeneously, however thick, cannot long sustain pressures exceeding the tensile strength of the metal employed. Sanctioning the soundness of the theory that only by built-up constructions the most powerful and yet reliable guns can be produced, the next point for consideration is the arrangement of the different metals entering into the fabrication, so that the stronger metal (steel) shall form the walls surrounding the bore, and that the superimposed layers of wrought-iron shall be so placed on that each part, from the bore to the exterior, shall be, as far as possible, under strain in accordance with its capacity for work, considered in reference to tangential strains. The English authorities state: "This object we may obtain by employing a single metal for the several portions, and so disposing the various layers over each other that the inner layers or tubes are compressed by those outside them, while the exterior tubes are at the same time put into a state of tension, the inner layers being thus strengthened at the expense of the outer portions of the metal. In this case we obtain the whole strength of all the layers except a part of that of the outer and unsupported ring It must not, however, be for one moment supposed that this theoretical perfection is ever reached; the nearest approach to it is far from perfect, and theoretical advantages have to give way largely to practical considerations of manufacture. Again, we may arrive at a similar result by employing metals varying in elasticity or in tenacity for the several parts, those possessing the largest amount of strength constituting, of course, the inner portions, so that where the greatest stress is felt it will be borne by the stronger material. These two methods are sometimes called respectively those of *initial tension* and of *varying elasticities.* They may be, and frequently are, both employed in the manufacture of a gun, as in the case of the so-called Woolwich guns."

The longitudinal strain is provided for by the thick solid-bottomed steel tube, and the breech-plug screwed into the wrought-iron coiled tube, superimposing the inner tube, brings into play (in the latest model) the strength resulting from locking the tube and other parts together. The construction, briefly, we know is a steel tube, over which is shrunk coiled wrought-iron tubes; the majority of the larger calibers, except the 100-ton gun, having only two layers of wrought-iron tubes; the latter more perfectly brings into use the principles of initial tension, by having the wrought-iron casing subdivided into three instead of two parts. On theoretical considerations, the large number of coils employed in the original Armstrong construction enabled the designers more perfectly to carry out the idea of initial tensions by shrinkage; yet its expensiveness led to its abandonment, and the substitution of larger and, in consequence, fewer coils; thus more imperfectly applying the principles which it was sought to follow as the true ones in making guns. Although economy, the object of the change, was attained, yet it is doubtful, from the large masses employed, if the result is more than a very rough approximation to the asserted theories of construction. The broad differences in the physical properties of wrought-iron and steel, i.e., differences in elasticity and ductility and tensile strength, render problematical the perfect co-operation of the two metals, *under repeated strains* such as obtain in the use of guns; and it would seem that the more elastic and less extensible steel, in imparting its stress to the adjacent iron *repeatedly,* would enlarge the latter by degrees, so that eventually it would form but an imperfect support to the former, which would in that case more or less bear, in the system, the burden of the work in resisting tangential strains; and that its rupture under severer treatment would be finally the result. The manner in which this system in manufacture is practically carried out needs only, in view of the full description printed for public use, be but generally stated.

The tubes are generally of Firth's production, and are furnished under contract to the Woolwich Arsenal. They are solid ingots which are first roughly bored and turned, and then tempered in rape-oil. The jackets or coils, shrunk over the steel tube, in the heaviest natures, range in number according to the length of the gun. Generally two layers of coils cover the breech part, all assembled in accordance with the principle of initial tension. The details of construction are fully given in English text-books, and need not be alluded to here. The 100-ton gun—the latest English muzzle-loading construction—generally speaking, differs from inferior calibers by the large number of shoulders provided on the steel tube, the latter being made in two parts, united together by a wrought-iron exterior band, and in the greater number of subdivisions of the jackets, or rather that the bands are relatively narrower than on other fabrications; besides, three layers obtain at breech, rendering it a more thoroughly built-up gun construction. Four of these guns—made by Sir William Armstrong & Co., Newcastle-on-Tyne—now form part of the armament of Great Britain and her Colonies, and now await their emplacements to be prepared for them at Malta and Gibraltar. We are informed that "guns have already been designed and could be readily made at Woolwich which would surpass the latter [100-ton gun] in power to as great an extent as they themselves surpass the 38-ton service-gun."

The English Government establishment, however, has not produced any muzzle-loading constructions higher than the 80-ton gun, a gun, from the large facilities and perfected machinery of Woolwich, giving us the best exhibit of the Armstrong-Fraser system. That no recent attempts, however, to introduce higher natures of muzzle-loading guns have been made is fully justified by the important developments of Krupp's experiments at Meppen in August, 1879, and by the disasters occurring on board the English ironclad the "Thunderer" in the same year; the first calling attention to the presumed superiority of breech-loading guns—since accorded—in affording less exposure to men; reduced size of embrasures, securing greater rapidity of fire; increased length of bore, and hence greater power; and also affording greater facilities for bore examinations, and permitting an ease in loading not afforded in long-bored muzzle-loading guns; and the latter exhibiting the dangers arising from the possibilities of double charging, and the cumbersomeness and complications of loading devices necessary for the use of muzzle-loading guns, more especially in the naval service, where economy of space is a matter of vital importance. Although the developments at Meppen and the Thunderer misfortune only occurred a few years ago, yet such was the moral effect that immediate steps were instituted to develop breech-loading guns of 12-inch caliber and lower natures.

The principal dimensions of the Woolwich and Elswick guns are as follows:

	Woolwich.	Elswick.
Total length of gun without carrier..in.	333	331
Caliber .... "	12	12
Bore:		
In calibers .... "	26	26
In inches. .... "	312	312 2
Total capacity ....cubic "	39,057	38,734
Chamber:		
Diameter .... "	15 5	14.3
Length .... "	58 35	87.43
Capacity ....cubic "	10,120	13,178
Diameter in rear opening........ "	....	12.4
Rifling:		
Twist in calibers		
Length ....in.	....	220 36
Number of grooves............. "	48	50

These constructions (of the same caliber, 12-inch) differ very little from each other in their main features, such as mode of construction, principal dimensions, breech fermeture, and length of bore, the only important variations being in the lengths and diameters of chambers, and their capacities; the Elswick gun having a less diameter and a greater length for this part of the bore, and also a greater capacity than the Woolwich pattern; this latter feature increasing the air-space in the chamber of the former over the latter when equal charges are used. It also, for the same diameter of the exterior, gives a stronger gun (both using the same metals) in its walls. A tabulated statement of these points of difference may be here inserted:

Powder-chamber.		*Powder-chamber.*	
Elswick:		R. G. F.:	
Length.........in.	86.25	Length .... in.	58.35
Diameter....... "	14.3	Diameter .. ... "	15.5
Capacity..cubic "	13,178	Capacity..cubic "	10,120

The Woolwich authorities have established 17.1 tons per square inch as the service-limit for pressures, yet Armstrong for his constructions reaches 25 tons per square inch, and in his 10.15-inch wire gun a pressure of 34 tons per square inch has obtained. Cast-iron alone, or cast-iron in combination with wrought, or with wrought-iron and steel, or with steel alone, in guns for, say, one caliber and a half thickness of walls, cannot endure the chambering, and in consequence the increased charges, which constructions made of steel alone, or steel in combination with wrought-iron, can sustain; and hence any plan using the inferior metal looking to a rivalry with the superior modern constructions which ignore the use of cast-iron would be a risk too hazardous to assume, and when the pressures reach, in guns using cast-iron, a limit of, say, not exceeding 35,000 to 37,000 pounds for a gun one and one half calibers thick, the service-limit should be regarded as reached, and the charges and chambering should be so regulated as to keep within these limits, which should be established as the limits of safety.

In steel guns a little less than one caliber is regarded as sufficient thickness of walls; and a caliber and one quarter, about, is used over the chambers of the 43-ton guns composed of steel and wrought-iron. In steel-tubed guns, surrounded by a wire and a part steel and part wrought-iron jacket, the thickness of walls given over the chamber is but eighty-five one-hundredths of a caliber. These figures illustrate the vast difference in the eyes of European gun constructors between the use of pure steel and the combination of steel and wrought-iron, and more especially in any construction in which cast-iron plays a prominent part. It would seem, therefore, independent of the recognized fact of the inferiority of cast-iron in strength, that the important element of weight would become largely a factor for consideration in judging of constructions using this metal, either alone or in combination with others. In fact, as much power can be secured from a 43-ton (12-inch) gun (steel and iron) as from a 12-inch 55- to 60-ton gun (built-up) of cast-iron and steel.

In a 44-ton (13-inch) wire gun we have the remarkable exhibit of a yield of 27,460 foot-tons muzzle-energy, or, say, 637 foot-tons per ton of metal. The cast-iron and steel constructions (60 tons) alluded to above only give 359 foot-tons per ton of metal. The 10.15-inch wire gun recently constructed has been tested, and the distinction between it and the last-mentioned gun is more pronounced in favor of wire than the 13-inch; the resulting muzzle-energy giving 760 foot-tons per ton of metal. The pressures are relatively higher in attaining these results, yet the strength of the combination is believed to warrant a large increase over the ordinary standard pressure adopted for the guns of the English service. Admitting that about 27,600 foot-tons muzzle-energy can be attained with a 13-inch of a weight of, say, 44 tons (wire), we find that it takes 50 per centum more weight (60 tons) in a gun (12-inch) using cast-iron to attain a much less muzzle-energy corresponding to the difference in calibers. The force of this testimony regarding weight is evidently, as far as it goes, against the use of cast-iron; and when we consider the question of its employment, pure and simple, this objection of increased weight necessary in the structure becomes a subject of the first importance, and one alone which at the threshold of the consideration of the problem of gun construction should lead us to doubt if it should be employed at all if we desire to attain a high standard in power and endurance in our future heavy ordnance armaments.

Independent of strength and increased weight, cast-iron guns of heavy natures require a cumbersome and expensive plant, consisting of deep pits, large furnaces, powerful cranes, and heavy and powerful lathes, etc., whereas in the built-up steel, and steel and wrought-iron systems, also wire guns, the numerous parts which go to make up the whole can, from their comparative lightness, be handled in the different operations of construction with far greater ease and less expense than obtain in the production of homogeneous masses consisting of but one piece, as found in systems where cast-iron enters either solely or largely into the fabrications. On the score of economy, it may be doubtful if any material advantage results in the use of cast-iron. English models cost about 14 cents per pound. To gain equal powers we would require, according to the ideas of constructors in cast-iron, at least a 60-ton gun to perform the same work as a 43-ton gun of steel and wrought-iron. If we estimate cast-iron at 12 cents per pound, we have a cost of $16,128 for a pure cast-iron gun of 60 tons; and admitting 14 cents per pound for wrought-iron and steel, we have a cost for a 43-ton gun of $13,484.80. If a net profit of 25 per centum for manufacturers is added to this latter figure, which is government cost, we have even then a less expensive construction than pure cast-iron in that country. See *Built-up Guns* and *Ordnance*.

ARMSTRONG PERCUSSION-FUSE.—This fuse is used with breech-loading rifled guns, and is placed below a time-fuse or plug which closes the top of the shell. It consists of three parts—body, pellet, and guard. The *body* is made of gun-metal, and is cast with a bottom through which a fire-hole is drilled, and primed with a perforated pellet of mealed powder, protected by a brass washer. The top, which is fitted in, has a steel point projecting down from its center, and four holes through it closed by a thin brass washer; these holes were intended to allow of the flame from a time-fuse passing into the pellet and so igniting the charge before impact. The body has a rim round it at the top to prevent its being placed in the shell head downwards. The *pellet* (equal parts of lead and tin) has four projections or feathers outside, two rather higher than the others. It is driven with composition like a tube, but has a percussion-cap at the top, protected by a thin brass disk, which can be pierced if driven on to the steel point above by a violent shock; the cap has three holes at the bottom for the passage of the flame from it to the composition below. The *guard* is supported in the upper part of the body on the feathers of the pellet, preventing any forward movement of the latter. On impact, passing the guard, the pellet continues its forward motion; the cap, striking on the steel point, is fired; the flame ignites the composition in the pellet, blows out the washer of the fire-hole in the bottom of the fuse, passes into the shell and explodes it. See *Fuse*.

ARMSTRONG PROJECTILE. — But one kind of projectile is used in the Armstrong breech-loading guns for the field-service, and this is so constructed as to act as a shot, shell, or case-shot, at pleasure. It consists, as shown in Fig. 1, of a very thin cast-iron shell, snugly inclosing forty-two segment-shaped pieces of cast-iron (B B), built up so as to form a cylindrical cavity in the center (D), which contains the bursting-charge and the concussion-fuse. The exterior of the shell is thinly coated with lead (C C), which is applied by placing the shell in a mold and pouring it in in a melted state. The lead is also allowed to percolate among the segments, so as to fill up the interstices, the central cavity being kept open by the insertion of a steel core. In this state the projectile is so compact that it may be fired without injury; while its resistance to a bursting-charge is so small that less than one ounce of powder is required to burst it. When the projectile is to be fired as a shot, it requires no preparation; but the expediency of using it otherwise than as a shell is doubted.

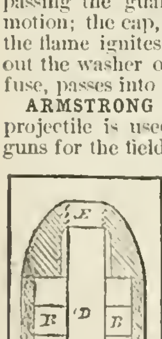


Fig. 1.

To make it available as a shell, the bursting-tube, the concussion- and time-fuses, are all to be inserted; the bursting-tube entering first, and the time-fuse being screwed in at the apex. If the time-fuse be correctly adjusted, the shell will burst when it reaches within a few yards of the object; or, failing in this, it will burst by the concussion-fuse when it strikes the object or grazes the ground near it. If it be required to act as a canister-shot upon an enemy close to the gun, the regulation of the time-fuse must be turned to the zero of the scale, and then the shell will burst on leaving the gun. The explosion of one of these shells in a closed chamber, where the pieces could be collected, resulted in the following number of fragments: 106 pieces of cast-iron, 90 pieces of lead, and 12 pieces of fuse, etc.—making in all 217 pieces.

The Armstrong projectiles for the muzzle-loading guns have rows of brass or copper studs projecting from their sides to fit into the grooves of the gun, which are constructed on the *shunt* principle. Fig. 2 represents a 10-inch Armstrong shell for penetrating armor-plates; It is made of wrought-iron or low steel, with very thick sides. There is no fuse, the explosion resulting from the heat generated by the impact, and the crushing in of the thin cap which closes the mouth of the powder-chamber. The sides and bottom of the shell being thick enough to resist crushing by the impact, and also to resist the explosive force of the bursting-charge, its effect will, after penetration, be expended on the backing of the armor, or the decks which the armor is intended to screen. Such projectiles are called "blind shells." See *Projectiles*.

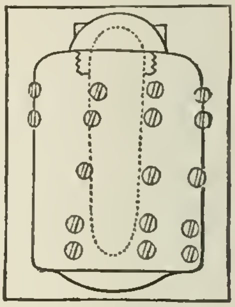

Fig. 2.

ARMY.—An army may be defined as an armed force under regular military organization, employed for purposes of national offense or defense. It may comprise the whole military men employed by the state, or only a portion under a particular commander. When an armed force is under no constituted authority, and imperfect in its organization and discipline, it cannot be said to be worthy of the name of an army, and may be little better than a horde of banditti. Of this nature are the *filibustering* expeditions in which certain portions of the citizens of the United States frequently engage. Through long ages of experience, the principles of military organization, and the laws to which armies are specially amenable, have gradually reached a high degree of perfection. The primitive wars among barbarous people are always stealthy, depending on the forest and the wilderness for their tactics, and considered successful if an enemy can be attacked unawares, despoiled, and carried into slavery. After a time, war advances to the position of an art, and is conducted by men who have received a certain training. An army becomes an instrument not only for vanquishing enemies, but for seizing countries. Even then the highest position of an army is not reached; for the defense of a country requires more military skill, perhaps, and a better organization of troops, than an attack.

Ancient Armies.

Egyptians. — The most extraordinary conqueror among the Egyptians, Sesostris, or Rhamses, lived sixteen centuries before the Christian Era; and although the evidence for his deeds of valor is very questionable, there is reason to believe that the organization of his army can be pretty accurately traced. His father, Amenophis, laid the foundation for the military glory of Sesostris. When the latter was born, Amenophis caused all the male children who were born on the same day as his son to be set apart as a special body, to be reared for a military life; they were taught everything that could strengthen their bodies, increase their courage, and develop their skill as combatants and leaders; and were to consider themselves bound as the chosen dependents or companions of the young Prince. In due time Sesostris became king of Egypt; and then he formed a sort of militia, distributed as military colonists, each soldier having a portion of land to maintain himself and his family. When this militia had been drilled to military efficiency, Sesostris headed them as an army for military conquest in Asia, and placed the chosen band above mentioned as officers over the different sections of the army. *Persians.*—In the great days of the Persian Empire, the flower of the army consisted of cavalry who were distinguished for their bravery and impetuosity of attack. The infantry were little better than an armed mob. The war-chariots, too, though calculated to strike terror when dashing into hostile ranks, were available only on level ground. As to the numbers of men composing the great Persian army, the statements are too wild to be trustworthy. Allowing for all exaggeration, however, it is certain that the Persian armies were very large. When Darius was opposed to Alexander the Great, his army was set down at various numbers—from 750,000 to 1,000,000 men. The king was in the center, surrounded by his courtiers and body-guard; the Persians and Susians were on the left; the Syrians and Assyrians on the right. The foot-soldiers, forming the bulk of the army, and armed with pikes, axes, and maces, were formed in deep squares or masses; the horsemen were in the intervals between the squares, and on the right and left flanks; and the chariots and elephants in front. *Lacedæmonians.*—The Greeks introduced many important changes in armies both in the organization and in the maneuvers. Every man, in the earlier ages of the country at least, was more or less a soldier, inured to a hard life, taught to bear arms, and expected to fight when called upon. The leading men in each State paid attention to organization and tactics in a way never before seen. It was not a standing army, but a sort of national militia, that gained Marathon, Platæa, and Mycale. So far as concerned the arrangement of armies, the Lacedæmonians invented the *phalanx*, a particular mode of grouping foot-soldiers. This phalanx consisted of eight ranks, one behind another; the front and rear ranks being composed of picked men, and the intermediate ranks of less tried soldiers. The number of men in each rank depended on the available resources of the commander. These men were mostly armed with spears, short swords, and shields. *Athenians.*—The Athenians made a greater number of distinctions than the Lacedæmonians in the different kinds of troops forming their army. They had heavy infantry, constituting the men for the phalanx, and armed with spears, daggers, corselets, and shields; light infantry, employed in skirmishes and in covering the phalanx, and armed with light javelins and shields; a sort of irregular infantry, who, with javelins, bows and arrows, and slings, harassed the enemy in march, and performed other services analogous in some degree to those of sharpshooters in a modern army. It is recorded that Miltiades, the Athenian hero at Marathon, invented the "double-quick march," to increase the momentum of a phalanx when rushing on the enemy. *Macedonians.*—Philip of Macedon, the father of Alexander the Great, having the sagacity to see that he could not vanquish his neighbors so long as he adopted the same formation and tactics as themselves, set about inventing something new. He resolved to have a standing army instead of a militia; to have at command a set of men whose trade was fighting, instead of citizens who were traders and soldiers by turn. As a further change, he made the phalanx deeper and more massive than it had been among the Lacedæmonians. He brought into use the Macedonian pike, a formidable weapon twenty-four feet in length. With a phalanx sixteen ranks in depth, four rows of men could present the points of their long pikes protruding in front of the front-rank, forming a bristling array of steel terrible to encounter. Besides these heavy infantry, there were light troops marshaled into smaller bodies for more active maneuvers. Philip organized three kinds of cavalry—heavy, armed with pikes, and defended by cuirasses of iron-mail; light, armed with lances; and irregular. *Thebans.*—This nation introduced the army formation of *columns* much deeper than broad, or having more men in file than in rank. A new kind of tactics was introduced in accordance with this formation; the movement being intended to pierce the enemy's line at some one point, and throw them into confusion. *Romans.*—These able warriors initiated changes in army matters which had a wide-spread influence on the nations of the civilized world. About the period 200 B.C., every Roman, from the age of seventeen to forty-six, was liable to be called upon to serve as a soldier; the younger men were preferred; but all were available up to the middle time of life. They went through a very severe drilling and discipline, to fit them alike for marching, fighting, camping, working, carrying, and other active duties. Every year the Senate decreed the formation of *legions*, or army corps, deputing this duty to the Consul or Prætor. Magistrates sent up the names of eligible men, and Tribunes selected a certain number from this list. The Roman legion, in its best days, had many excellent military qualities—great facility of movement; a power of preserving order of battle unimpaired; a quick rallying-power when forced to give way; a readiness to adapt itself to varying circumstances on the field of battle; a formidable impetuosity in attack; and a power of fighting the enemy even while retreating. The heavy infantry were armed with javelins, heavy darts, pikes, and swords; the lighter troops with bows and arrows, slings, and light javelins; while the defensive armor comprised shields, cuirasses, helmets, and greaves. Those ancient nations which had no distinctive features in their armies need not be noticed here.

Mediæval Armies.

The downfall of the Roman Empire marked the dividing-point between ancient and mediæval times in military matters, as well as in other things that concern the existence of nations. The barbarians and semi-barbarians who attacked on all sides the once mighty but now degenerate Empire gradually gained possession of the vast regions which had composed it. The mode in which these conquests were made gave rise to the *feudal system*. What all had aided to acquire by conquest, all demanded to share in proportions more or less equal. Hence arose a division of the conquered territory; lands were held from the Chief by feudal tenure, almost in independent sovereignty. When European kingdoms were gradually formed out of the wrecks of the Empire, the military arrangements put on a peculiar form. The king could not maintain a standing army, for his Barons or feudal chieftains were jealous of allowing him too much power. He could only strengthen himself by obtaining their aid on certain terms, or by allowing them to weaken themselves in intestine broils, to which they had always much proneness. Each Baron had a small army composed of his own militia or retainers, available for battle at short notice. The contests of these small armies, sometimes combined and sometimes isolated, make up the greater part of the wars of the Middle Ages. Of military tactics or strategy, there was very little; the campaigns were desultory and indecisive; and the battles were gained more by individual valor than by any well-concerted plan. One great exception to this military feudality was furnished by the Crusades. So far as concerns armies, however, in their organization and discipline, these expeditions effected but little. The military forces which went to the Holy Land were little better than armed mobs, upheld by fanaticism, but not at all by science or discipline. Numbers and individual bravery were left to do the work, combination and forethought being disregarded. A much greater motive power for change, during the Middle Ages, was the invention of gunpowder. When men could fight at a greater distance than before, and on a system which brought mechanism to the aid of valor, everything connected with the military art underwent a revolution. Historically, however, this great change was not very apparent until after the period usually denominated the Middle Ages. The art of making good cannon and hand-guns grew up gradually, like other arts; and armies long continued to depend principally on the older weapons—spears, darts, arrows, axes, maces, swords, and daggers. During the greater part of the fourteenth and fifteenth centuries, the chief armies were those maintained by the Spaniards and the Moors on one European battleground, by the English and the French on another, and by the several Italian republics on a third. In those armies the cavalry were regarded as the chief arm. The knights and their horses alike were frequently covered with plate- or chain-armor; and the offensive weapons were lances, swords, daggers, and battle-axes. A kind of light cavalry was sometimes formed of archers on smaller horses. As to army formation, there was still little that could deserve the name; there was no particular order of battle; each Knight sought how he could best distinguish himself by personal valor; and to each was usually attached an Esquire, abetting him as a second during the contest. Sometimes it even happened that the fate of a battle was allowed to depend on a combat between two Knights. No attempt was made until towards the close of the fifteenth century to embody a system of tactics and maneuvers for cavalry; and even that attempt was of the most primitive kind. Nor was it far otherwise with the foot-soldiers; they were gradually becoming acquainted with the use of firearms; but, midway as it were between two systems, they observed neither completely; and the army in which they served presented very little definite organization.

Modern Armies.

The formation of Standing Armies may be said to have introduced the modern military system. When the remarkable exploit of Jeanne d'Arc (Joan of Arc) had enabled Charles VII. to check the victorious progress of the English in France, he set about remodeling his army. By gradual changes, and amid great difficulty, he converted his ill-governed forces into a disciplined standing army. During the reign of his son, Charles VIII. (1483–98), the consequences of this change made their appearance. Charles conducted a well-appointed army into Italy (1494), in support of some pretensions which he had to the throne of Naples. The change made by Charles VII. was not simply that of substituting a compact standing army for an ill-organized medley of feudal troops and of mercenaries; feudalism itself gave way under the influence of this combined with other reforming agencies. So far as concerned the actual formation and discipline of the standing army above noticed, a few changes were from time to time introduced: pistols and carbines were given to the cavalry; cuirasses were worn by the heavy troopers; and new evolutions were introduced. During the Thirty Years' War (1618–48), Gustavus Adolphus and Wallenstein adopted opposite modes of dealing with masses of infantry: the former spread them out to a great width, and only six ranks in depth; whereas the latter adopted a narrower front, with a depth of twenty to thirty ranks. Frederick the Great, in the next century, introduced a most complicated system of tactics and drilling; insomuch that when he could maneuver, he nearly always won his battles; but when the result depended on bold and unexpected onslaughts, he was more frequently a loser than a winner. The great military leader in the early part of the present century, Napoleon Bonaparte, made a larger use than any previous European general of the method of moving masses of troops with great celerity, beating the enemy in detail before they could combine in one spot. It is desirable to present, in the most condensed form, a few statistics of the actual armies of Europe; leaving to other articles all details concerning special armies.

France.—A law passed in 1872 enacts that every Frenchman, with a few specified exceptions, is liable to personal service in the army, and forbids substitution. Every Frenchman not declared unfit for military service, or specially exempted therefrom, must be for five years in the active army (composed of those who have reached the age of twenty years), for four years in the reserve of the active army, for five years in the territorial army, and for six years in the reserve of the territorial army. By the law of July 24, 1873, France is divided, for military purposes, into eighteen regions, each occupied by a corps d'armée, containing two divisions of infantry, one brigade of cavalry, one of artillery, one battalion of engineers, one squadron of the military train. When the present reorganization is completed, the *active* army will be composed of 156 regiments of infantry (line, light, Zouaves, Algerian tirailleurs, etc.), 25 single battalions, and 293 companies (depots, etc.); making in all, for the infantry, 279,986 men; of cavalry, 67 regiments in France, 3 in Algiers, 13 depots of these regiments, and a Cavalry School, comprising 67,888 men; artillery, 40 regiments and 17 companies, with 58,096 men; engineers, 4 regiments, having 13,551 men; of the military train, 11,486 men; in all, for the active army, 441,007. On the war-footing this number would be increased to 1,104,735, without taking account of sanitary corps, gendarmes, etc. Including the *territorial* army, its reserve force, and the reserves of the active army, the total military force of France is 2,505,000. The Budget of 1876 provided for 490,321 men, including gendarmes, etc.

Germany.—By the Imperial Constitution, April 16, 1871, the Prussian obligation to serve in the army is extended to the whole Empire. Every German capable of bearing arms is bound to be in the standing army for seven years, as a rule from the end of his twentieth to the beginning of his twenty-eighth year. Of the seven years, three must be in active service, and four in the reserve. Then he must serve for five years in the landwehr. The whole of the land forces of the Empire form a united army, all the troops being bound unconditionally to obey the Emperor in war and peace. The army of the German Empire consists of eighteen corps d'armée; viz., the corps d'armée of the guard, thirteen Prussian corps d'armée (Nos. I.–XI., XIV.—comprising the troops of Baden —and XV.), the corps d'armée of Saxony (XII.), of Würtemberg (XIII.), two of Bavaria (I. and II.), and the division of Hesse. In time of peace the German army has: (1) of infantry, 146 regiments of the line, 26 battalions of chasseurs, with 4687 commissioned and non-commissioned officers of the landwehr, amounting to 274,711 men; (2) of cavalry, 93 regiments, containing 65,513 men; (3) of artillery, 35 regiments of mounted, 13 of foot artillery, having 45,439 men; (4) of engineers, 19 battalions, 9568 men. In all, with 2056 staff officers, military train, etc., 17,036 officers, 401,659 men. On the war-footing, this force is increased by the following additions: field-troops, 16,976, officers, 676,486 men; depot-troops, 4431 officers, 245,793 men; garrison-troops, 9599 officers, 354,247 men. Total of the German army in time of war: 31,006 officers and 1,276,526 men, with 287,746 horses. The maximum number of troops employed by Germany in the war with France was 1,350,787 men and 263,735 horses.

Austria.—The military forces of the Austro-Hungarian Empire are divided into the standing army, the landwehr, and the landsturm. Subjects of the Empire are universally liable to service. The term of service is ten years, three of which the soldier must spend in active service, being afterwards enrolled for seven years in the army of reserve. He is still further liable to serve two years in the landwehr. The regiments of the standing army are under the control of the Minister of War for the Empire, while the landwehr is controlled by the Austrian and Hungarian Ministers of National Defense. The Emperor-King is the supreme chief of the whole of the military and naval forces of the Empire. The Austrian infantry constitutes 80 regiments of the line, with 148,480 men; the chasseurs, 40 battalions, with 21,451 men; of the cavalry there are 41 regiments (dragoons, hussars, lancers), 43,993 men; of artillery, 13 regiments of field-artillery and 12 battalions of fortress-artillery—in all, 28,695 men. The engineers and pioneers make three regiments, 8898 men. The sanitary troops and military train have 5748 men. The miscellaneous establishments (schools, magazines, etc.) number 25,174. In all, for the active army in time of peace, 284,435 (of whom 253,513 are combatants). On the war-footing these numbers are thus augmented: infantry, 485,680; chasseurs, 59,340; cavalry, 58,671; artillery, 70,614; engineers, 24,502; sanitary troops and military train, 45,727. Then the Austrian landwehr (infantry, chasseurs, and cavalry) comprises 3669 men in peace, 145,045 in war; and the Hungarian landwehr (the Honveds) 13,591 in peace and 206,707 in war. The total of the Austrian military forces in peace-time is therefore 301,695; in war, 1,137,401.

Russia.—According to a law of military reorganization, the Russian forces are to be raised by annual conscription, to which all are liable who have completed their twenty-first year and are not physically incapacitated. Substitution is prohibited. The period of service is fifteen years—six in active service and nine in the reserve. The Russian military forces are composed of regular and irregular troops. The regular troops comprise 164 regiments of infantry, 281,012 men; cavalry, 52 regiments, 42,444 men; artillery, 33,021 men; engineers, 9819 men; train, 4617 men. Total of field-troops in time of peace, 370,913. In war as follows: infantry, 568,253 men; cavalry, 47,379; artillery, 40,846; engineers, 13,306; train, 21,329—total, 691,113. With local and other troops (in fortresses, etc.), and reserve troops, the Russian army in Europe amounts, on the peace-footing, to 19,103 officers and 508,674 men; in war, 22,871 officers and 879,755 men. The army of the Caucasus amounts in peace to 125,643; in war, to 167,841. The army of Turkestan to 22,906; of Siberia, from 25,000 to 27,000. Besides some thousand troops as gendarmes and in various military establishments, there is a grand total for the regular Russian army of 33,000 officers and 733,000 men; on the war-footing, 39,380 officers and 1,213,259 men. In addition there are the irregular troops, comprising about 190,000 men, chiefly cavalry.

Denmark.—All able-bodied young men twenty-one years of age are liable to serve eight years in the regular army of Denmark and eight years in the reserve. Denmark has thirty-one battalions of infantry (guards, line, reserve), comprising 26,750 men; five regiments of cavalry, with 2122 men; two regiments and two battalions of artillery, with 6523 men; two battalions of engineers, with 580 men. The total, line and reserve, is 1031 officers, 35,975 men; on the war-footing, 52,656 men.

Sweden and Norway.—There are five classes of soldiers in Sweden; the enlisted troops, the national militia (indelta), the conscription troops (bevaering or landvaern), the militia of Gothland, and the volunteers. Of the soldiers of the line there is a total of 35,646 men; of the reserve (landvaern), 86,101; of the Gothland militia and volunteers, 150,830. Norway has an army of its own, divided into the troops of the line, with reserve, military train, the landvaern, the civic guards, and the landstorm. The troops of the line are 12,000 in time of peace; in time of war not more than 18,000 without the assent of the Storthing.

Holland.—The army of the Netherlands is formed partly by conscription and partly by enlistment; and there is besides a militia. The European army has, of infantry, 1122 officers and 43,690 men; cavalry, 184 officers and 4318 men; engineers, 1035 men; artillery, 421 officers and 10,610 men. With the staff, etc., the total force is 62,068 officers and men. There is besides in the East Indies a force of 27,659 officers and men.

Belgium.—The standing army is formed by conscription. Substitution is permitted. The legal period of service is eight years. Belgium has 74,000 infantry (16 regiments), 8848 cavalry (7 regiments and 2 squadrons), 14,513 artillery (6 regiments), 2486 engineers. In all, and without officers, 99,847.

Italy.—The Sardinian law of conscription forms the basis of the Italian military system. The infantry of the line under arms on the peace-footing number 86,017; the bersaglieri, 16,818; depots, 11,560; the cavalry, 18,449; the artillery, 19,732; engineers, 3027; carbineers, 20,915; administrative troops, etc., 7047,—giving a total of 183,205. On the war-footing, these several forces are so increased as to give a total of 541,575; and with the addition of the provincial militia, 743,656.

Spain.—The army of Spain was reorganized in 1868 after the model of that of France. The active army has 60,000 infantry, 9000 cavalry, 2500 engineers, and 8500 artillery, making a total of 80,000 men. The reserves increase this number to 216,000. There is besides an army of 54,500 in Cuba, 9400 in Porto Rico, and of 9000 in the Philippines.

Switzerland.—The federal army has 1269 engineers, 8401 artillery, 1942 cavalry, 6078 tirailleurs, 65,991 infantry, and 364 of a sanitary corps. In all, 84,045. There are, besides, of the reserves, 51,102; the landwehr, 65,562,—giving a total available military force of 201,578.

Turkey.—In 1871 the Turkish regular army had infantry to the number of 72,000; cavalry, 9000; artillery, 9500; engineers, 1600; with 1200 miscellaneous troops amounting to 93,300. Before the war of 1877 it was proposed that by 1878 the regular army should be increased to 152,000. The irregulars (Bashi-bazouks, Spahis, etc.) are about 70,000. And the contingents which the Dependent States are bound to furnish are severally: Upper Albania, 10,000; Bosnia, 30,000; Egypt, 15,000; Tunis and Tripoli, 4000.

All the various matters relating to the formation, organization, discipline, arms, equipments, duties, and tactics of armies, will be found succinctly treated under appropriate headings. See *British Army*, *East India Army*, and *United States Army*.

ARMY ADMINISTRATION.—The whole of the operations connected with the raising, clothing, paying, maintaining, and controlling of the British army are included in the term Army Administration. They are distinct matters from military command and discipline. The Sovereign has the supreme command of the British army; but the Secretary of State for War is her responsible representative in all that concerns administration—the Commander-in-Chief being her representative in matters relating to military command and discipline. The Secretary is the organ through whom the wishes of the Sovereign are reconciled with the wishes and intentions of Parliament. Until the war with Russia in 1854, the Administrative Departments were much scattered; their defective organization led in great part to the miseries suffered by the British troops in the Crimea; but now they are all consolidated under the Secretary of State for War.

ARMY CORPS.—When an army is very large, three or four divisions are joined together and form an *Army Corps*. The officer commanding an army corps should be of a higher grade than he who commands a division. This grade, in the U. S. army, would be that of *Lieutenant-General.* An army corps is most generally composed of all arms of service, and is, to all intents and purposes, an army complete in itself. Two or more army corps, or armies, would be under the command of the *General*, or of a "*General-in-Chief.*" It is to be observed that the functions of General Officers are to command armies, or fractions of an army greater than a regiment, when mobilized. In time of peace, when the regiments are not formed into brigades or divisions, but are distributed over districts of country, the function of the General is to command the troops in these districts, which are then designated by the terms "military departments." See *Corps d'Armée*.

ARMY ESTIMATES.—In the spring of every year, the British Government having formed a plan concerning the extent and appliances of the military force for that year, the War Office sends to the Treasury a series of accounts setting forth the probable cost of everything required. The accounts are called the Army Estimates. If they are approved by the Treasury, the Chancellor of the Exchequer adverts to these, along with other estimates, in his annual "financial statement," made to the House of Commons in his capacity as Guardian of the Public Purse. In preparing the Army Estimates the Secretary of State for War applies to the heads of all the departments under him for detailed accounts of their probable requirements. Another functionary then incorporates and adjusts these into a whole; they are submitted to the Treasury; and, if approved, are presented to the House as the Army Estimates. Should the Commons grant the money, the Accountant-General of the War Office makes the requisite drafts or demands from time to time; and the Treasury authorizes the Paymaster-General of the forces to honor these drafts. The money itself is in the Bank of England; this establishment receives a certain annual sum from the government for managing such financial matters.

The Army Estimates are drawn up in conformity with a model which differs little from year to year. There are certain great headings, each comprising many minor divisions, viz.: 1. Regular forces (4 votes); 2. Auxiliary and reserve forces (4 votes); 3. Ordnance establishments and manufactures, and purchases of stores (4 votes); 4. Works and buildings (barracks, fortifications, etc.); 5. Educational establishments (schools, libraries, etc.); 6. Administration of the army; 7. Non-effective services (half-pay, retiring allowances, pensions, etc.). The various items are more or less sifted by the House of Commons; and any one or more of them can be refused altogether, or granted in diminished amount. The Army Estimates for 1879–80, which may be cited here as an illustrative example, refer to the period from April 1, 1879, to March 31, 1880. The total number of men, including the staff of the militia forces, on the home and colonial establishment of the army, and exclusive of those serving in India, was 135,625. The total number serving in India was 62,653, which are charged against the Indian Treasury. The horses were 26,218, of which 10,830 were for Indian service. Without going into any details, we will simply give the amounts under the six great headings:

1. Regular forces—pay and allowances.	£4,914,200
2. Auxiliary and reserve forces.	1,258,500
3. Ordnance services (provisions, clothing, arms, stores)	5,531,000
4. Works and building	853,300
5. Various services (education, administration, etc.)	432,900
6. Non-effective services	2,625,800
	£15,645,700

Similar annual estimates are made for the support of nearly all other armies of the world.

ARMY FRONT.—The great majority of the tactical formations for infantry proposed are practically useless because of an improper connection between the total number of infantry in the army, the number of infantry there should be to each pace of front, and the normal order in which the infantry will move under fire. Let A = the total number of infantry in an army; F, the number of men in the front line; P, the number of paces in that front line; m, the number of infantry which late experience shows there ought to be to each pace of the front; and $2n$, the number of paces in the normal interval between skirmishers (front rank men) when moving under fire, n being the consequent interval between skirmishers, when the front and rear ranks are on the same line, in one rank. Then

$$m\,P = A; \text{ and } P = n\,(F - 1);$$

whence

$$F = \frac{A + m\,n}{m\,n}.$$

Since m, n, and $m\,n$ are always insignificant in comparison to A, F, and P, practically speaking

$$P = \frac{A}{m} \text{ and } F = \frac{A}{m\,n}.$$

Suppose the army in the field consists of 45,000 infantry; from the above, it appears that its front should be 12,000 paces (nearly 6 miles) in extent, and should be occupied by 4000 men. In this case m has been taken as 5 and n as 3, practically a useful interval. Such brief and practical rules as these will at once enable officers in time of war to so place their troops and make such disposition of divisions, brigades, etc., in any position, as to act offensively or defensively and, at the same time, hold in hand troops to turn the enemy's flank, or to prevent the enemy from turning his own. Nothing definite can be laid down as to the distance between the different lines of skirmishers, supports, etc., as everything depends on the nature of the ground.

ARMY HOSPITAL CORPS.—A body of men recruited from the ranks of the English army for the purpose of looking after the sick and wounded, and for carrying out such instructions as may be given to them by the Medical Officers with reference to diet and treatment, and in administering of medicines ordered, and giving such necessary attendance as the sick require. The men act as bakers and cooks, and perform all duties which render them useful to the patients.

ARMY HYGIENE.—In the English army, a branch of the Medical Department having for its object the sanitary condition of the army, whether in quarters or in the field.

ARMY LIST.—The name of a publication issued monthly by authority of the War Office. It contains the names of all Commissioned Officers in the British Army. Then come the General and Field Officers of the dying-out Indian Army. Next the names of all Officers who hold military honors or Staff Appointments. The bulk of the work, however, is taken up with an enumeration of all the regiments in the Queen's Army, and all the Officers in each regiment, arranged according to the numerical rank of the regiments. To this are added lists of the Officers of the Rifle Brigade, Colonial Corps, Royal Artillery, Royal Engineers, Royal Marines, Control, and Army Medical Department; and of Officers retired on full-pay and on half-pay. Next follow the Officers of the Militia, Yeomanry, and Volunteers; and then the Militia and Volunteer Officers of the several Colonies. A full index, an obituary, a list of the changes gazetted during the past month, and of the new regulations, complete the work. A larger work of similar but non-official character, *Hart's Army List*, by a more condensed arrangement of type gives all the information contained in the official list and much in addition.

ARMY MUTUAL-AID ASSOCIATION.—A Mutual-Benefit Society of officers of the United States army, organized January 13, 1879. Its object is to aid the families of the deceased members in a prompt, simple, and substantial manner. Any person actually holding a commission in the army may become a member of this Association, provided he is under fifty years of age, can procure a surgeon's certificate of good health, and is unobjectionable to the executive committee. The initiation-fee is an amount equal to a half-dollar for each full year which the candidate shall have completed on admission. For the purposes of assessment, on the first of January of each year the members are distributed into nine classes, according to their respective ages (determined by the last preceding birthday) at date of classification, and the assessment of the members of the several classes is as follows:

Class.	Assessment.
1. Under thirty years	$2 00
2. Thirty to thirty-five years	2 50
3. Thirty-five to forty years	3 00
4. Forty to forty-five years	3 50
5. Forty-five to fifty years	4 00
6. Fifty to fifty-five years	4 50
7. Fifty-five to sixty years	5 00
8. Sixty to sixty-five years	5 50
9. All over sixty-five years	6 00

The officers of the Association consist of a President, a Vice-president, and a Secretary, who is also Treasurer; all of whom are elected from the members, by ballot, at an annual meeting, and hold their offices for two years and until their successors are qualified. At all of the meetings of this Association, ten members, representing a majority of the whole number, constitute a quorum for business. There is an Executive Committee, consisting of the President, Vice-president, and Secretary, and of two other members, elected at the annual meetings, and holding their offices for one year and until their successors are qualified. A majority of the Executive Committee constitute a quorum for business. The Executive Committee has general supervision over the affairs of the Association; passes upon all applications for membership; prescribes forms; audits all claims and accounts, and decides all questions that may arise in connection therewith; and directs the Treasurer to draw his drafts for all payments. They attend generally to the government and financial affairs of the Association, and have power to fill all vacancies in the Committee until the succeeding election. They meet on the first Monday of each month, or oftener upon the call of the President. The Executive Committee is also empowered, during the lifetime of a member, to revoke or annul his certificate of membership, if it should be made apparent that the same was issued upon a palpable mistake or omission in the declaration of the applicant, or upon an insufficient inquiry by the Medical Examiner as to the condition of his health at the time of his application. The Executive Committee also have power to terminate the membership of any officer who may be dropped from the army for desertion, dismissed by sentence of Court-Martial, or who resigns to avoid trial by Court-Martial; and the Committee have the further power to require, as the condition of continued membership, a new and thorough medical examination by a Medical Officer of the army in the case of any one who the Committee may have good reason to believe shall have become addicted to habits of intemperance or immorality calculated to seriously impair his risk. The Executive Committee may at any time, in the name of the Association, take measures to procure incorporation for it, or petition Congress for such legislation as would in their judgment facilitate the collection of the Assessments, and the custody and disbursement of the funds of the Association, through the Pay Department of the army and the Treasury, or otherwise, as in the judgment of the Executive Committee may seem most expedient. Upon the death of a member the Treasurer, under the direction of the Executive Committee, withdraws from the credit of each member in the special reserve fund the amount of one assessment upon him, or when necessary levy an extra assessment, and the money thus obtained is disposed of as follows: The Treasurer, with the least possible delay, pays to the beneficiary or beneficiaries the net benefit, which is so much of such aggregate assessment, after deducting five per centum for expenses, as shall not exceed a maximum of either twenty-five hundred dollars or a total of three dollars *per capita* of the membership when the death occurs. Any surplus acquired from one aggregate assessment so taken or levied upon a death in excess of these limitations is accumulated in the general reserve fund until the same shall be sufficient to pay a future benefit, when no assessment is appropriated or levied therefor; but such surplus, or so much as may be necessary, is applied to such benefit, and the remainder, if any, carried forward for a like purpose. No benefit is payable by this Association upon the suicide of any member who has not been a member in good standing for more than one year, unless the Executive Committee shall be fully convinced that such suicide was induced by insanity. In case of any one who, having been a member, and having paid all his assessments and dues for more than one year, shall have committed suicide, the fact of insanity shall be presumed in the absence of convincing evidence to the contrary. The decision of the Executive Committee entered upon the minutes of their meeting is, however, finally binding upon all concerned in every case. Any member may change the person or persons designated as beneficiaries by filing with the Secretary a certificate setting forth the fact. Assignments of the benefit to others than widows, children, or other relatives are not, however, to be encouraged, and will not be accepted unless approved by the Executive Committee. The meetings of the Association are held at Washington, D. C. The annual meetings are held on the second Tuesday in January of each year, at which time the Executive Committee audit the accounts of the Treasurer, and submit a report of the transactions of the Association for the preceding year. The proceedings of these meetings, accompanied by the reports and a list of the members, are promptly published for the information of the Association. Special meetings are called upon the written request of ten or more members, and at all meetings the absent members may be represented by proxy, in writing, given to those attending. In order that members may have timely notice of the numerical strength of the Association, and be informed of the basis upon which the number of assessments for each year is computed, the Executive Committee cause to be published in the two military newspapers which have the largest army circulation, as early in the beginning of each year as practicable, a notice which gives the total membership of January 1st, and the number of assessments payable by each member.

It is proposed that additional groups, not exceeding two, may be formed whenever one hundred members of the Parent-Association (having signified their desire to join the same) have been duly accepted by the Executive Committee. Of the additional groups authorized to be formed, the first group formed is designated and known as Group B, and the second as Group C. For purposes of assessment members of Groups B and C are separately classified, and the assessment of members is as follows:

Class.	Assessment.
1. Under thirty years	$4 00
2. Thirty to thirty-five years	5 00
3. Thirty-five to forty years	6 00
4. Forty to forty-five years	7 00
5. Forty-five to fifty years	8 00
6. Fifty to fifty-five years	9 00
7. Fifty-five to sixty years	10 00
8. Sixty to sixty-five years	11 00
9. Sixty-five to seventy years	12 00
10. Seventy years and upwards	13 00

The funds of the Parent-Association are not in any case whatever, or in any manner, either temporarily or otherwise, applicable to or to be used in the payment of the expenses or liabilities of the groups; and the expenses, liabilities, and benefits of Groups B and C are borne by the members thereof respectively, and the records, accounts, and funds of each group are kept separate and distinct, and in no case are the funds pertaining to one group applied to or used in payment of the expenses, liabilities, or benefits of any other group. The membership, classes, and assessments, January 1, 1884, were as follows:

Class.	Membership.	Assessments.	Amount.
1	105	$2 00	$210 00
2	131	2 50	327 50
3	133	3 00	399 00
4	202	3 50	707 00
5	167	4 00	668 00
6	90	4 50	405 00
7	28	5 00	140 00
8	16	5 50	88 00
	872		$2,944 50

ARMY OF OBSERVATION.—The question of moving out to meet a relieving army involves, frequently, the question of raising the siege. If the besieging army is strong enough to permit it, a force is usually detached to watch the movements of the relieving army, while the main body remains prosecuting the siege operations. This detached body is known as an Army of Observation. No important siege should be undertaken where there is danger from a heavy succoring force from without, unless the besieging force is of sufficient strength not only to keep the garrison within their works whilst the ordinary siege operations are pushed forward, but to detach a force of sufficient strength to observe the movements of any body that may seem large enough to threaten the besieging force and to hold it in check long enough, if attacked, to concentrate the entire force on some favorable defensive position.

ARMY ORGANIZATION.—Napoleon, at the period of the preparations for his descent upon England, had a moment of leisure which he could bestow upon his military organization. Then, for the first time, it is believed, was introduced a systematic organization of grand masses, termed *Army Corps;* each one comprising within itself all the elements of a complete army, and apt for any emergency. Since then this has served as a type to France and other European States in their organization. An army is now composed of one or more army corps, made up of infantry and cavalry; an artillery equipage, comprising several batteries; several artillery parks of reserve; with a grand one to which is attached a bridge-train. Each army corps consists of one or more Divisions; each division of several Brigades; the brigade comprising two Regiments. Two batteries of foot-artillery, of six pieces each, are attached to each infantry division; and one of horse-artillery, of the same strength, to each division of heavy cavalry. Besides, for each army corps of infantry there is a reserve of several batteries; and a few served by foot-artillery. In some cases, one of the batteries of reserve is served by the horse-artillery. A company of engineer troops, termed *Sappers*, is generally attached to each infantry division; and to each infantry army corps a brigade of light cavalry, with a company of *Pontoniers*, which has charge of the bridge-train. In France, each brigade is commanded by a *Maréchal de Camp*, a grade corresponding to our Brigadier-General; each division by a *Lieutenant-General*, which corresponds to our Major-General; and an army corps by a *Maréchal de France.* The particular organization of the General Staff, and the different arms of service, would lead to details of no importance here. The proportion, however, of each arm of an army to the others is a subject of great interest, as upon this depends, in a great degree, the more or less of excellence in the military institutions of a State. The infantry, from its powers of endurance, its capabilities for battle in all kinds of ground, and its independence of those casualties by which the other arms may be completely paralyzed, is placed as the *first arm;* and upon it is based the strength of all the others. It generally forms about *four fifths* of the entire force. In all States where the military art is justly appreciated the cavalry arm is placed in the *second rank* to the infantry. To it an army is often indebted for turning the scales of victory, and giving a decisive character to the issue. To it, the infantry, when exhausted by fatigue, or broken, often owes its safety, and through the respite gained by its charges finds time to breathe and re-form. Without it, much of advanced-post duty, patrols, and detachment service requiring great celerity would be but badly performed. But the arm of cavalry by itself can effect but little, and, in many circumstances, does not suffice even for its own safety. The smallest obstacles are sufficient to render it powerless; it can neither attack nor hold a post without the aid of infantry; and at night is alarmed, and justly so, at every phantom. The proportion borne by the cavalry to the infantry should vary with the features of the seat of war; being greater in a champagne than in a broken or mountainous country. The proportion of *one fourth* of the infantry for the first, and *one sixth* for the last, is generally admitted by received military authority as the best. The artillery is placed *third in rank* among the arms. Its duties are to support and cover the other arms; keep the enemy from approaching too near; hold him in check when he advances; and prevent him from *debouching* at particular points. To perform these duties it is considered that an allowance of *one piece for each thousand men* of the other arms, and *one in reserve*, forms the proper quota of this arm. It is to be remarked, however, that this proportion supposes the other arms in an excellent state of organization and discipline. In the contrary case, the quota of artillery must be increased; for it inspires poor troops with confidence, as they rely upon it to keep off the enemy, and to cover their retreat. But here arises another disadvantage, as artillery is utterly incapable of defending itself, and therefore, when present in an over-proportion, it must necessarily sustain great losses in guns and the other *matériel*. The arm of engineering, although requiring more science and a higher grade of talent for its duties than any other, takes the *last place in tactical considerations.* To it is intrusted all that pertains to opposing passive obstacles to an enemy's advance, and removing those which he may have raised. To it is assigned that most difficult of all tasks to the soldier, patient endurance of manual toil, and a disregard of everything but the work in hand, whilst exposed to the enemy's fire. The proportion of engineer troops will depend in a great measure upon the character of the operations undertaken; being most in sieges, and least in those depending mainly on maneuvers. In the French service the engineers are one half the strength of the artillery —a large number, but rendered necessary by the peculiar military position of that country. The troops which compose the three principal arms are generally subdivided into two classes, *heavy* and *light;* partly arising from the nature of their weapons, and partly from their destination on the field of battle. This subdivision is less marked in the infantry than in that of the other arms; for although in most foreign armies a portion of the infantry carries a saber with the musket, still this additional weapon is of rather questionable utility; for the musket is the one which, under all circumstances of attack and defense, will be resorted to. All infantry now receive the same instruction; but whether a portion of it ought not to be reserved especially for the duties consigned to light troops is still a disputed point. One thing is certain, that perfection is more easily reached by confining the individual to one branch of his art than by requiring him to make himself conversant with the whole. Still it might be often found inconvenient, at the least, if infantry were not able to perform all the functions required of it. The service of light infantry often demands great individual address, intelligence, and well-developed physical powers—a combination of qualities not easily found, and seldom, indeed, without careful habitual training. Whereas, in infantry of the line, the qualities of the individual are of less importance, as results here depend almost solely upon the action of the mass. The habitual order of battle of light infantry is the *dispersed order;* and whether acting offensively or defensively, it depends for its results upon the effect of its fire, resorting to the close order, and using the bayonet only exceptionally. As each individual, although immediately supported by his own file-closer, and those on his right and left, is still often thrown upon his own resources, being obliged to take cover where he can most conveniently find it, he must be a good marksman, cool, deliberate, and circumspect; since it may become necessary to keep an enemy occupied hours and even days together, pressing on him at one moment and yielding to him the next, or hold with tenacity, and disputing inch by inch some particular point, as it may suit the views of the General in command. In infantry of the line, as success depends upon the action of the mass, *ensemble*, coolness, and determination should characterize all its movements, whether it delivers its fire in line, forms in column to attack with the bayonet, or throws itself into square, to await the charge of the enemy's cavalry. The duties of light infantry are to open an engagement, and, after it is fairly got under way, to keep it going; turning it to advantage if successful, otherwise breaking it off. In its relations to the infantry of the line, it should cover the flanks of the latter; clear the way for its advance by rooting the enemy out of all covers, and then holding them if requisite. Upon it devolves all advanced-post, detachment, and advanced- and rear-guard service. To the infantry of the line is confided everything where firmness is the essential requisite: as the attack or defense of key-points, the formation of all supports and reserves, whether on the field or in the attack and defense of posts. There is a third class of infantry, termed *riflemen*, which does not form a part proper of the arm of infantry; partaking, when properly constituted, more of the character of partisan than of regular troops; being chosen only from that portion of a population whose habits lead them to a daily use of fire-arms and give them an unerring aim. As an auxiliary in the defense of particular localities, where they are secure from the attack of the bayonet, or of cavalry, and can deliver their fire with that deliberation which their weapon demands, riflemen will often be found invaluable; as nothing is more dreaded by troops generally than this lurking and often invisible foe, whose whereabouts is only divined by the destruction he deals around him. In cavalry, the distinction between heavy and light is more strongly marked, and the functions of each more clearly defined than in infantry. The *cuirassiers*, from their defensive armor and heavy saber, which in both man and horse call for great physical powers, constitute the true heavy cavalry. The *dragoons* and *hussars* belong to the light, and the *lancers* indifferently perform the functions of either. The most essential quality of all cavalry, which distinguishes it from all other arms, and gives it the faculty of taking an enemy frequently at disadvantage, is that of celerity. If to this the rider unites boldness, and even, when called for, recklessness, it makes of this arm a truly fearful one. Cavalry, to attain its ends, should unite several essential conditions; horses and weapons in good condition; sufficient depth of ground both in front and rear to gather speed for the charge, or space for rallying; to be led boldly but skillfully into action; have its flanks covered against a surprise; and be followed by a support, or reserve, to cover the retreat, or secure from the effects of confusion the line charging, if brought up unexpectedly by the enemy. As the functions of heavy cavalry are to bear down all opposition and present an impassable wall to the enemy's efforts, its duties are confined to the battle-field; there, placed in the reserve, it is held in hand until the decisive moment arrives, when it is launched forth to deal a blow from which the enemy hopelessly struggles to recover, either to achieve victory or to fend off utter defeat. To light cavalry are intrusted the important duties of securing from surprise the flanks of the heavy; to watch over the safety of horse-artillery, and to perform the services required of them by infantry divisions, and those of detachment service in general. The artillery, which had for a long period, and even still, preserves the character of eminent respectability, has of late years begun to infuse a dash of the dare-devil spirit of the cavalier into its ranks. If it has not yet taken to charging literally, it has, on some recent occasions, shown a well-considered recklessness of obstacles and dangers, fully borne out by justly deserved success. The distinction between light and heavy in this arm arises not only from the difference of caliber in the pieces, but also in a difference of their tactical application. The heavy field-caliber is reserved for batteries in position, and is seldom shifted during the action. The light field-caliber are served either by foot- or horse-artillery, and follow the movements of the other arms. Improvements both in the *matériel* and the tactics of artillery have been very marked within late years. Formerly, considered only in the light of an auxiliary on the battle-field, artillery now aspires, and with indisputable claims, to the rank of a principal arm. The tactical applications of artillery on the field depend on the caliber. To the heavy are assigned the duties of occupying positions for strengthening the weak points of the field of battle; for securing the retreat of the army; for defending all objects whose possession might be of importance to the enemy, as villages, defiles, etc.; and for overturning all passive obstacles that cover the enemy, or arrest the progress of the other arms. The light pieces, served by foot-artillery, follow the movements of the infantry; covering the flanks of its position, preparing the way for its onset, and arresting that of the enemy. It is of this that the principal part of the artillery in reserve is composed. The horse-artillery is held in hand for decisive moments. When launched forth, its arrival and execution should be unexpected and instantaneous. Ready to repair all disasters and partial reverses, it, at one moment, temporarily replaces a battery of foot, and at the next is on another point of the field, to force back an enemy's column. In preparing the attacks of cavalry, this arm is often indispensable and always invaluable; brought with rapidity in front of a line, or opposite to squares of infantry, within the range of canister, its well-directed fire, in a few discharges, opens a gap, or so shakes the entire mass that the cavalier finds but a feeble obstacle where, without this aid, he would in vain have exhausted all his powers. See *Army*.

ARMY REGISTER.—The official list of the United States army, published annually, showing the position, rank, and duties of officers, regiments, companies, etc., with the promotions and casualties during the preceding twelve months.

ARMY REGULATIONS.—A book so called, published in the name of the President of the United States "for the government of all concerned." The Constitution provides that "Congress shall have power to make rules, for the government and *regulation* of the land and naval forces." The only Acts of Congress in force authorizing the President to make regulations better defining the powers and duties of officers are contained in the 5th section of the Act of March 3, 1813, and the 9th section of the Act approved April 26, 1816. The first of these acts is an act for the better organization of the General Staff of the army, and the second relates (with the exception of the last section, concerning forage and private servants) to the same subject. By the 5th section of the Act of 1813 it is provided, "That it shall be the duty of the Secretary of the War Department, and he is hereby authorized, to prepare general regulations better defining and prescribing the respective duties and powers of the several officers in the Adjutant-General, Inspector-General, Quartermaster-General, and Commissary of Ordnance Departments, of the Topographical Engineers, of the Aides of Generals, and generally of the General and Regimental Staff; which regulations, when approved by the President of the United States, shall be respected and obeyed until altered or revoked by the same authority. And the said general regulations, thus prepared and approved, shall be laid before Congress at their next session."

Remarking here that the regulations to be prepared and approved refer *only* to the powers and duties of the officers of the several Staff Departments enumerated in the Act, it follows that no other regulations made by the President can derive any force whatever from this Act. The 9th section of the Act of 1816 therefore only continued this then existing power of the President in providing "That the several officers of the Staff shall respectively receive the pay and emoluments, and retain all the privileges, secured to the Staff of the army by the Act of March 3, 1813, and not incompatible with the provisions of this Act; and that the regulations in force before the reduction of the army be recognized, as far as the same shall be found applicable to the service; subject, however, to such alterations as the Secretary of War may adopt, with the approbation of the President." It would seem, therefore, that whatever may be contained in the President's army regulations of a legislative character concerning officers of the army not belonging to Staff Departments must, if valid, be a legitimate deduction from some positive law, or depend for its legality upon the exercise of authority delegated to the constitutional Commander-in-Chief or other Military Commander, in the rules made by Congress for the government of the army. Congress has delegated to the President authority to prescribe the uniform of the army; authority to establish the ration; and besides the authority given by law to other Military Commanders, he also has been authorized to relieve, in special cases, an inefficient Military Commander from duty with any command; to assign any senior to duty with mixed corps, so that the command may fall by law on such senior in rank; to limit the discretion of Commanding Officers in special cases, in regard to what is needful for the service; and hence also he has been given authority to carve out special commands from general commands in particular cases. These are all-important functions, but they do not authorize *special cases* to be made general rules, and it is much to be regretted that the lines of separation between regulations and the orders of the Commander-in-Chief have not been kept distinct.

ARMY RESERVE.—A force, under the present organization of the British army, composed of men who have enlisted for twelve years, a portion of which service, viz., six and not less than three years, must be passed with the colors, the residue being spent in the reserve. This condition of service is known as "short service." Other soldiers are eligible to enter the reserve force, viz., those who have exceeded the first term of their engagement, say men after thirteen or fourteen years' service, and who do not exceed thirty-four years in age. Under the system which now obtains, a considerable reserve force may be expected to be formed, and it is estimated that with an army of 180,000 men, of whom three fourths are to serve only six years with the colors, there will accrue by 1882 a large reserve of trained men, all under thirty-two years of age.

The Army Enlistment Act of 1867 formed a body of men called the enrolled pensioners and others into two classes: First class, not exceeding 20,000 men, liable for service anywhere, and consisting of men who are serving or have served in the army, and whose service does not exceed first term of enlistment. Second class, not exceeding 30,000, liable for service in the United Kingdom only, consisting of persons already enrolled, out-pensioners. The Act of 1870 has modified the above, and the result has been that enrollment for second class, except for pensioners, has been suspended. (Second class therefore consists entirely of enrolled pensioners, who are called out for twelve days annually, under S. O. of Pensioners, and number about 15,000.) Enrollment in the first class is encouraged, and men are eligible to enter this class up to the age of thirty-four; the retaining fee amounts to £6 per annum (but no claim to future pension), and all men enlisted under short service are to be passed into this class, who will ultimately be the reserve of the standing army.

ARMY SCHOOLS.—The colleges, academies, and schools relating to military matters may be grouped into three classes—those intended to increase the military efficiency of the officers and men; those for imparting military knowledge to persons not yet in military service; and those which bear relation to the ordinary school-tuition of soldiers of the ranks and their children. The principal of those in the first group are the Royal Military College at Sandhurst, the Royal Military Academy at Woolwich, the School of Instruction at Chatham, the Department of Artillery Studies at Woolwich, the School of Artillery at Shoebury, the School of Musketry at Hythe, the Royal Artillery Institution at Woolwich, and the United States Artillery School. The chief among the second group are the Royal Military Asylum (better known as the Duke of York's School), the Regimental Schools, the Garrison Schools, and the United States Military Academy. Chelsea College or Hospital is an Asylum for veterans, not a school of instruction. Most of these educational establishments will be found most briefly described in this work, either under the names of the places where they exist, or of the arm of the service to which they belong.

ARMY SERVICE CORPS.—A branch of the Control Department, in England, officered from the Supply and Transport Sub-department. The officers of this corps rank as follows: Commissary-Major, Deputy Commissary-Captain, Assistant Commissary-Lieutenant. The corps consists of clerks, tradesmen, mechanics, skilled laborers, drivers, etc., who are required for the various duties connected with the supply, store, pay, and transport service.

ARMY WAGON.—A wagon designed for the use of foot-soldiers on the plains, and so constructed that the men can quickly jump off the seats when attacked, and spring back again at once. The term is also applied to wagons for stores and ammunition.

ARMY WORK CORPS.—When the British generals engaged in the Crimean War, in the latter months of 1854, knew that the siege-army would need to winter outside Sebastopol, grave difficulties were presented to their notice. The distance from the landing-place at Balaklava to the front of the siege-camp was not less than eight miles; and the only road was a mud-track, almost impassable in wet weather. How to get the heavy guns, the shot and shell, the provisions and the general stores up to the front was a question not easy of solution. The British soldiers were too few even for the ordinary military duties, and yet they were called upon for services of an extra and arduous nature. When these facts became known in England, a suggestion was made that an "Army Work Corps" should be formed, to consist of strong and efficient railway excavators, Cornish miners, and well-sinkers; that these should have with them all the tools and appliances for making roads and digging wells; and that they should be accompanied by traveling workshops and skilled artisans, to effect that which might require more skill than physical labor. The immediate necessities of Lord Raglan, in regard to bringing up supplies, were met by the construction of a railway from Balaklava to the heights outside Sebastopol, by special contract with Messrs. Peto & Brassey; but the large amount of bodily labor continually needed for various services led to the formation of the Army Work Corps. The raising and organization of this force were intrusted to Sir Joseph Paxton. As soon as he had obtained 1000 efficient men he sent them out; and their value was so soon felt by Lord Raglan that other detachments gradually followed, until the corps comprised 3500 men in the latter months of 1855. The men were paid well and they worked well; and as their engagement related only to the special duties connected with the siege-camp, the country was not saddled with any burden after the need for these services had ceased. They did not require to be drilled for their duties, like sappers; and they were ready for work at once, as artisans or laborers. There were some cases of disagreement between the men and their employers, after the whole of the British had returned from the Crimea, in a matter of wages due; but this was a question of detail, and did not affect the usefulness of the corps. The experience gained has been valuable, as showing in what way, under special circumstances, ordinary workmen and laborers may be employed as assistants to a military force.

ARNAOUTS—ARNOUTS.—A corps of Grecian militia organized during the war of Russia against the Porte in 1769.

ARQUEBUS.—The first form of hand-gun which could fairly be compared with the modern musket. Those of earlier date were fired by applying a match by hand to the touch-hole; but about the time of the battle of Morat, in 1476, guns were used having a contrivance suggested by the trigger of the arbalest or cross-bow, by which the burning match could be applied with more quickness and certainty. Such a gun was the arquebus. Many of the Yeomen of the Guard were armed with this weapon, on the first formation of that corps in 1485. The arquebus being fired from the chest, with the butt in a right line with the barrel, it was difficult to bring the eye down low enough to take good aim; but the Germans soon introduced an improvement by giving a hooked form to the butt, which elevated the barrel; and the arquebus then obtained the name of the *haquebut.* Frequently written *Arquebuse, Harquebus,* and *Harquebuse.*

Arquebusier.

ARQUEBUSADE.—Shot of an arquebus. Also distilled water from a variety of aromatic plants, as rosemary, millefoil, etc., applied to a bruise or wound; so called because it was originally used as a vulnerary in gun-shot wounds.

ARQUEBUSIERS.—Soldiers armed with the arquebus and haquebut. The former were common in the English army in the time of Richard III., the latter in that of Henry VIII.

ARRAY.—Order of battle, as an army in battle *array;* disposition in regular lines.

ARRAYER.—A title given to certain military officers in England in the early part of the fifteenth century. There were two of them in each county, sometimes called Commissaries of Musters. Their duties were set forth in an ordinance of Henry V., from the terms of which it appears that the Arrayers were Army Inspectors, or, rather, Militia Inspectors, and in some sense precursors to the modern Lord-Lieutenant of Counties.

ARREST.—1. A French word, similar in its import to the Latin word *Retinaculum.* It consisted of a small piece of steel or iron which was formerly used in the construction of fire-arms to prevent the piece going off. A familiar phrase among military men in France is, *Ce pistolet est en arrêt.*—"This pistol is in arrest," or "is stopped."

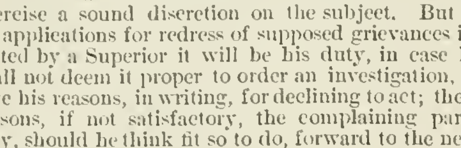
2. The temporary confinement of officers in barracks, quarters, or tents, pending trial by Court-Martial, or the consideration of their imputed offenses previous to deciding whether they shall or shall not be tried. Private soldiers are usually placed under guard, and non-commissioned officers are placed in arrest in quarters. None but Commanding Officers have power to place officers under arrest, except for offenses expressly designated in the Twenty-fourth Article of War. Officers are not put in arrest for light offenses. For these the censure of the Commanding Officer will, in most cases, answer the purposes of discipline. An officer in arrest may, at the discretion of his Commanding Officer, have larger limits assigned him than his tent or quarters, on written application to that effect. Close confinement is not to be resorted to unless under circumstances of an aggravated character. In ordinary cases, and where inconvenience to the service would result from it, a Medical Officer is not put in arrest until the Court-Martial for his trial convenes. The arrest of an officer or the confinement of a soldier is reported to his immediate Commander as soon as practicable. All prisoners under guard, without written charges, are released by the Officer of the Day at guard-mounting, unless orders to the contrary be given by the Commanding Officer. On a march, Field-officers and Non-commissioned Staff-officers in arrest follow in rear of their respective regiments. Company officers and Non-commissioned officers in arrest follow in the rear of their respective companies, unless otherwise specially ordered. An officer under arrest does not wear a sword, or visit officially his Commanding or other Superior Officer, unless sent for. In case of official business he makes known his object in writing. Whenever officers are ordered in arrest, or for trial, from their proper stations to other military posts, they may, during the time they remain at such posts under arrest, awaiting trial or sentence, be allowed to occupy public quarters provided there are any vacant that can be assigned to them without infringing upon the rights of other officers regularly stationed on duty at the post. Under these circumstances they forfeit any and all claims they may have had to quarters in kind, or commutation therefor elsewhere. See *65th Article of War.*

ARRESTE OF THE GLACIS.—In fortification, the junction of the talus which is formed at all the angles.

ARREST IN ORDER OF TRIAL.—Before an officer or soldier, or other person subject to military law, can be brought to trial, he must be charged with some crime or offense against the Rules and Articles of War, and placed in arrest. The Articles of War direct that whenever any officer shall be charged with a crime, he shall be arrested and confined in his barracks, quarters or tent, and deprived of his sword by the Commanding Officer. And that "Non-commissioned officers and soldiers, charged with crimes, shall be confined until tried by a Court-Martial, or released by proper authority." The arrest of an officer is generally executed through a Staff-Officer; by an Adjutant, if ordered by the Commanding Officer of a regiment; or by an officer of the General Staff, if ordered by a Superior Officer; and sometimes by the officer with whom the arrest originates. On being placed in arrest, an officer resigns his sword. If this form be sometimes omitted, the custom is invariably observed of an officer in arrest not wearing a sword. By the custom of the army, it is usual, except in capital cases, to allow an officer in arrest the limits of the garrison or even greater limits, at the discretion of the Commanding Officer, who regulates his conduct by the dictates of propriety and humanity. A Non-commissioned officer or soldier is confined in charge of a guard; but, by the custom of the service, the Non-commissioned Staff and Sergeants may be simply arrested. The Articles of War declare "that no officer or soldier who shall be put in arrest or imprisonment shall continue in his confinement more than eight days, or until such time as a Court-Martial can be conveniently assembled." The latter part of this clause evidently allows a latitude which is capable of being abused; but, as in a free country there is no wrong without a remedy, an action might be brought against the offender in a Civil Court, if the mode of redress for all officers and soldiers who conceive themselves injured by their Commanding Officer be not sufficient.

It is declared by the Articles of War that "no officer commanding a guard, or Provost-marshal, shall refuse to receive or keep any prisoner committed to his charge by any officer belonging to the forces of the United States: provided, the officer committing shall, at the same time, deliver an account in writing, signed by himself, of the crime with which the said prisoner is charged;" and it is also declared that "no officer commanding a guard, or Provost-marshal, shall presume to release any prisoner committed to his charge without proper authority for so doing, nor shall he suffer any person to escape, on the penalty of being punished for it by the sentence of a Court-Martial. Every officer or Provost-marshal to whose charge prisoners shall be committed shall, within twenty-four hours after such commitment, or as soon as he shall be relieved from his guard, make report in writing, to the Commanding Officer, of their names, their crimes, and the names of the officers who committed them, on the penalty of being punished for disobedience or neglect, at the discretion of a Court-Martial." Thus the liberty of the citizen under military law, so far as is consistent with the ends of justice, seems to be guarded with precautions little inferior to those which secure personal liberty under the civil laws of the State. The penalty of an officer's breaking his arrest, or leaving his confinement before he is set at liberty by his Commanding Officer, or by a Superior Officer, is declared to be cashiering by sentence of a General Court-Martial. A Court-Martial has no control over the nature of the arrest of a prisoner, except as to his personal freedom in Court; the Court cannot, even to facilitate his defense, interfere to cause a close arrest to be enlarged. The officer in command is alone responsible for the prisoners under his charge. Individuals placed in arrest may be released, without being brought before a Court-Martial, by the authority ordering the arrest or by superior authority. It is not obligatory on the Commander to place an officer in arrest on application to that effect from an officer under his command. He will exercise a sound discretion on the subject. But in all applications for redress of supposed grievances inflicted by a Superior it will be his duty, in case he shall not deem it proper to order an investigation, to give his reasons, in writing, for declining to act; these reasons, if not satisfactory, the complaining party may, should he think fit so to do, forward to the next Common Superior, together with a copy of his application for redress. An officer has no right to demand a Court-Martial, either on himself or on others; the General-in-Chief or officer competent to order a Court being the judge of its necessity or propriety. Nor has any officer who may have been placed in arrest any right to demand a trial, or to persist in considering himself under arrest, after he shall have been released by proper authority. An officer under arrest will not make a visit of etiquette to the Commanding Officer or other Superior Officer, or call on him, unless sent for; and in case of business, he will make known his object in writing. It is considered indecorous in an officer in arrest to appear at public places.

ARRICK PROJECTILE.—This projectile consists of a cast-iron body having a conical base, to which is attached a sabot combined of an annular key and a concave and convex disk. Upon discharge, the ring is flattened out against the base of the projectile, and



Arrick Projectile.

takes the impression of the grooves, communicating rotation to the projectile; at the same time the annular key is driven forward upon the base, filling the space between the projectile and the lands, and is claimed to center the base of the projectile. The sabot is prevented from turning on the projectile by a series of flanges cast on the base, which fit into recesses on the sabot, and from stripping by means of a strong bolt screwed into the base of the shot. See *Expanding Projectiles.*

ARROW.—1. In fortification, a work placed at the salient angles of the glacis, communicating with the covered-way. 2. A missile weapon of defense, straight, slender, pointed, and barbed, to be shot with a bow. See *Archers.*

ARROW-POISONS.—The ingredients selected for the preparation of toxic compounds vary greatly in different localities, vegetal poisons predominating in the warmer regions, while the organic are preferred in the colder latitudes. This is attributable to the fact that poisonous plants are scarce in the northern portions of the continents, and that organic poisons deteriorate rapidly in the tropics. There are numerous instances also in which the alleged poison is of the most harmless nature, the belief in its potency being based mainly upon the amount of dancing and deviltry performed by an awe-inspiring Shaman. The first group, to which reference will be made, consists of three poisons prepared by the Moqui of Arizona. The first of these is called Ti-ki le-li-wi—poison-ointment. Poison given internally to cause death, whether in powder or liquid, has no definite name beyond its being "bad medicine." The "poison-ointment" is prepared in this wise: A rattlesnake is tormented until it bites itself, when the Priest of the "Snake Order" dips the arrow-point, as well as a short portion of the shaft, into the blood obtained from the serpent. It is stated that a wound from such an arrow will cause death in from three to four days under ordinary circumstances, and in a much shorter time if the victim has been fasting for a day or two, a condition in which an Indian is frequently found even in times of peace. The second variety is prepared from the humble-bee, which, after being maddened by being disturbed in the nest and struck at by withes and branches, is killed. The insects are then gathered and crushed in a primitive stone mortar, where the mass is thoroughly macerated, after which the arrows are anointed in a manner similar to the preceding. Wounds are not liable to cause dangerous results, although they become exceedingly inflamed and very painful, the effects being attributable to the presence of formic acid. The third variety is prepared by crushing a number of large red ants—a variety found all over the northern elevated areas—in a similar manner as the preceding, and in which the arrows are dipped. This poison is not necessarily a fatal one, though instances have been given on "Indian authority." The Indians state that if a man be wounded with an arrow freshly poisoned he will be debilitated (after the first symptoms of excitement are over), from which he may not recover for several weeks or perhaps a month. The last two substance may be prepared by any one of the tribe, as they are used in hunting, but the first named is prepared only, as has been stated, by the Priest of The Snake Order, and is used in warfare with neighboring Indians only. The Apaches, occupying the habitable areas of Arizona, immediately south of the Moqui Pueblos, prepare a poison composed of the venom of the rattlesnake mixed with the decomposed liver of a deer or antelope. A rattlesnake is searched for at one of the prarie-dog towns, and when discovered is secured to the ground by means of a forked stick so as to prevent its escape and yet not to injure it. An assistant then pierces a deer's liver, which has been procured for the purpose, and upon inserting a short pole, thrusts it toward the serpent, who repeatedly buries its fangs. In this manner the venom is secured, and when the snake refuses to bite again it is destroyed. The liver is then placed upon a tall, upright pole, where it is allowed to decompose, after which it is crushed in a small dish, when the arrows are dipped into the mass and allowed to dry. Poisoned arrows are carried in double quivers, and tied together with a black band or piece of cloth to distinguish them from harmless ones. Serpent-venom is employed by the Siris of western Sonora. After a small excavation has been made in the ground a cow's liver is introduced together with centipedes, scorpions, and a rattlesnake. After teasing these creatures for a while with the hope that the liver might receive most of the venom discharged during their angry struggles, it is removed and crushed into a jelly, into which the arrows are dipped.

Apache arrows which have been properly besmeared with poison are readily distinguished from the ordinary weapons by the dark reddish-brown coating over the anterior portion of the shaft immediately back of the arrow-head. The latter also presents the same appearance at times, though were this the only portion to which poison had been applied there would be difficulty in identification, as the arrow-points are generally secured to the end of the shaft by the liberal application of mesquite-gum, after which the sinew-threads are applied for greater security. The Shoshone and Bannock Indians of western Nevada prepare poison in the following manner: An antelope or a deer is entrapped or caught by wounding it, when a rattlesnake is brought and made to bite it. The animal is immediately killed and the blood collected in a vessel procured for the purpose. Into this the arrows are dipped and afterward allowed to dry, when they are ready for use. It is probable that the snake-venom exerts no influence in this instance, as the amount absorbed into the system of the animal between the moments of being bitten and killed would be very slight indeed. The Pah-Utes, just south of the Shoshones, remove the heart of a large mammal and place it into a corresponding cavity in the ground. Rattlesnake-fangs, with the poison-sacs, are then ground into a pulp, with a horned toad or two, which mass is then emptied into the cavity of the heart and allowed to decompose. The whole mass is said to dry into a tough mass resembling caoutchouc. This is finally cut into small pieces. In poisons prepared by the combination of serpent-venom and decomposed organic matter it is not positively known which, if not both, of the substances acts as the toxic agent. Cases thus far observed or recorded have resulted in septicæmia and death. One in particular, a mere scratch upon the shoulder-blade, died in great misery in less than a week, though not before the flesh had literally dropped from the back as far down as the hips. It is probable that the septic poison of the organic matter remains active for a greater period of time than the serpent-venom, being favored by immediate drying in the drier atmosphere of the extreme western plateaus. Dr. S. Wier Mitchell's experiments do not demonstrate to what length of time serpent-venom may be kept in a dried state and retain its virulence. The active principle (crotaline) may remain active under favorable conditions for an indefinite length of time, but then the symptoms would be exhibited in a manner strikingly similar to those after a fresh wound inflicted by the serpent, which thus far has not been observed. Professor F. V. Hayden and Colonel James Stevenson have both observed the Blackfeet and Assiniboine Indians procure the pure serpent-venom by causing a secured snake to bite a clean piece of bark. The arrows were applied directly to this without the admixture of any other substances. Curious superstitions exist in connection with this strange custom among various tribes. An intelligent Sisseton Dakota states that his father had been a great Shaman in his time and knew all the "secrets of the plants." He had a poison which, if rubbed upon a bullet, would cause the bullet to strike the desired object if the gun was merely held in the direction without regard to accurate aim. Though, if the hunter had once raised his weapon and failed to shoot, the bullet would be worthless unless again handed to the Shaman. Another mode of preparing bullets was by drilling small holes into them with the point of a knife, into which was spread a paste made of the bark-scrapings of the cactus (*Opuntia Missouriense*). The Pitt River Indians prepare, at times, a mixture of the juice of the wild parsnip and the decomposed liver of a dead dog. This is also practiced by neighboring tribes in California, although the custom appears to have originated with the former, as far as can be ascertained at this day. Among the southern Esquimaux the body of a dead whaler is cut into small pieces and distributed among his friends who are of the same profession, each of whom, after rubbing the point of his lance upon it, dries and preserves his piece as a sort of talisman. The Kiatera-mut, a tribe of the same stock, believe that to be successful in whale-hunting the body of a whaler must be procured by murdering him, when the fatty portions are removed from the body and boiled, carefully skimming off such fragments as may form a scum, which are then allowed to become putrid. The points of the weapons are greased with this substance, which is considered to give them unfailing success in hunting, both afloat and on shore. Numerous substances of a questionable character are found in all tribes, but their efficacy, in the cases for which they are recommended, can never be ascertained, as an Indian will not admit a failure so long as he can escape detection.

ARROW-WOOD.—A species of *Viburnum*, from the long straight stems of which the Indians dwelling between the Mississippi and the Pacific make their arrows.

ARSENAL.—The name given to a great military or naval repository, where the munitions of war are to some extent manufactured, but more particularly stored until required for use. Every dockyard, every magazine, every armory, is to some extent an Arsenal; and therefore the meaning of the word is not quite definite. In France, the chief Arsenals are at Cherbourg, Brest, and Toulon. In England, although Deptford is a considerable storehouse for naval clothing and provisions, and Weedon and the Tower great repositories for military stores, the only establishment vast enough to deserve the name of Arsenal is at Woolwich. This is truly a remarkable and important place. In the spring of 1859, when war was raging in Italy between the French and Sardinians on one side, and the Austrians on the other, and when an uneasy feeling pervaded the whole country, there were for a short time more than 10,000 men employed in Woolwich Arsenal. There were at that time nearly 12,000 pieces of iron ordnance in store, of which 7000 were of modern make and of heavy caliber. This store was supplementary to that which is always kept at the dockyards of Woolwich, Chatham, Sheerness, Portsmouth, Plymouth, and Pembroke. There were resources at the Arsenal for bringing forward, fitting, and issuing these reserve guns at the rate of 200 per week, or double this number on an emergency; and many hundreds were within a brief period shipped thence, to strengthen the forts in the Mediterranean, in the Colonies, and around the coasts. All the shot and shell used down to the period of the Crimean War were ordered of private makers; but the charge was so enormous during the early months of that war that the government resolved to try the manufacture at Woolwich; this was done, with a very manifest saving of expense. It has been calculated that the Arsenal, when at full work, could produce large shot and shell with six times the rapidity with which those missiles were used by the British outside Sebastopol during the eleven months' siege. These observations do not apply to rifles or muskets; none of these weapons are made at Woolwich. There have been times, however, during the year 1859, when nearly a *hundred million* rifle-bullets were in store at the Arsenal. The Arsenal is divided into two great sections, of which the one is the depot for the storage of arms and all military equipments, whether for land or naval service; the other being occupied by the manufacturing departments. The latter comprise the Gun Factories, where all cannon are made; the Carriage Departments, for gun-carriages and all means of transport; and the Laboratory, whence come all cartridges, shot, shell, bullets, and warlike weapons.

In the United States, Armories and Arsenals were not established until after the Revolutionary War; but powder was manufactured in Virginia in 1776. General Washington chose Springfield, Mass., in 1777, as a suitable location for an Arsenal, and small-arms were manufactured before 1787; an Arsenal was also built in Carlisle, Pa., about the same time. The erection of an Armory was begun at Harper's Ferry in 1795, and Congress ordered three or four more to be built in the same year, still more in 1808, and again after the War of 1812, Congress adopted the plan of having an Arsenal in each State. In 1847 the United States had 2 Armories and 17 Arsenals; in 1860, 23 in all, 9 of which were enlarged during our Civil War, the Springfield Armory alone having capacity to complete 1000 muskets per day. The late General Rodman, in connection with the Ordnance Department, made great improvements in the art of casting cannon cooled from within, and the introduction of mammoth grain powder for use in large guns is due to him. Recently it has been decided to concentrate all manufacture of arms in three or four places, where all the regular operations are to be carried on.

The Arsenals and Armories now established are as follows, to wit: Benicia Arsenal, Benicia, Cal.; Kennebec Arsenal, Augusta, Me.; Watertown Arsenal, Watertown, Mass.; Fort Union Arsenal, N. M.; Springfield Armory, Springfield, Mass.; Watervliet Arsenal, West Troy, N. Y.; Indianapolis Arsenal, Ind.; New York Arsenal, Governor's Island, New York Harbor; Pikesville Arsenal, Pikesville, Md.; Rock Island Arsenal, Ill.; Frankford Arsenal, Philadelphia, Pa.; San Antonio Arsenal, Tex.; Washington Arsenal, Washintgon, D. C.; Fort Monroe Arsenal, Old Point Comfort, Va.; Augusta Arsenal, Augusta, Ga.; Jefferson Barracks Arsenal, Mo.; Vancouver Arsenal, Vancouver, W. T.; Allegheny Arsenal, Pittsburg, Pa.

The principal manufacturing operations of the Ordnance Department are now performed at the following Arsenals, to wit: Watertown, engaged in the production of sea-coast carriages and projectiles for heavy guns; Springfield Armory, in the manufacture of small-arms; Watervliet, in the manufacture of leather-work; Frankford Arsenal, in small-arm ammunition; and Fort Monroe Arsenal, in sea-coast carriages and on experimental duties. The remaining Arsenals are either engaged in small repairs or are simply storage-depots for the care and preservation, issue and receipt, of ordnance and ordnance-stores. It is believed that, except small-arms and small-arm ammunition, the more important ordnance and ordnance-stores, more especially those for field and siege artillery, and those to be provided for the use of our sea-coast defenses, such as cannon, heavy sea-coast carriages, projectiles, and ammunition, and other stores and appliances for their service and maneuver, also harness and the more elaborate articles of leather-work, should all be made at one grand Arsenal of Construction. See *Armory*.

ARSENIC.—The name applied in popular language to a well-known poisonous substance, arsenious acid; but, strictly speaking, the term is restricted to the metal, of which the symbol is As and the equivalent is 75.0. The metal arsenic is rarely found free in nature, but in a state of combination it occurs largely. The metal is generally prepared from arsenious acid (AsO_3) by mixing it with its own weight of charcoal, placing the mixture in a well-covered crucible, and subjecting the whole to heat, when the metal set free by the charcoal rises, and condenses in the upper part or cover of the crucible. Metallic arsenic is very brittle, can easily be reduced to powder by hammering, or even pounding in a mortar; and when a freshly-cut surface is examined, it presents a brilliant dark steel-gray luster, which, however, readily tarnishes on exposure to the air. The metal, as such, is not considered poisonous; but when introduced into the animal system, it is there faintly acted upon by the juices, and in part dissolved, at the same time exhibiting poisonous properties. When heated in the open air, it burns with a peculiar bluish flame, and emits a characteristic alliaceous odor. The only use to which the metal arsenic is applied in the arts is in the manufacture of leaden shot of the various sizes, when its presence in small quantity in the lead renders the latter much more brittle than it ordinarily is. Of all the compounds of arsenic the most important is the one already alluded to, viz., arsenious acid, which is an oxide of arsenic. With sulphur, arsenic forms two important compounds: *realgar* (AsS_2), a red, transparent, and brittle substance, which is employed in the manufacture of the signal-light called *White Indian Fire;* and *orpiment* (AsS_3) or *king's yellow*, a cheap pigment of a yellow color. With hydrogen, arsenic forms arseniuretted hydrogen (AsH_3), a very poisonous gas.

ARTESIAN WELLS.—The Artesian Well so frequently sunk by the Military Engineer has of late been the subject of several special reports from the office of the Chief of Ordnance, United States Army. Usually they are perpendicular borings into the ground, through which water rises, from various depths, according to circumstances, above the surface of the soil. The possibility of obtaining water in this way in a particular district depends on its geological structure. All rocks contain more or less water. Arenaceous rocks receive water mechanically, and according to their compactness and purity part with a larger or smaller proportion of it. A cubic yard of pure sea-sand can contain, in addition to the quantity of dry sand which occupies that space, about one third of its bulk of water. It would part with nearly the whole of this into a well sunk in it, and regularly pumped from. Chalk and other rocks, composed of fine particles, closely compacted together, contain as large a proportion of water. From the existence, however, of numerous crevices in chalk through which the water freely flows, and from the general presence of a larger quantity of water than the porous rock is able to retain, wells sunk in chalk often yield water. There is yet a third class of rocks, which are perfectly impervious to water: such are clays, which are absolutely retentive, neither allowing water to be obtained from them nor to pass through them. When such rocks occur in basins in alternating layers, and in such order that pervious beds are inserted between impervious ones, it is evident that if a perforation is made through the retentive barrier-bed in the lower portion of the basin, the water contained in the water-logged strata will rise through the bore to a height depending upon the pressure of water which has accumulated in the confined sloping space between the two impervious beds. There is a number of porous beds composing the cretaceous measures, resting on the impervious gault, and these, again, are covered by the equally impervious series of the London clay, which form the strata on the surface, and extend to a considerable depth. The edges of the chalk-beds are largely exposed in the higher grounds around London; the water falling on the whole area of these exposed edges, sinks into the more or less porous cretaceous beds, and would, in course of time, by continued accessions, fill up the basin, were it not prevented by the clay above. By driving a bore through this superior bed, the inferior water-logged strata are reached, and the subterranean water rises to the surface, and flows continuously, by means of hydrostatic pressure. Many such Wells exist in London and its vicinity; those which form the ornamental fountains in Trafalgar Square descend into the upper chalk to a depth of 393 feet. The most famous Artesian Well, perhaps, is that of Grenelle, in the outskirts of Paris, where the water is brought from the gault at a depth of 1798 feet.

In California, Colorado, Idaho, and other Western States, wells are largely used for irrigation, and for supplying water at Military Posts, inasmuch as there are no rains, during certain seasons, in those localities. There are over 1000 of these wells in California alone, most of which are flowing. Since 1855, there have been 76 flowing wells sunk in the Desert of Sahara, Africa, yielding over 13,000,000 gallons of water daily. Since then, a beautiful oasis has been formed around each well, literally "making the desert to blossom as a rose."

In 1851 London had Artesian Wells that supplied over 12,000,000 gallons of water daily. The well at Trafalgar Square, 393 feet deep, is said to yield 600,000 gallons of water per day. One at the Government Works in Orange Street yields a larger amount. Hughes writes that a well at Woolwich, 580 feet deep, yields 1,400,000 imperial gallons in 24 hours, and another near London, only 171 feet deep, yields nearly 2,500,000 gallons per day. Wells in the county of Kent, near London, in 1867 furnished 7,000,000 gallons per day, which was distributed to 34,504 houses with a population of 240,000. In the year 1854, the "Bootle Well" in Liverpool yielded 1,100,000 gallons in 24 hours.

The following is a synopsis of a few of the most noted deep wells:

Wells.	Finished.	Depth in feet.	Capacity gallons per day.
Grenelle. Paris	1841	1,792	500,000
Passey, France	1860	2,000	5,660,000
Kissengen, Bavaria	1850	1,878½	1,077,000
Spermberg, Prussia		4,170	
Belcher's Sugar-house. St. Louis		2,199	108,000
Insane Asylum, St. Louis		3,843½	
Louisville, Kentucky		2,066	330,000
Terre Haute, Indiana		1,900	
Near Lake Charles, Louisiana		440	93,600
Columbus, Ohio		2,775½	
Charleston, South Carolina		1,250	
New Orleans, Louisiana		630	
United States Mint, Philadelphia		458	90,000
Continental Hotel, Philadelphia.		206	72,000
City of Waukegan, Illinois	1875	1,110	300,000
National Rubber Co., Bristol R. I.	1880	35	300,000

The Pierce Well-Excavator Company, New York, are the contractors with the United States Government, and are at present sinking a deep well at David's Island, New York Harbor. After noticing the important details of the well-boring machinery, we will briefly describe the manner in which this Company drills an Artesian Well. Before designing and introducing their highly improved machinery, Artesian Wells in this country were sunk with what is termed walking-beam machines—that is, such machines as have been and are now used in the oil regions of Pennsylvania for drilling oil-wells. Such an apparatus weighs from 15 to 20 tons. The derrick is usually built 72 feet high. An engine and boiler of about 15 to 20 horse-power is required to operate such a machine. The derrick must be built and taken down for every well. Setting up a walking-beam machine and getting ready to work requires the labor of four men from two to three weeks to build the tower, set the engine and boiler, and get ready for work.

In the following drawing, Fig. 1 shows a *rope-socket* of a new pattern. A double reamer is sometimes used with the drilling-machine, for straightening crooked holes, but the *reamer* shown in Fig. 2 is most commonly used for trimming a flat hole and making it round and straight. Fig. 3 represents a *wedge* or *club bit*, also used for drilling hard rock. The *Z-bit*, Fig. 4, is a combined wedge bit, reamer and double reamer, and with it all the different kinds

Fig. 1.

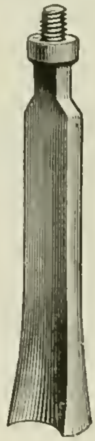


Fig. 2.

Fig. 3.

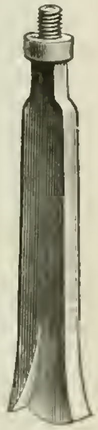

Fig. 4.

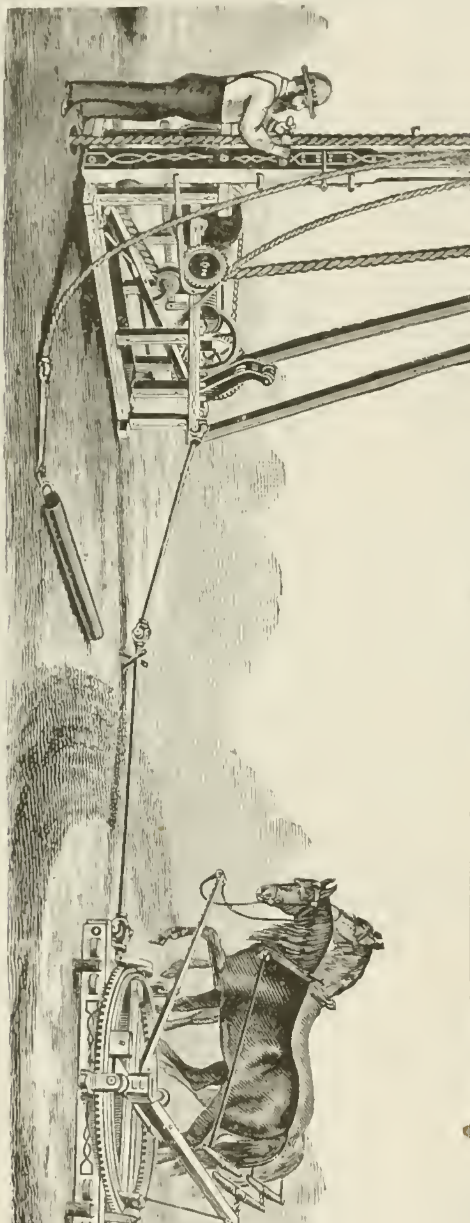
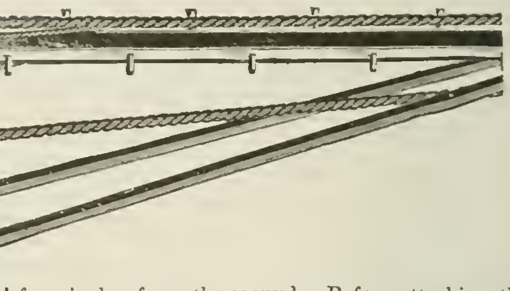
of work can be done, i.e., drilling rock, earth or sand, and crooked or flat holes can be made straight and round with it. The rods break in drilling, and for raising the portions broken off various ingenious devices, known as *slip-sockets*, *horn-sockets*, *pin-sockets*, *grabs*, *rope-spears*, *rope-knives*, *rope-grabs*, *boot-jacks*, etc., have been contrived. The *slip-socket*, shown in Fig. 5, and the *grabs*, shown in Fig. 6, are most commonly used as fishing-tools for recovering bits, drilling-tools, bars of iron, or other things that might accidentally or carelessly be dropped or lost in the drilled hole. The success of an Artesian Well depends much upon the proper selection of pipe for the well-tubing. Heavy lap-welded wrought-iron pipe, $\frac{5}{16}$ inch thick, with screw and collar connections, is best adapted to Artesian Well work. This pipe is used to drive through sand, clay, or other earth formations until solid rock is reached; the drilling is then continued in the rock, no pipe being required. All other pipe, usually $\frac{1}{4}$ inch thick, is used for casing wells after they have been drilled to the required depth and it is necessary to case off salt or mineral waters. Fig. 7. shows a cement or terra-cotta pipe or tile that is used in bored wells. These pipes are one to two inches thick, and can be had in almost all countries from 2 to 30 inches in diameter. For bored wells 8 to 12 inches internal diameter is preferable. The joints can be made water-tight by using hydraulic cement, and by this means brackish or surface water and foul drainage can be entirely avoided, which is of vast importance in most places, often preventing sickness and many fatal diseases. Fig. 8 represents a style of punched, rolled and fitted sheets of iron, that can be used to advantage for well-casing, water-pipes, and many other purposes. This is a desirable style when transportation is an object, as the piping can, in all sizes of common or galvanized iron, be

Fig. 5.

Fig. 6.

nested and packed very close, in rolls weighing from 100 to 300 pounds, and fitted either with flange, sleeve and nipple, or lug slip joints. When it is desired to use wood casing for drilled wells it is well to make the strips quite narrow, and if the casing is to be driven very hard it will facilitate the work by putting a hoop around the bottom or making a sheet-iron band, 4 or 6 inches wide, and riveting it around the bottom section to prevent jamming or spreading.





Drilling an Artesian Well—Pierce Well-Excavator Company.

In drilling the well, we will suppose the earth above the rock to equal or exceed 50 feet. Having located the site, set the drill-jack and horse-power in position, as shown in the accompanying engraving. The horse-power may be used on either side of the jack. Care must be taken to set the drill-jack so that when the drill, etc., are hung up on the machine they will hang parallel with the mast. Use the longest piece of tumbling rod on the ground next to the horse-power. This can be laid over two stakes driven in the ground crosswise, thus: ×, or on a block of wood near the center joint. This lies about four inches from the ground. Before attaching the horses the bull-wheel should be turned over with the cogs upward, and every cog on the large bull-wheel ring should be rubbed full of soft tallow or common axle-grease. Stake the horse-power down very firm and solid, attach the horses to the horse-power, and walk them around it for half an hour, or until they get accustomed to the motion of the power and to walking in a circle. Next attach the tumbling-rods, start the horses very slow and steady until they get used to the revolving of the tumbling-rods and the main shaft of the machine, then pass the drill-rope from the spool down under the roller at the foot of the mast, then through the pulley of the drill-lever, then over the top of mast-pulley and down to the ground. Screw the Z-bit into the auger-stem, to which

Fig. 7.

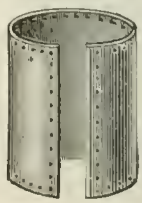


Fig. 8.

also screw the rope-socket, tie the end of the rope very securely into the rope-socket, place the crank on the ratchet-wheel shaft, and wind the tools up so they will swing above the ground. Oil every pulley, journal, or bearing about the machine, where there is any friction; also every link in the winding-chain. The pulley in the mast-head and the pinion-wheels of the horse-power should be well oiled every two or three hours. When the well is to be drilled through earth, throw out about one foot in depth with a shovel. If the ground is frozen this can be done with a drill, the same as if rock. Throw two buckets of water in the hole. Put the swiveled pulley on the drill-lever at the hole nearest to the front of the machine, so as to get the shortest stroke in starting. Let the horses walk around slowly and steadily at first, then push the lever-catch shifter at the left-hand side of the bottom of the machine. This will release the drill-lever, and the drill will work up and down.

The man in charge of the machine must turn the drill around about one fifth of a revolution every stroke. As the drill chops the clay or earth, and mixes it into the consistency of mush or soft mud, the drill can be lowered gradually by raising the pawl of the ratchet-wheel. Let the ratchet-wheel move one notch at a time, as one notch of the ratchet-wheel allows the drill to settle about an eighth of an inch. After the drill has worked down about two feet, the lever-catch shifter at the left-hand side of the machine is then raised and drawn forward with the left foot. This causes the catch to hold the drill-lever down, and the churning motion of the drill is stopped. Then throw the clutch-lever (on the left-hand side of the jack) outward from the machine; this throws the clutch in gear, and the drilling-tools are raised from the well. When the tools are raised to a proper height and out of the hole, throw the clutch out and let a sand-pump down to the bottom of the hole, and churn up and down very quickly, about four inches, twenty times. This will fill the sand-pump. Then bear down on the belt-tightener and the machine will raise the sand-pump out. Repeat this two or three times, then throw in two more buckets of water. Let the drill down in the hole by raising the pawl of the ratchet-wheel up hard against the rim of the ratchet-wheel, to let the ratchet-wheel turn by friction against the arm of the pawl. This lets the drill down to the bottom of the hole. Then continue the churning of the drill as before. Every time the hole is sand-pumped more water should be thrown in. After a depth of ten feet is drilled, four feet in depth of water may be kept in the hole.

The drilling may be continued in this manner until the rock, gravel, or quicksand is reached. If the latter fills the hole as fast as taken out, a tube can be made out of boards 6 inches in diameter for very short distances, or piping can be used, where the depth of gravel, etc., above the rock is more than 25 feet. This is placed in the drilled hole, and driven down through the stratum of sand or gravel by using the auger-stem (or drill-rod) for a driver. A hole 7 or 8 inches in diameter can be easily drilled in earth with a 6-inch Z-bit, by using plenty of water and swaying the drill-rope a little each way as the drill makes its downward stroke. When the rock is reached the hole can be cleaned out with the sand-pump, and the hole is of proper size to guide the tools in drilling the rock. The drilling can then be continued to any required depth, care being taken to keep the bit an eighth of an inch smaller than the internal diameter of the pipe. The process of drilling in solid rock is very simple, care only being taken to keep the drill-bit full size, not feeding the drill down too fast, keeping the rope tight, and drilling on what is called the "spring of the rope," thus making a straight hole. Have 3 to 6 feet of water in the hole while drilling, turn the drill six to eight times in one direction, about one fifth of a revolution each stroke, then backward to cause the drill to cut a round hole.

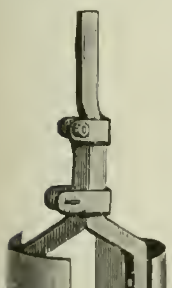

Fig. 9.

In drilling wells for water, where 5 to 10 barrels of water per day is required, it is usually necessary to continue the drilling until there is from 10 to 20 feet of water in the drilled hole. If 50 or 100 barrels of water per day is needed, usually a depth of 30 or 40 feet of water will furnish the required amount. The capacity of the well can be tested with the machine any time by the use of the sand-pump, as it can be filled and emptied three to four times per minute; it holds from three to five gallons of water, and a continued use of same for one or two hours will show the capacity of well. If it runs into the well as fast as taken out, it will not be necessary to continue the drilling any farther. For prospecting for mineral, oil, or coal, the drilling may be continued if there should be 100 to 500 feet of water in the hole. The drilling is done the same as if there was no water, with the advantage that it is not necessary to throw any in the hole. The sand-pump works the same in a great depth of water as it would if there was but 6 feet of water. If it is desired or necessary to make the well as economically as possible, pipe can be used, made of sheet-iron about $\frac{1}{16}$ inch in thickness, a half-inch smaller than the drilled hole. This usually costs, or can be made, for 20 cents or 30 cents per foot. This pipe is used by placing it in the hole, so the bottom end of it will come about 4 feet below the bottom of the heavy pipe that was first used. If it is necessary to shut off sand, the bottom end of this pipe may be flanged outward a little, and a few buckets of cement thrown down outside of the pipe, which settles around the pipe above the flange, and the result is that a water-tight connection is made with the rock. This effectually shuts off all surface-water or sand. The drilling can be commenced in the bottom of an old well, without removing the stones, or interfering with the walls, or getting into the well, in which case a common square wood box, 6 inches inside, can be used in the bottom of an old well for a guide to start the tools straight. If this machine is used, it is not advisable to use an excavator or boring tools in earth above the rock, as this machine will drill in earth as rapidly as boring can be done with the excavator or borer.

An enlarged view of the well-auger invented and used by the Pierce Well-Excavator Company is shown in Fig. 9. The most practical size is 12 to 17 inches in diameter, and with reamer attachment will bore a 24- to 36-inch hole. The peculiar shape and construction of this patent borer enables it to bore through frozen ground, hard-pan, or slate, as well as clay and gravel. Side-draught is impossible. The cutters penetrate with a draw-cut, making a straight hole. The outer corners of the cutters being farthest from the center, no friction can come upon the sides of the borer. The pods or barrel of the auger being 2 inches less in diameter than the cutters, air and water pass behind them, avoiding suction when raising the borer from the well. This borer has all the combined advantages of a clay- and boulder-auger, as it will take up stones half as large as the diameter of the hole, and wells can be put in without the aid of other tools or attachments for boring. All of the above points are essential in a successful well-boring tool. Before the invention of these augers, borers were made for the same purpose, constructed in such a manner that when filled with earth the hole was entirely filled, and they could not be withdrawn without great suction, as the air and water could not pass below the auger when withdrawing it from the hole. Pipes and tubes have been used for air-passages in earth-borers, but they were failures, as they became clogged with mud. See *Well-boring.*

ARTICLES OF WAR.—There can be no doubt that the prerogative to command and regulate the whole military force of the kingdom, whether consisting of the feudal tenants, or of the militia, or of paid troops, resided in the Crown of England. Nevertheless the power of the Sovereign was restricted by a provision that he should exercise his military jurisdiction only "according to the laws and usages of the realm." In the reign of Edward VI., however, Parliament asserted authority over military matters by passing an act for the government of the army; various offenses, as losing, selling, or fraudulently exchanging horses or armor; desertion; detaining the pay of soldiers; and taking rewards for granting them discharges, were put under the jurisdiction of the Civil Magistrate. It was also provided that the Act should be read once a month by every Field-Officer to the soldiers under his command, and once a quarter by the Governor or Captain of every garrison or fortress. At this period, however, there was no standing army, the feudal system was still in force, every man in the realm was more or less a soldier; military law was accordingly restricted to such persons as were actually serving in the field, the process of civil judicature being obviously inapplicable to their case—but directly the soldier ceased to belong to the force in actual campaign, the civil power stepped in and claimed cognizance of his offenses.

Until the Civil War in the reign of Charles I., it is probable that no regular permanent Code of Rules or Articles for enforcing military discipline was in existence; the ruling authority had promulgated its orders for the government and regulation of the army as occasion required. Each war, each expedition, had its own edict, which fell into disuse again upon the disbanding of the army, which inevitably followed the cessation of hostilities. The experience of ages and the precedents of former wars, therefore, enabled the authorities to frame a sufficiently comprehensive code in case of need; accordingly, soon after the outbreak of the Civil War, the necessities of the case compelled the Parliament to enact Ordinances or Articles of War. The first complete "*Lawes and Ordinances of Warre*" (as he called them) were issued by Essex, the Commander-in-Chief of the Parliamentary Army in 1642. These Articles are remarkable and interesting, as undoubtedly forming the groundwork of those now in use. Two years after the publication of Essex's Ordinances, on the marching of the Scottish army into England, soon after the ratification of the solemn league and covenant, "Articles of War" were issued for its government. These Articles, although very dissimilar to those of Essex, considering that both were in force in the same kingdom at the same time, and were applicable to armies fighting on the same side, nevertheless treat mainly of the same offenses. The form of judicature established consisted of two Courts of Justice, called "Councils of War," the one superior and the other inferior. The Superior Court, also called the "Court of War," took cognizance of the more serious offenses, and likewise heard appeals from the decision of the Lower Court, called the "Martial Court." No trace of the constitution of these Courts is now to be found except that "the Judges were sworn to do justice." Within a few months of the promulgation of the latter (August, 1644), the same Parliament that was the author of the petition of right passed an ordinance establishing a system of martial law, applicable not only to soldiers, but to all persons alike. By this Ordinance, the Earl of Essex, Captain-General of the parliamentary forces, together with fifty-six others named therein (among whom were peers, members of the House of Commons, gentry, and officers of the army), were constituted "Commissioners," and any twelve of them authorized to hear and determine all such causes as "belong to military cognizance," according to the Articles mentioned in the Ordinance, and to proceed to the trial, condemnation, and execution of all offenders against the said Articles, and to inflict upon them such punishment, either by death or otherwise, *corporally*, as the said Commissioners, or the major part of them then present, should judge to appertain to justice, according to the measure of the offense. Under cover of this ordinance, which, after one refusal by the peers, was subsequently renewed, Parliament proceeded to issue a variety of orders for the conduct of the war and the regulation of the army; and many persons were tried by Court-Martial and executed. After the expiration of this last ordinance, the absolute executive power, in all matters of military law, fell into the hands of Cromwell, who claimed it as his right, in virtue of his office of General-in-Chief. "The General," says Whitlocke, "sent his order to several garrisons to hold Courts Martial for the punishment of soldiers offending against the Articles of War; provided that if any be sentenced to lose life or limb, then they transmit to the Judge-Advocate the examinations and proceedings of the Court-Martial, that the *General's* pleasure may be known thereon." On one occasion, deeming it necessary, for the sake of discipline, to make an immediate example, Cromwell seized several officers with his own hand, called a Court-Martial on the field, condemned them to death, and shot one forthwith at the head of his regiment. It will thus be seen that the administration of martial law was almost invariably in the hands of the most considerable power in the State—it alternated between King and Parliament, and between Parliament and Dictator, as each became uppermost in the realm. On the restoration of Charles II., the army, with the exception of about five thousand men, consisting of General Monk's regiment called "the Coldstream," the first regiment of foot, the royal regiment of Horse-Guards, called the "Oxford Blues," and a few other regiments, was disbanded. The force kept on foot was the first permanent military force, or "Standing Army," known in England; and from it the present army dates its origin.

A statute passed in the reign of Charles II., entitled "An Act for ordering the forces in the several counties of this kingdom," recites that, "within all his Majesty's realms and dominions, the sole and supreme power, government, command, and disposition of the militia, and of all forces by sea and land, and of all forts and places of strength is, and by the laws of England ever was, the undoubted right of his Majesty, and his royal predecessors, kings and queens of England." With the exception of some slight encroachment on the part of the Crown, and protests on the part of the Parliament, matters remained in very much the same state till the Revolution, at which period military law assumed a permanent and definite form, as it now exists. The only allusions to the military power of the Crown, in the Bill of Rights, are, "that the raising and keeping of a standing army in time of peace, *without consent of Parliament*, is contrary to law;" and that "subjects, if Protestants, may have arms for their defense, suitable to their condition, and as allowed by law." In the first year, however, of the reign of William and Mary, British regiments, jealous of the supposed preference shown by William for his Dutch troops, mutined at Ipswich. The king suppressed the mutiny with a strong hand, at the same time communicating the event to Parliament. Parliament, anxious to devise means for the convenient application of a code of laws for the regulation and management of the army, and at the same time determined to place a check upon the exercise of the military power of the King, passed, on the 3d April, 1689, for a period of six months only, the first Mutiny Act, the preamble of which is as follows: "Whereas, the raising or keeping a standing army within this kingdome, in time of peace, unlesse it be with the consent of Parlyament, is against law; and whereas it is judged necessary, by their majestyes and this present parlyament that, during this time of warr, severall of the forces which are now on foote should be continued and others raised, for the safety of the kingdome, for the common defence of the Protestant religion, and for the reducing of Ireland. And whereas no man can be prejudged of life or limb, or subjected to any kinde of punishment by martiall law, or in any other manner than by the judgment of his peeres, and according to the knowne and established lawes of this realme; yet, nevertheless, it being requisite for retaining such forces as are or shall be raised during this exigence of affaires in their duty, that an exact discipline be observed; and that soldiers who shall mutiny or stirr up sedition, or who shall desert their majestye's service, be brought to more exemplary and speedy punishment than the usual formes of law will allow." The Act provides for the assembling and constitution of Courts-Martial, for the oath of members, for the punishment of desertion, mutiny, sedition, false musters, etc.; for the regulation of billets; and is ordered to be read at the head of every regiment, troop, or company, at every muster, "that noe soldier may pretend ignorance." No power is, however, reserved to the Sovereign to make Articles of War. This Act was renewed soon after its expiration; and with the exception of about three years only, viz., from 10th April, 1698, to 20th February, 1701, has been annually re-enacted (with many alterations and amendments) ever since.

Under the Constitution of the United States, Congress only can make rules of government and regulation for the land forces, and those rules, commonly called *Articles of War*, were originally borrowed jointly from the English Mutiny Act annually passed by Parliament, and their Articles of War established by the king. The existing Articles for the government of the army of the United States, enacted April 10, 1806, are substantially the same as those originally borrowed July 30, 1775, and enlarged by the old Congress from the same sources, September 20, 1776. The Act consists of but three sections. The first declares: "The following shall be the Rules and Articles by which the *armies* of the United States shall be governed;" and gives one hundred and one articles, all noticed in these pages. Each Article is confined, in express terms, to the persons composing the army. The second section contains the only exception in the cases as follows: "In time of war, all persons *not* citizens of, or owing allegiance to, the United States of America who shall be found lurking, as *spies*, in or about the fortifications or encampments of the armies of the United States, or any of them, shall suffer death, according to the *law and usage of nations*, by sentence of a General Court-Martial." The third section merely repeals the previous Act for governing the army. The Articles of War, therefore, are, and under the Constitution of the United States can be, nothing more than a code for the government and regulation of the army. Or, in other words, within the United States these Articles are "a system of rules superadded to the common law for regulating the citizen in his character of a soldier," and applicable to no other citizens. Beyond the United States another code is essential; for although armies take with them the Rules and Articles of War, and the custom of war in like cases, in a foreign country the soldier must be tried by some tribunal for offenses which at home would be punishable by the ordinary courts of law. It is impossible to subject him to any foreign dominion, and hence, in the absence of rules made by Congress for the government of the army under such circumstances, the will of the Commander of the Troops, *ex necessitate rei*, takes the place of law, and the declaration of his will is called Martial Law. The most casual reader of our Articles of War will be struck by the fact that whereas the Mutiny Act of Great Britain is annually subjected to the supervision of Parliament, and altered or modified according to circumstances, yet the Rules and Articles of War passed in 1806 have remained upon our statute-book from that day to the present without any general revision. Another fact equally important is that while the king of Great Britain not only *commands* but *governs* the British army, and therefore modifies the government of the army at his pleasure, the President of the United States is simply the Commander of our army, under such rules for raising, supporting, governing, and regulating it as Congress may appoint. The necessity of attention to the military establishment on the part of Congress is therefore manifest, and it is most earnestly to be hoped that, in their wisdom, they will, at some early day, fulfill their constitutional obligations of raising, governing, and regulating armies: 1. By establishing a system of recruiting which will bring into the ranks soldiers who will make good officers; 2. By providing that all commissioned officers shall be appointed from enlisted soldiers, or from military academies, and making rules precisely regulating the manner in which such appointments shall be made; 3. In making rules for a system of promotion partly by seniority and partly by merit; 4. In passing other remunerative laws, such as prize-money, field-allowances, indemnification for losses, etc.; 5. In accurately defining the powers, rights, and duties of all officers and soldiers; 6. In providing remedies for wrongs, including appeals to federal civil courts, to determine the true exposition of military laws in dispute; and 7. In revising the penal code, and better adapting it to a system of government which will provide rewards for good conduct, and not simply punishments for bad.

The Armies of the United States are governed by the following Rules and Articles. The word officer, as used therein, is understood to designate commissioned officers; the word soldier is understood to include non-commissioned officers, musicians, artificers, and privates, and other enlisted men, and the convictions mentioned therein are understood to be convictions by Court-Martial.

ARTICLE 1. Every officer now in the Army of the United States shall, within six months from the passing of this Act, and every officer hereafter appointed shall, before he enters upon the duties of his office, subscribe these Rules and Articles.

ART. 2. These Rules and Articles shall be read to every enlisted man at the time of, or within six days after, his enlistment, and he shall thereupon take an oath or affirmation, in the following form: "I, A. B., do solemnly swear (or affirm) that I will bear true faith and allegiance to the United States of America; that I will serve them honestly and faithfully against all their enemies whomsoever; and that I will obey the orders of the President of the United States, and the orders of the officers appointed over me, according to the Rules and Articles of War." This oath may be taken before any commissioned officer of the army.

ART. 3. Every officer who knowingly enlists or musters into the military service any minor over the age of sixteen years without the written consent of his parents or guardians, or any minor under the age of sixteen years, or any insane or intoxicated persons, or any deserter from the military or naval service of the United States, or any person who has been convicted of any infamous criminal offense, shall, upon conviction, be dismissed from the service, or suffer such other punishment as the Court-Martial may direct.

ART. 4. No enlisted man, duly sworn, shall be discharged from the service without a discharge in writing, signed by a field-officer of the regiment to which he belongs, or by the commanding officer when no field-officer is present; and no discharge shall be given to any enlisted man before his term of service has expired, except by order of the President, the Secretary of War, the commanding officer of a department, or by sentence of a General Court-Martial.

ART. 5. Any officer who knowingly musters as a soldier a person who is not a soldier shall be deemed guilty of knowingly making a false muster, and punished accordingly.

ART. 6. Any officer who takes money, or other thing, by way of gratification, on mustering any regiment, troop, battery, or company, or on signing muster-rolls, shall be dismissed from the service, and shall thereby be disabled to hold any office or employment in the service of the United States.

ART. 7. Every officer commanding a regiment, an independent troop, battery, or company, or a garrison, shall, in the beginning of every month, transmit through the proper channels, to the Department of War, an exact return of the same, specifying the names of the officers then absent from their posts, with the reasons for and the time of their absence. And any officer who, through neglect or design, omits to send such returns shall, on conviction thereof, be punished as a Court-Martial may direct.

ART. 8. Every officer who knowingly makes a false return to the Department of War, or to any of his superior officers authorized to call for such returns, of the state of the regiment, troop or company, or garrison under his command; or of the arms, ammunition, clothing, or other stores thereunto belonging, shall, on conviction thereof before a Court-Martial, be cashiered.

Art. 9. All public stores taken from the enemy shall be secured for the service of the United States; and for neglect thereof the commanding officer shall be answerable.

Art. 10. Every officer commanding a troop, battery, or company is charged with the arms, accouterments, ammunition, clothing, or other military stores belonging to his command, and is accountable to his Colonel in case of their being lost, spoiled, or damaged otherwise than by unavoidable accident, or on actual service.

Art. 11. Every officer commanding a regiment, or an independent troop, battery, or company, not in the field, may, when actually quartered with such command, grant furloughs to the enlisted men, in such numbers and for such time as he shall deem consistent with the good of the service. Every officer commanding a regiment, or an independent troop, battery, or company, in the field, may grant furloughs not exceeding thirty days at one time, to five per centum of the enlisted men, for good conduct in the line of duty, but subject to the approval of the commander of the forces of which said enlisted men form a part. Every company officer of a regiment, commanding any troop, battery, or company not in the field, or commanding in any garrison, fort, post, or barrack, may, in the absence of his field-officer, grant furloughs to the enlisted men for a time not exceeding twenty days in six months, and not to more than two persons to be absent at the same time.

Art. 12. At every muster of a regiment, troop, battery, or company, the commanding officer thereof shall give to the mustering officer certificates, signed by himself, stating how long absent officers have been absent and the reasons of their absence. And the commanding officer of every troop, battery, or company shall give like certificates, stating how long absent non-commissioned officers and private soldiers have been absent and the reasons of their absence. Such reasons and time of absence shall be inserted in the muster-rolls opposite the names of the respective absent officers and soldiers, and the certificates, together with the muster-rolls, shall be transmitted by the mustering officer to the Department of War, as speedily as the distance of the place and muster will admit.

Art. 13. Every officer who signs a false certificate relating to the absence or pay of an officer or soldier shall be dismissed from the service.

Art. 14. Any officer who knowingly makes a false muster of man or horse, or who signs, or directs, or allows the signing of any muster-roll knowing the same to contain a false muster, shall, upon proof thereof by two witnesses, before a Court-Martial, be dismissed from the service, and shall thereby be disabled to hold any office or employment in the service of the United States.

Art. 15. Any officer who, willfully or through neglect, suffers to be lost, spoiled, or damaged any military stores belonging to the United States shall make good the loss or damage, and be dismissed from the service.

Art. 16. Any enlisted man who sells, or willfully or through neglect wastes, the ammunition delivered out to him shall be punished as a Court-Martial may direct.

Art. 17. Any soldier who sells or, through neglect, loses or spoils his horse, arms, clothing, or accouterments, shall suffer such stoppages, not exceeding one half of his current pay, as a Court-Martial may deem sufficient for repairing the loss or damage, and shall be punished by confinement or such other corporal punishment as the Court may direct.

Art. 18. Any officer commanding in any garrison, fort, or barracks of the United States who, for his private advantage, lays any duty or imposition upon, or is interested in, the sale of any victuals, liquors, or other necessaries of life brought into such garrison, fort, or barracks for the use of the soldiers, shall be dismissed from the service.

Art. 19. Any officer who uses contemptuous or disrespectful words against the President, the Vice-President, the Congress of the United States, or the Chief Magistrate or legislature of any of the United States in which he is quartered, shall be dismissed from the service, or otherwise punished, as a Court-Martial may direct. Any soldier who so offends shall be punished as a Court-Martial may direct.

Art. 20. Any officer or soldier who behaves himself with disrespect toward his Commanding Officer shall be punished as a Court-Martial may direct.

Art. 21. Any officer or soldier who, on any pretense whatsoever, strikes his Superior Officer, or draws or lifts up any weapon, or offers any violence against him, being in the execution of his office, or disobeys any lawful command of his Superior Officer, shall suffer death, or such other punishment as a Court-Martial may direct.

Art. 22. Any officer or soldier who begins, excites, causes, or joins in any mutiny or sedition, in any troop, battery, company, party, post, detachment, or guard, shall suffer death, or such other punishment as a Court-Martial may direct.

Art. 23. Any officer or soldier who, being present at any mutiny or sedition, does not use his utmost endeavor to suppress the same, or, having knowledge of any intended mutiny or sedition, does not, without delay, give information thereof to his Commanding Officer, shall suffer death, or such other punishment as a Court-Martial may direct.

Art. 24. All officers, of what condition soever, have power to part and quell all quarrels, frays, and disorders, whether among persons belonging to his own or to another corps, regiment, troop, battery, or company, and to order officers into arrest, and non-commissioned officers and soldiers into confinement, who take part in the same, until their proper Superior Officer is acquainted therewith. And whosoever, being so ordered, refuses to obey such officer or non-commissioned officer, or draws a weapon upon him shall be punished as a Court-Martial may direct.

Art. 25. No officer or soldier shall use any reproachful or provoking speeches or gestures to another. Any officer who so offends shall be put in arrest. Any soldier who so offends shall be confined, and required to ask pardon of the party offended, in the presence of his Commanding Officer.

Art. 26. No officer or soldier shall send a challenge to another officer or soldier to fight a duel, or accept a challenge so sent. Any officer who so offends shall be dismissed from the service. Any soldier who so offends shall suffer such corporal punishment as a Court-Martial may direct.

Art. 27. Any officer or non-commissioned officer, commanding a guard, who, knowingly and willingly, suffers any person to go forth to fight a duel, shall be punished as a challenger; and all seconds or promoters of duels, and carriers of challenges to fight duels, shall be deemed principals, and punished accordingly. It shall be the duty of any officer commanding an army, regiment, troop, battery, company, post, or detachment, who knows or has reason to believe that a challenge has been given or accepted by any officer or enlisted man under his command, immediately to arrest the offender and bring him to trial.

Art. 28. Any officer or soldier who upbraids another officer or soldier for refusing a challenge shall himself be punished as a challenger; and all officers and soldiers are hereby discharged from any disgrace or opinion of disadvantage which might arise from their having refused to accept challenges, as they will only have acted in obedience to the law, and have done their duty as good soldiers, who subject themselves to discipline.

Art. 29. Any officer who thinks himself wronged by the commanding officer of his regiment, and, upon due application to such commander, is refused redress, may complain to the General commanding in the State or Territory where such regiment is stationed. The general shall examine into said complaint and take proper measures for redressing the wrong complained of; and he shall, as soon as possible, transmit to the Department of War a true statement of such complaint, with the proceedings had thereon.

ART. 30. Any soldier who thinks himself wronged by any officer may complain to the commanding officer of his regiment, who shall summon a Regimental Court-Martial for the doing of justice to the complainant. Either party may appeal from such Regimental Court-Martial to a General Court-Martial; but if, upon such second hearing, the appeal appears to be groundless and vexatious, the party appealing shall be punished at the discretion of said General Court-Martial.

ART. 31. Any officer or soldier who lies out of his quarters, garrison, or camp, without leave from his superior officer, shall be punished as a Court-Martial may direct.

ART. 32. Any soldier who absents himself from his troop, battery, company, or detachment, without leave from his Commanding Officer, shall be punished as a Court-Martial may direct.

ART. 33. Any officer or soldier who fails, except when prevented by sickness or other necessity, to repair, at the fixed time, to the place of parade, exercise, or other rendezvous appointed by his Commanding Officer, or goes from the same, without leave from his Commanding Officer, before he is dismissed or relieved, shall be punished as a Court-Martial may direct.

ART. 34. Any soldier who is found one mile from camp, without leave in writing from his Commanding Officer, shall be punished as a Court-Martial may direct.

ART. 35. Any soldier who fails to retire to his quarters or tent at the beating of retreat shall be punished according to the nature of his offense.

ART. 36. No soldier belonging to any regiment, troop, battery, or company shall hire another to do his duty for him, or be excused from duty, except in cases of sickness, disability, or leave of absence. Every such soldier found guilty of hiring his duty, and the person so hired to do another's duty, shall be punished as a Court-Martial may direct.

ART. 37. Every non-commissioned officer who connives at such hiring of duty shall be reduced. Every officer who knows and allows such practices shall be punished as a Court-Martial may direct.

ART. 38. Any officer who is found drunk on his guard, party, or other duty shall be dismissed from the service. Any soldier who so offends shall suffer such punishment as a Court-Martial may direct.

ART. 39. Any sentinel who is found sleeping upon his post, or who leaves it before he is regularly relieved, shall suffer death, or such other punishment as a Court-Martial may direct.

ART. 40. Any officer or soldier who quits his guard, platoon, or division without leave from his Superior Officer, except in case of urgent necessity, shall be punished as a Court-Martial may direct.

ART. 41. Any officer who, by any means whatsoever, occasions false alarms in camp, garrison, or quarters, shall suffer death, or such other punishment as a Court-Martial may direct.

ART. 42. Any officer or soldier who misbehaves himself before the enemy, runs away, or shamefully abandons any fort, post, or guard, which he is commanded to defend, or speaks words inducing others to do the like, or casts away his arms or ammunition, or quits his post or colors to plunder or pillage, shall suffer death, or such other punishment as a Court-Martial may direct.

ART. 43. If any commander of any garrison, fortress, or post is compelled by the officers and soldiers under his command to give up to the enemy or to abandon it, the officers or soldiers so offending shall suffer death, or such other punishment as a Court-Martial may direct.

ART. 44. Any person belonging to the armies of the United States who makes known the watchword to any person not entitled to receive it, according to the rules and discipline of war, or presumes to give a parole or watchword different from that which he received, shall suffer death, or such other punishment as a Court-Martial may direct.

ART. 45. Whosoever relieves the enemy with money, victuals, or ammunition, or knowingly harbors or protects an enemy, shall suffer death, or such other punishment as a Court-Martial may direct.

ART. 46. Whosoever holds correspondence with, or gives intelligence to, the enemy, either directly or indirectly, shall suffer death, or such other punishment as a Court-Martial may direct.

ART. 47. Any officer or soldier who, having received pay, or having been duly enlisted in the service of the United States, deserts the same, shall, in time of war, suffer death, or such other punishment as a Court-Martial may direct; and in time of peace, any punishment, excepting death, which a Court-Martial may direct.

ART. 48. Every soldier who deserts the service of the United States shall be liable to serve for such period as shall, with the time he may have served previous to his desertion, amount to the full term of his enlistment; and such soldier shall be tried by a Court-Martial and punished, although the term of his enlistment may have elapsed previous to his being apprehended and tried.

ART. 49. Any officer who, having tendered his resignation, quits his post or proper duties without leave, and with intent to remain permanently absent therefrom, prior to due notice of the acceptance of the same, shall be deemed and punished as a deserter.

ART. 50. No non-commissioned officer or soldier shall enlist himself in any other regiment, troop, or company without a regular discharge from the regiment, troop, or company in which he last served, on penalty of being reputed a deserter, and suffering accordingly. And in case any officer shall knowingly receive and entertain such non-commissioned officer or soldier, or shall not, after his being discovered to be a deserter, immediately confine him and give notice thereof to the corps in which he last served, the said officer shall, by a Court-Martial, be cashiered.

ART. 51. Any officer or soldier who advises or persuades any other officer or soldier to desert the service of the United States shall, in time of war, suffer death, or such other punishment as a Court-Martial may direct; and in time of peace, any punishment, excepting death, which a Court-Martial may direct.

ART. 52. It is earnestly recommended to all officers and soldiers diligently to attend divine service. Any officer who behaves indecently or irreverently at any place of divine worship shall be brought before a General Court-Martial, there to be publicly and severely reprimanded by the President thereof. Any soldier who so offends shall, for his first offense, forfeit one sixth of a dollar; for each further offense he shall forfeit a like sum, and shall be confined twenty-four hours. The money so forfeited shall be deducted from his next pay, and shall be applied, by the Captain or senior officer of his troop, battery, or company, to the use of the sick soldiers of the same.

ART. 53. Any officer who uses any profane oath or execration shall, for each offense, forfeit and pay one dollar. Any soldier who so offends shall incur the penalties provided in the preceding Article; and all moneys forfeited for such offenses shall be applied as therein provided.

ART. 54. Every officer commanding in quarters, garrison, or on the march shall keep good order, and, to the utmost of his power, redress all abuses or disorders which may be committed by any officer or soldier under his command; and if, upon complaint made to him of officers or soldiers beating or otherwise ill-treating any person, disturbing fairs, or markets, or committing any kind of riot, to the disquieting of the citizens of the United States, he refuses or omits to see justice done to the offender, and reparation made to the party injured, so far as part of the offender's pay shall go toward such reparation, he shall be dismissed from the service, or otherwise punished as a Court-Martial may direct.

ART. 55. All officers and soldiers are to behave themselves orderly in quarters and on the march; and whoever commits any waste or spoil, either in walks or trees, parks, warrens, fish-ponds, houses, gardens, grain-fields, inclosures, or meadows, or maliciously destroys any property whatsoever belonging to inhabitants of the United States (unless by order of a General Officer commanding a separate army in the field), shall, besides such penalties as he may be liable to by law, be punished as a Court-Martial may direct.

ART. 56. Any officer or soldier who does violence to any person bringing provisions or other necessaries to the camp, garrison, or quarters of the forces of the United States in foreign parts shall suffer death, or such other punishment as a Court-Martial may direct.

ART. 57. Whosoever, belonging to the Armies of the United States in foreign parts, or at any place within the United States or their Territories during rebellion against the supreme authority of the United States, forces a safeguard, shall suffer death.

ART. 58. In time of war, insurrection, or rebellion, larceny, robbery, burglary, arson, mayhem, manslaughter, murder, assault and battery with an intent to kill, wounding, by shooting or stabbing, with an intent to commit murder, rape, or assault and battery with an intent to commit rape, shall be punishable by the sentence of a General Court-Martial, when committed by persons in the military service of the United States, and the punishment in any such case shall not be less than the punishment provided for the like offense by the laws of the State, Territory, or District in which such offense may have been committed.

ART. 59. When any officer or soldier is accused of a capital crime, or of any offense against the person or property of any citizen of any of the United States, which is punishable by the laws of the land, the commanding officer, and the officers of the regiment, troop, battery, company, or detachment to which the person so accused belongs, are required, except in time of war, upon application duly made by or in behalf of the party injured, to use their utmost endeavors to deliver him over to the civil magistrate, and to aid the officers of justice in apprehending and securing him, in order to bring him to trial. If, upon such application, any officer refuses or willfully neglects, except in time of war, to deliver over such accused person to the civil magistrates, or to aid the officers of justice in apprehending him, he shall be dismissed from the service.

ART. 60. Any person in the military service of the United States who makes or causes to be made any claim against the United States, or any officer thereof, knowing such claim to be false or fraudulent; or

Who presents or causes to be presented to any person in the civil or military service thereof, for approval or payment, any claim against the United States or any officer thereof, knowing such claim to be false or fraudulent; or

Who enters into any agreement or conspiracy to defraud the United States by obtaining, or aiding others to obtain, the allowance or payment of any false or fraudulent claim; or

Who, for the purpose of obtaining, or aiding others to obtain, the approval, allowance, or payment of any claim against the United States or against any officer thereof, makes or uses, or procures or advises the making or use of, any writing or other paper, knowing the same to contain any false or fraudulent statement; or

Who, for the purpose of obtaining, or aiding others to obtain, the approval, allowance, or payment of any claim against the United States or any officer thereof, makes, or procures or advises the making of, any oath to any fact or to any writing or other paper, knowing such oath to be false; or

Who, for the purpose of obtaining, or aiding others to obtain, the approval, allowance, or payment of any claim against the United States or any officer thereof, forges or counterfeits, or procures or advises the forging or counterfeiting of, any signature upon any writing or other paper, or uses or procures or advises the use of, any such signature, knowing the same to be forged or counterfeited; or

Who, having charge, possession, custody, or control of any money or other property of the United States, furnished or intended for the military service thereof, knowingly delivers, or causes to be delivered, to any person having authority to receive the same, any amount thereof less than that for which he receives a certificate or receipt; or

Who, being authorized to make or deliver any paper certifying the receipt of any property of the United States, furnished or intended for the military service thereof, makes, or delivers to any person, such writing, without having full knowledge of the truth of the statements therein contained, and with intent to defraud the United States; or

Who steals, embezzles, knowingly and willfully misappropriates, applies to his own use or benefit, or wrongfully or knowingly sells or disposes of any ordnance, arms, equipments, ammunition, clothing, subsistence-stores, money, or other property of the United States, furnished or intended for the military service thereof; or

Who knowingly purchases, or receives in pledge for any obligation or indebtedness, from any soldier, officer, or other person who is a part of or employed in said forces or service, any ordnance, arms, equipments, ammunition, clothing, subsistence-stores, or other property of the United States, such soldier, officer, or other person not having lawful right to sell or pledge the same,—

Shall, on conviction thereof, be punished by fine or imprisonment, or by such other punishment as a Court-Martial may adjudge. And if any person, being guilty of any of the offenses aforesaid while in the military service of the United States, receives his discharge or is dismissed from the service, he shall continue to be liable to be arrested and held for trial and sentence by a Court-Martial, in the same manner and to the same extent as if he had not received such discharge nor been dismissed.

ART. 61. Any officer who is convicted of conduct unbecoming an officer and a gentleman shall be dismissed from the service.

ART. 62. All crimes not capital, and all disorders and neglects, which officers and soldiers may be guilty of, to the prejudice of good order and military discipline, though not mentioned in the foregoing Articles of War, are to be taken cognizance of by a General or a Regimental Garrison, or Field-Officers' Court-Martial, according to the nature and degree of the offense, and punished at the discretion of such Court.

ART. 63. All retainers to the camp, and all persons serving with the Armies of the United States in the field, though not enlisted soldiers, are to be subject to orders, according to the rules and discipline of war.

ART. 64. The officers and soldiers of any troops, whether militia or others, mustered and in pay of the United States, shall, at all times and in all places, be governed by the Articles of War, and shall be subject to be tried by Courts-Martial.

ART. 65. Officers charged with crime shall be arrested and be confined in their barracks, quarters, or tents, and be deprived of their swords by the Commanding Officer. And any officer who leaves his confinement before he is set at liberty by his Commanding Officer shall be dismissed from the service.

ART. 66. Soldiers charged with crimes shall be confined until tried by Court-Martial or released by proper authority.

ART. 67. No provost-marshal, or officer commanding a guard, shall refuse to receive or keep any prisoner committed to his charge by an officer belonging to the forces of the United States; provided the officer committing shall, at the same time, deliver an account in writing, signed by himself, of the crime charged against the prisoner.

ART. 68. Every officer to whose charge a prisoner is committed shall, within twenty-four hours after such commitment, or as soon as he is relieved from his guard, report in writing, to the Commanding Officer, the name of such prisoner, the crime charged against him, and the name of the officer committing him; and if he fails to make such report, he shall be punished as a Court-Martial may direct.

ART. 69. Any officer who presumes, without proper authority, to release any prisoner committed to his charge, or suffers any prisoner so committed to escape, shall be punished as a Court-Martial may direct.

ART. 70. No officer or soldier put in arrest shall be continued in confinement more than eight days, or until such time as a Court-Martial can be assembled.

ART. 71. When an officer is put in arrest for the purpose of trial, except at remote military posts or stations, the officer by whose order he is arrested shall see that a copy of the charges on which he is to be tried is served upon him within eight days after his arrest, and that he is brought to trial within ten days thereafter, unless the necessities of the service prevent such trial; and then he shall be brought to trial within thirty days after the expiration of said ten days. If a copy of the charges be not served, or the arrested officer be not brought to trial, as herein required, the arrest shall cease. But officers released from arrest, under the provisions of this Article, may be tried, whenever the exigencies of the service shall permit, within twelve months after such release from arrest.

ART. 72. Any General Officer, commanding the Army of the United States, a separate army, or a separate department, shall be competent to appoint a General Court-Martial, either in time of peace or in time of war. But when any such commander is the accuser or prosecutor of any officer under his command, the Court shall be appointed by the President, and its proceedings and sentence shall be sent directly to the Secretary of War, by whom they shall be laid before the President, for his approval or orders in the case.

ART. 73. In time of war the commander of a division, or of a separate brigade of troops, shall be competent to appoint a General Court-Martial. But when such commander is the accuser or prosecutor of any person under his command, the Court shall be appointed by the next higher commander.

ART. 74. Officers who may appoint a Court-Martial shall be competent to appoint a Judge-Advocate for the same.

ART. 75. General Courts-Martial may consist of any number of officers from five to thirteen, inclusive; but they shall not consist of less than thirteen when that number can be convened without manifest injury to the service.

ART. 76. When the requisite number of officers to form a General Court-Martial is not present in any post or detachment, the Commanding Officer shall, in cases which require the cognizance of such a Court, report to the Commanding Officer of the Department, who shall thereupon order a Court to be assembled at the nearest post or department at which there may be such a requisite number of officers, and shall order the party accused, with necessary witnesses, to be transported to the place where the said Court shall be assembled.

ART. 77. Officers of the Regular Army shall not be competent to sit on Courts-Martial to try the officers or soldiers of other forces, except as provided in Article 78.

ART. 78. Officers of the Marine Corps, detached for service with the Army by order of the President, may be associated with officers of the Regular Army on Courts-Martial for the trial of offenders belonging to the Regular Army, or to forces of the Marine Corps so detached; and in such cases the orders of the senior officer of either corps, who may be present and duly authorized, shall be obeyed.

ART. 79. Officers shall be tried only by General Courts-Martial; and no officer shall, when it can be avoided, be tried by officers inferior to him in rank.

ART. 80. In time of war a field-officer may be detailed in every regiment, to try soldiers thereof for offenses not capital; and no soldier, serving with his regiment, shall be tried by a Regimental or Garrison Court-Martial when a field-officer of his regiment may be so detailed.

ART. 81. Every officer commanding a regiment or corps shall, subject to the provisions of Article 80, be competent to appoint, for his own regiment or corps, Courts-Martial, consisting of three officers, to try offenses not capital.

ART. 82. Every officer commanding a garrison, fort, or other place, where the troops consist of different corps, shall, subject to the provisions of Article 80, be competent to Appoint, for such Garrison or other place, Courts-Martial, consisting of three officers, to try offenses not capital.

ART. 83. Regimental and Garrison Courts-Martial, and field-officers detailed to try offenders, shall not have power to try capital cases or commissioned officers, or to inflict a fine exceeding one month's pay, or to imprison or put to hard labor any non-commissioned officer or soldier for a longer time than one month.

ART. 84. The Judge-Advocate shall administer to each member of the court, before they proceed upon any trial, the following oath, which shall also be taken by all members of regimental and garrison courts-martial: "You, A. B., do swear that you will well and truly try and determine, according to evidence, the matter now before you, between the United States of America and the prisoner to be tried, and that you will duly administer justice, without partiality, favor, or affection, according to the provisions of the Rules and Articles for the government of the Armies of the United States, and if any doubt should arise, not explained by said Articles, then according to your conscience, the best of your understanding, and the custom of war in like cases; and you do further swear that you will not divulge the sentence of the Court until it shall be published by the proper authority; neither will you disclose or discover the vote or opinion of any particular member of the Court-Martial, unless required to give evidence thereof, as a witness, by a Court of Justice, in a due course of law. So help you God."

ART. 85. When the oath has been administered to the members of a Court-Martial, the President of the Court shall administer to the Judge-Advocate, or person officiating as such, an oath in the following form: "You, A. B., do swear that you will not disclose or discover the vote or opinion of any particular member of the Court-Martial, unless required to give evidence thereof, as a witness, by a Court of Justice, in due course of law; nor divulge the sentence of the Court to any but the proper authority, until it shall be duly disclosed by the same. So help you God."

ART. 86. A Court-Martial may punish, at discretion, any person who uses any menacing words, signs, or gestures in its presence, or who disturbs its proceedings by any riot or disorder.

ART. 87. All members of a Court-Martial are to behave with decency and calmness.

ART. 88. Members of a Court-Martial may be challenged by a prisoner, but only for cause stated to the Court. The Court shall determine the relevancy and validity thereof, and shall not receive a challenge to more than one member at a time.

ART. 89. When a prisoner, arraigned before a General Court-Martial, from obstinacy and deliberate design stands mute, or answers foreign to the purpose, the Court may proceed to trial and judgment, as if the prisoner had pleaded not guilty.

ART. 90. The Judge-Advocate, or some person deputed by him, or by the General or officer commanding the Army, detachment, or garrison, shall prosecute in the name of the United States; but when the prisoner has made his plea, he shall so far consider himself counsel for the prisoner as to object to any leading question to any of the witnesses, and to any question to the prisoner, the answer to which might tend to criminate himself.

ART. 91. The depositions of witnesses residing beyond the limits of the State, Territory, or District in which any Military Court may be ordered to sit, if taken on reasonable notice to the opposite party and duly authenticated, may be read in evidence before such Court in cases not capital.

ART. 92. All persons who give evidence before a court-martial shall be examined on oath, or affirmation, in the following form: "You swear (or affirm) that the evidence you shall give, in the case now in hearing, shall be the truth, the whole truth, and nothing but the truth. So help you God."

ART. 93. A Court-Martial shall, for reasonable cause, grant a continuance to either party, for such a time, and as often, as may appear to be just: *Provided*, That if the prisoner be in close confinement, the trial shall not be delayed for a period longer than sixty days.

ART. 94. Proceedings of trials shall be carried on only between the hours of eight in the morning and three in the afternoon, excepting in cases which, in the opinion of the officer appointing the Court, require immediate example.

ART. 95. Members of a Court-Martial, in giving their votes, shall begin with the youngest in commission.

ART. 96. No person shall be sentenced to suffer death except by the concurrence of two thirds of the members of a General Court-Martial, and in the cases herein expressly mentioned.

ART. 97. No person in the military service shall, under the sentence of a Court-Martial, be punished by confinement in a penitentiary unless the offense of which he may be convicted would, by some statute of the United States, or by some statute of the State, Territory, or District in which such offense may be committed, or by the common laws as the same exists in such State, Territory, or District, subject such convict to such punishment.

ART. 98. No person in the military service shall be punished by flogging, or by branding, marking, or tattooing on the body.

ART. 99. No officer shall be discharged or dismissed from the service except by order of the President, or by sentence of a General Court-Martial; and in time of peace no officer shall be dismissed except in pursuance of the sentence of a Court-Martial, or in mitigation thereof.

ART. 100. When an officer is dismissed from the service for cowardice or fraud, the sentence shall further direct that the crime, punishment, name, and place of abode of the delinquent shall be published in the newspapers in and about the camp, and in the State from which the offender came, or where he usually resides; and after such publication it shall be scandalous for an officer to associate with him.

ART. 101. When a Court-Martial suspends an officer from command, it may also suspend his pay and emoluments for the same time, according to the nature of his offense.

ART. 102. No person shall be tried a second time for the same offense.

ART. 103. No person shall be liable to be tried and punished by a General Court-Martial for an offense which appears to have been committed more than two years before the issuing of the order for such trial, unless, by reason of having absented himself, or of some other manifest impediment, he shall not have been amenable to justice within that period.

ART. 104. No sentence of a Court-Martial shall be carried into execution until the whole proceedings shall have been approved by the officer ordering the Court, or by the officer commanding for the time being.

ART. 105. No sentence of a Court-Martial inflicting the punishment of death shall be carried into execution until it shall have been confirmed by the President; except in the cases of persons convicted, in time of war, as spies, mutineers, deserters, or murderers, and in the cases of guerrilla marauders convicted, in time of war, of robbery, burglary, arson, rape, assault with intent to commit rape, or of violation of the laws and customs of war; and in such accepted cases the sentence of death may be carried into execution upon confirmation by the Commanding General in the Field, or the Commander of the Department, as the case may be.

ART. 106. In time of peace no sentence of a Court-Martial directing the dismissal of an officer shall be carried into execution until it shall have been confirmed by the President.

ART. 107. No sentence of a Court-Martial appointed by the commander of a division or of a separate brigade of troops, directing the dismissal of an officer, shall be carried into execution until it shall have been confirmed by the General commanding the Army in the Field to which the division or brigade belongs.

ART. 108. No sentence of a Court-Martial, either in time of peace or in time of war, respecting a General Officer, shall be carried into execution until it shall have been confirmed by the President.

ART. 109. All sentences of a Court-Martial may be confirmed and carried into execution by the officer ordering the Court, or by the officer commanding for the time being, where confirmation by the President, or by the Commanding General in the Field, or Commander of the Department, is not required by these Articles.

ART. 110. No sentence of a Field-Officer detailed to try soldiers of his regiment shall be carried into execution until the whole proceedings shall have been approved by the Brigade Commander, or, in case there be no Brigade Commander, by the Commanding Officer of the post.

ART. 111. Any officer who has authority to carry into execution the sentence of death or of dismissal of an officer may suspend the same until the pleasure of the President shall be known; and in such case he shall immediately transmit to the President a copy of the order of suspension, together with a copy of the proceedings of the Court.

ART. 112. Every officer who is authorized to order a General Court-Martial shall have power to pardon or mitigate any punishment adjudged by it, except the punishment of death or of dismissal of an officer. Every officer commanding a regiment or garrison in which a Regimental or Garrison Court-Martial may be held shall have power to pardon or mitigate any punishment which such Court may adjudge.

ART. 113. Every Judge-Advocate, or person acting as such, at any General Court-Martial, shall, with as much expedition as the opportunity of time and distance of place may permit, forward the original proceedings and sentence of such Court to the Judge-Advocate-General of the Army, in whose office they shall be carefully preserved.

ART. 114. Every party tried by a General Court-Martial shall, upon demand thereof, made by himself or by any person in his behalf, be entitled to a copy of the proceedings and sentence of such Court.

ART. 115. A Court of Inquiry to examine into the nature of any transaction of, or accusation or imputation against, any officer or soldier, may be ordered by the President or by any Commanding Officer; but, as Courts of Inquiry may be perverted to dishonorable purposes, and may be employed, in the hands of weak and envious Commandants, as engines for the destruction of military merit, they shall never be ordered by any Commanding Officer, except upon a demand by the officer or soldier whose conduct is to be inquired of.

ART. 116. A Court of Inquiry shall consist of one or more officers, not exceeding three, and a Recorder, to reduce the proceedings and evidence to writing.

ART. 117. The Recorder of a Court of Inquiry shall administer to the members the following oath: "You shall well and truly examine and inquire, according to the evidence, into the matter now before you, without partiality, favor, affection, prejudice, or hope of reward: so help you God." After which the President of the Court shall administer to the Recorder the following oath: "You, A. B., do swear that you will, according to your best abilities, accurately and impartially record the proceedings of the Court and the evidence to be given in the case in hearing: so help you God."

ART. 118. A Court of Inquiry, and the Recorder thereof, shall have the same power to summon and examine witnesses as is given to Courts-Martial and the Judge-Advocates thereof. Such witnesses shall take the same oath which is taken by witnesses before Courts-Martial, and the party accused shall be permitted to examine and cross-examine them, so as fully to investigate the circumstances in question.

ART. 119. A Court of Inquiry shall not give an opinion on the merits of the case inquired of unless specially ordered to do so.

ART. 120. The proceedings of a Court of Inquiry must be authenticated by the signatures of the Recorder and the President thereof, and delivered to the Commanding Officer.

ART. 121. The proceedings of a Court of Inquiry may be admitted as evidence by a Court-Martial, in cases not capital, nor extending to the dismissal of an officer: *Provided*, That the circumstances are such that oral testimony cannot be obtained.

ART. 122. If, upon marches, guards, or in quarters, different Corps of the Army happen to join or do duty together, the officer highest in rank of the Line of the Army, Marine Corps, or Militia, by commission, there on duty or in quarters, shall command the whole, and give orders for what is needful to the service, unless otherwise specially directed by the President, according to the nature of the case.

ART. 123. In all matters relating to the rank, duties, and rights of officers, the same rules and regulations shall apply to officers of the Regular Army and to volunteers commissioned in, or mustered into, said service, under the laws of the United States, for a limited period.

ART. 124. Officers of the militia of the several States, when called into the service of the United States, shall on all detachments, Courts-Martial, and other duty wherein they may be employed in conjunction with the regular or volunteer forces of the United States, take rank next after all officers of the like grade in said regular or volunteer forces, notwithstanding the commissions of such militia officers may be older than the commissions of the said officers of the regular or volunteer forces of the United States.

ART. 125. In case of the death of any officer, the Major of his regiment, or the officer doing the Major's duty, or the second officer in command at any post or garrison, as the case may be, shall immediately secure all his effects then in camp or quarters, and shall make, and transmit to the office of the Department of War, an inventory thereof.

ART. 126. In case of the death fo any soldier, the Commanding Officer of his troop, battery, or company shall immediately secure all his effects then in camp or quarters, and shall, in the presence of two other officers, make an inventory thereof, which he shall transmit to the office of the Department of War.

ART. 127. Officers charged with the care of the effects of deceased officers or soldiers shall account for and deliver the same, or the proceeds thereof, to the legal representatives of such deceased officers or soldiers. And no officer so charged shall be permitted to quit the regiment or post until he has deposited in the hands of the Commanding Officer all the effects of such deceased officers or soldiers not so accounted for and delivered.

ART. 128. The foregoing Articles shall be read and published once in every six months, to every garrison, regiment, troop, or company in the service of the United States, and shall be duly observed and obeyed by all officers and soldiers in said service.

All persons who, in time of war, or of rebellion against the supreme authority of the United States, are found lurking or acting as spies, in or about any of the fortifications, posts, quarters, or encampments of any of the armies of the United States, or elsewhere, are triable by a General Court-Martial, or by a Military Commission, and on conviction thereof suffer death.

ARTIFICE.—Among the French, a term understood as comprehending everything which enters the composition of fire-works, as the sulphur, saltpeter, charcoal, etc. See *Fire-works*.

ARTIFICER.—1. One who makes fire-works, or works in the artillery laboratory and prepares the shells, fuses, grenades, etc. 2. A military mechanic, such as a carpenter, blacksmith, or mason.

ARTIFICIAL LIMBS.—From the days of the German knight Götz von Berlichingen, artificial arms have been made which have been marvels of ingenuity. Even the arm of that famous knight, still on exhibition in a German museum, is a piece of mechanism so intricate in the combination of its motions as to have been without a rival for nearly five hundred years. All modern improvements belong to the present decade.

The tendency of the manufacturers—modern as well as ancient—has been to make an arm with every motion of the natural; in this they have succeeded—that is, so far as patterning after Götz and producing an article very primitive in its construction, too complicated to be durable and too intricate to be serviceable. Until man becomes capable of combining art with nature and harmonizing the artificial member with the nervous system, in short, giving it life, he will fail in supplying the loss in all its detail. Any amount of machinery will not accomplish it; and the more complication he has, the more distant he gets from the most useful substitute. A glance at the anatomy of the human arm reveals it as a marvel of mechanism. What a combination of movements, and what unlimited control man has over it! Each finger has its three joints, with every joint under control. The hand has its wrist, enabling it to conform to any angle. The forearm has the ulna and the radius, enabling the hand to rotate. Withal, what marvelous strength each finger and joint commands, all operated by sinews and muscles, each joint supplied with cushions and a lubricating sac, whose function it is to reduce friction to the minimum. The parts of this wonderful machine are hinged together with such nicety that the engraver is enabled to etch the finest plate, or the brawny smith to wield the heaviest sledge.

Does the reader think that the hand alone does this variety of work?—Operates voluntarily by an intelligence of its own? Sever the brachial nerve, and we will have a member as dead and limpsy as an empty coat-sleeve. Remove the arm from the body and irritate the nerves or contract the muscles, and we will have a motion as awkward and spasmodic as may be observed in an artificial arm with jointed fingers. Hence all the dexterous movements we observe in the normal hand depend upon some power outside of itself, and that power is the mind. If we look a little deeper in the physiology of the natural arm and hand we will observe that nature has made a curious provision for one of its failings. Every joint suffers wear from attrition, and were it not for this provision they would soon become loose and rattle as bad as a worn-out gudgeon. Not a drop of blood flows through the avenues of the hand that does not carry with it fresh material to supply the wasted parts. From the first beat of the heart of the child not yet born, until man has ceased to be an animate being, this human repair-shop is in active operation and knows no rest. This cursory glance at the natural arm will fix in the mind three facts: first, that the hand is a delicate piece of mechanism of great strength; second, that it is in concert with and operated by the human will; and third, that it suffers wear, but is constantly undergoing repairs by the action of the circulatory system.

With these facts well impressed, we may make a comparison with the artificial arm. What a disparity! It cannot be connected with the mind, nor with the heart. If the joints of the fingers are made strong enough to withstand a small proportion of the strain of the natural hand, it must necessarily be made too

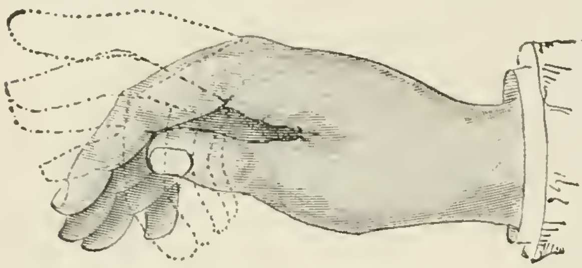

Fig. 1.—The Marks Rubber Hand.

heavy for endurance. If the springs are made stiff enough to have a grasping power of a pound, the exertion to operate them is fatiguing and renders them impracticable.

Nothing has tended so much to the very highest development of artificial arms and hands as an accident which happened more than a quarter of a century ago to the celebrated French tenor M. Roger, who lost his right arm above the elbow. It was necessary for his future appearance on the stage that he should have an artificial limb which would serve the purposes of histrionic action and permit him to grasp a sword and draw it from its scabbard. Such a contrivance was invented in 1845 by Van Petersen a Prussian mechanician, and the French Academy of Sciences commissioned MM. Gambey, Rayer, Velpeau, and Magendie to report upon it. For a history of the nature of the limb, the reader is referred to the

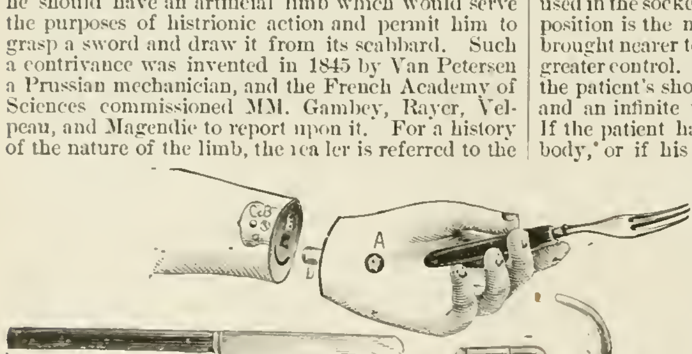

Fig. 2.—Applications of the Marks Hand.

report which appeared in the *Comptes Rendus* for that date. The apparatus, which weighs less than 18 ounces, was tested upon a soldier who had lost both arms. By its aid he was enabled to pick up a pen, take hold of a leaf of paper, etc.; and the old man's joy during the experiment was so great that the Academy presented him with a pair of these arms. Van Petersen's conceptions have been extended and improved by Messrs. Charrière, the celebrated surgical mechanics of Paris, aided by M. Huguier, the well-known surgeon. A very marvelous arm has also been almost simultaneously constructed by M. Bechard, which, by means of a single point of traction, placed in pronation, executes first the movement of supination, next in succession the extension of the fingers and abduction of the thumb: the hand is then wide open.

In 1863, Mr. A. A. Marks, an American of varied experience, invented the rubber hand (Fig. 1), which was attached to the forearm by means of a spindle held in position by a set-screw, easily detached and replaced by a hook, fork, knife, or brush. The fingers were of soft, elastic rubber, molded to a graceful shape and yielding to pressure. Its advantages were its naturalness in appearance and to the touch, and its great durability. It might fall or strike anything without breaking or impairing it. These advantages alone commended it to favor, and many of them were made. In the course of time an improvement was suggested—that of making the fingers ductile, so that they might be made to assume different positions; by the assistance of the opposite hand, or by pressing the hand against any hard surface, the fingers may be placed in any desired position, each one giving the hand a new appearance; thus obviating the monotony of the old style, and making it more pleasing to the wearing and less observable to the inquisitive. The fingers, when bent, will hold a valise or package of considerable weight, or hold the reins of a horse in driving.

Fig. 2 represents the manner in which the hand is now attached to the fore-arm; also the attachment in the palm of hand for holding various useful articles. It may be thus described: The hand is held to the forearm by inserting the spindle, D, in the socket, E; it is then locked by a spring. The hand in this position has a rotary motion. A knife, fork, brush, or hook can be inserted in the palm. The knife or fork will enable the wearer to feed himself without exhibiting his loss; the hook to carry heavy weights and perform laborious work; the brush will enable the wearer to wash his opposite hand. By pressing on the button, A, these articles may be released; by pressing on the button, C, the hand can be detached, and any of the articles above named may be used in the socket without the hand. The hook in this position is the most useful appendage; it is thereby brought nearer to the stump, and, consequently, under greater control. By it as much weight can be carried as the patient's shoulder will endure; shoveling, hauling, and an infinite variety of heavy work can be done. If the patient has suffered an amputation close to the body, or if his hand is unjointed at the wrist, it is more desirable, for obvious reasons, to dispense with the wrist-attachment and depend on the palm-attachment entirely for holding these articles.

Fig. 3 represents an arm and hand for amputation below the elbow. The hand is dressed with a glove (which is always to be worn), holding a pen in the act of writing. This has been regarded as a wonderful accomplishment, when, really, it is less difficult than many services the hand is capable of performing. The joints at the elbow are of leather, thus affording a rotary motion to the forearm which cannot be had with steel joints.

Fig. 4 represents an artificial arm for amputation above the elbow. The joint is adjustable, and can be tightened or loosened as the patient desires. The arm is held to the person by straps or suspenders passing over and under the opposite shoulder. The elbow-joint is operated by a leather cord attached to the forearm and passing through the upper arm, and attached by a buckle to the suspender. By urging the shoulder forward this cord is drawn upon and the forearm brought to any desired angle. It is thus seen that the arm and hand are simple in their construction, practical in their application, light, strong, and durable.

Artificial legs, having fewer requirements to perform than artificial arms, are comparatively simple in structure. The ordinary *Bucket-leg*, in common

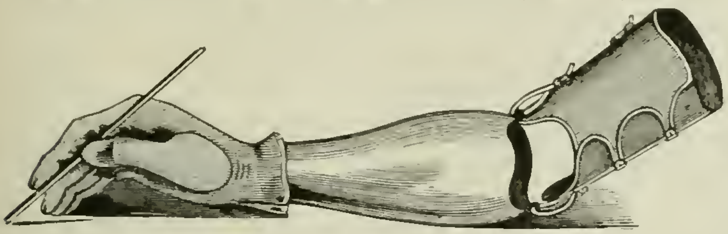

Fig. 3.—Arm and Hand for Amputation below the Elbow.

use amongst the poorer classes, consists of a hollow sheath or bucket, accurately conformed to the shape

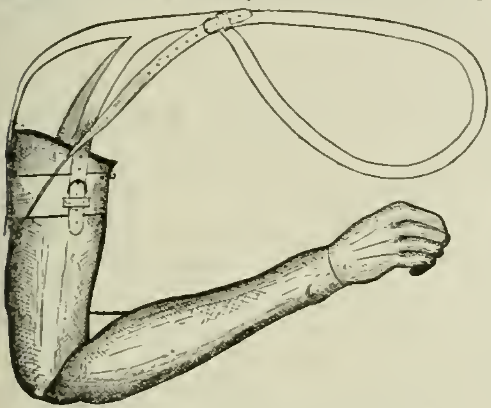

Fig. 4.—Arm for Amputation above the Elbow.

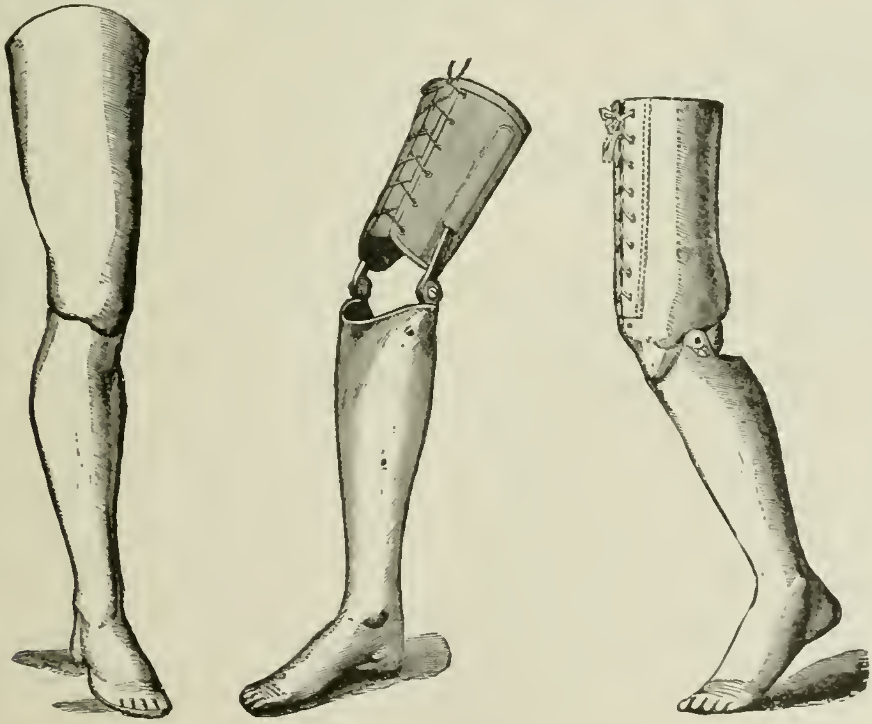
of the stump, and having—in lieu of the more symmetric proportions of the leg—a "pin" placed at its



A B C

Fig. 5.—The Marks Rubber Legs.

lower end to insure connection between it and the ground. This form of leg is strongly to be recommended when expense is an object, as it really fulfills all the conditions excepting external similitude embraced by a better piece of mechanism. It is likewise occasionally employed with benefit by those patients who, from lack of confidence, prefer learning the use of an artificial leg by first practicing with the commonest substitute. As, when the body rests on a single leg, the center of gravity passes through the tuberosity of the ischium, it is essential that the *bucket* should be so made as to have its sole point of bearing against this part of the pelvis.

Of the more complicated forms of artificial leg, four are especially popular. The first of these is of English origin, and, owing to its having been adopted by the late Marquis of Anglesea, is known as the *Anglesea-leg*. For a description of it the reader is referred to Gray's work on "Artificial Limbs," one of the firm of Grays having been the constructor of the legs used by the Marquis. This was for a long time *the* fashionable artificial leg. The second leg worthy of notice is that invented by an American named Palmer, and called the *Palmer-leg*. From its lightness and the greater ease of walking with it, it has long superseded the Anglesea leg in America. In the third of these legs, also invented in America and known as the *Bly-leg*, the principal faults of the two other legs have been completely overcome. The advantages of this leg are thus summed up: (1) Adaptation to all amputations either above or below the knee. (2) Rotation and lateral action of the ankle-joint. (3) Power on the part of the patient to walk with ease on any surface however irregular, as, owing to the motion of the ankle-joint, the sole of the foot readily accommodates itself to the unevenness of the ground, which is an advantage never before possessed by any artificial limb. (4) The ankle-joint is rendered perfectly indestructible by ordinary wear, owing to its center being composed of a glass ball resting in a cup of vulcanite. (5) The action of the ankle-joint is created by five tendons, arranged in accordance with the position assigned to them in a natural leg. These tendons are capable of being rendered tight or loose in a few instants, so that the wearer of the leg has the power of adjusting with precision the exact degree of tension from which he finds the greatest comfort in walking, and also of giving the foot any position most pleasing to the eye. (6) There is a self-acting spring in the knee-joint, urging the leg forward in walking, and imparting automatic motion, thus avoiding the least trouble to the patient, who finds the leg literally and not metaphorically walk by itself. (7) At the knee-joint there is a mechanical arrangement representing the crucial ligaments, and affording natural action to that articulation by which all shock to the stump in walking is avoided. The fourth of these legs, contrived by Mr. Marks, the inventor of the rubber hand already described, not only possesses all the valuable features of the other legs, but has novel points of value in addition. India-rubber is largely used in its construction. In the drawing (Fig 5), A represents a full-length leg standing erect, to be applied in all cases where amputation occurs above the knee-joint. B represents a leg to be applied where the leg has been amputated below the knee-joint and the stump is flexible enough and sufficiently long to enable the wearer to use it in walking. It also represents the leg with the heel compressed, and in its position after taking the step and when firmly planted on the ground. C is termed a knee-bearing leg. It is to be applied where amputation takes place below the knee, and where the stump is too short or contracted at right angles, so the knee-joint cannot be used in walking. This figure represents the leg slightly bent at the knee, and bearing well upon the toe, as in the act of lifting it to take the next advance-step.

The accompanying drawing (Fig. 6) shows the India-rubber foot before being applied to the leg. This rubber foot constitutes the main feature in the

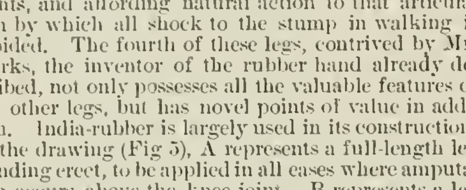


Fig. 6.—The Marks Rubber Foot.

legs shown in the figures. It is made mostly of India-rubber of a very spongy, light, and elastic character. A piece of willow wood, nearly filling the rubber heel at the top, or surface, where the leg rests, runs down about one fourth of the distance towards the lower part of the heel; also forward and downwards to the joint at the ball of the foot. This piece of wood is the base upon which the foot is built, and is also the medium whereby the foot is joined firmly to the leg. The leg itself is made of light, tough willow in all cases, except the thigh-piece shown in B, and the front part of the thigh-piece in C, both of which are made of leather. The entire leg and foot are covered with fine buckskin, neatly coated with a lifelike, waterproof finish, making it both light and strong. It will be seen that there are no movable ankle-joints in these limbs, the necessity for which being entirely obviated by the Elastic Rubber Foot, which gives all the motion required in walking, and also the ease, firmness, elasticity, and reliance absolutely necessary in a perfect artificial leg. The rubber foot also gives all the required lateral motion to the foot when stepping upon sideling or uneven ground. This leg dispenses with all machinery of whatever character, and has been in use by the Government, for officers, soldiers, and seamen who lose their limbs in service, for the last twenty years, giving great satisfaction.

Fig. 7 gives a rear view of the knee-joint of the leg, A. The T-joint is fastened to the upper part or thigh-piece of the leg, and the gudgeons of the T are held in adjustable, oblique boxes, which are easily set at any time by the screws passing through the caps into the main leg, so as to keep the joint to work tight and still, yet free and perfectly flexible, the small projecting bar attached to the T with the button-shaped ball operating upon the spiral spring, so as to throw the foot forward when bent in walking, and so as to hold the foot under when bent at right angles in a sitting position.

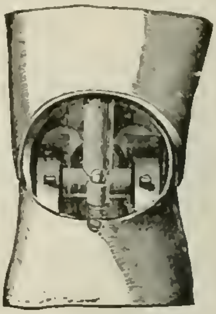

Fig. 7.

In cases of arrested development of the lower limbs, short-legged persons may be made of the ordinary height by the use of two artificial feet placed twelve or more inches below the true feet, and attached to the legs by means of metallic rods, jointed at the knee and ankle.

Other parts not entitled to be called limbs can also be replaced by mechanical art—such as the nose, lips, ears, palate, cheek, and eye. In the present advanced state of plastic surgery, deficiencies of the nose, lips, and palate can usually be remedied by an operation; cases, however, may occur where an artificial organ is required. Artificial ears are moulded of silver, painted the natural color, and fixed in their place by a spring over the vertex of the head. Loss of an eye causes sad disfigurement; but the artificial eyes of Boissonneau, which have been shown in all the recent public exhibitions, completely throw all others in the shade, and cannot be detected without the closest inspection.

In the United States service every officer, non-commissioned officer, enlisted or hired man, of the land or naval forces of the United States, who in the line of his duty as such, or through disease contracted in the service as such, loses a limb or the use of a limb, receives once every five years an artificial limb or appliance, or commutation therefor, as he shall elect, under such regulations as the Surgeon-General of the Army may prescribe; and the period of five years shall be held to commence with the filing of the first application after the seventeenth day of June, in the year 1870. The money value allowed as commutation is—for legs $75; for arms, feet, and apparatus for resection, $50 each. Necessary transportation to have artificial limbs fitted is furnished by the Quartermaster-General of the Army, the cost of which is refunded out of any money appropriated for the purchase of artificial limbs.

ARTIFICIAL LINE OF SIGHT.—In gunnery, the right line from the eye to the object to be hit, passing through the front and rear sights.

ARTIFICIAL POINT-BLANK.—Point-blank and point-blank range are terms formerly supposed to possess great importance in gunnery. The point-blank is the point at which the line of sight intersects the trajectory the second time; or, more practically speaking, it is that point which, being aimed at, is struck by the projectile. The *natural point-blank* corresponds to the *natural line of sight* when this line is horizontal, and the distance of this point from the muzzle is called the point-blank range. An *artificial point-blank* is one corresponding to an *artificial line of sight*.

To hit an object within the point-blank, the piece is aimed below it. To hit an object beyond the point-blank, the muzzle has to be raised, which is effected by elevating the notch on the rear-sight along a vertical leaf, on which are graduated distances. In this manner artificial point-blanks (corresponding to the artificial lines of sight) are established, the piece being aimed as when at point-blank. See *Point-blank*.

ARTILLERY.—The history of artillery may be said to date from the discovery of gunpowder, which is popularly attributed to Roger Bacon and Barthold Schwarz, two Monks of the thirteenth century, although a mixture of niter, charcoal, and sulphur was used for explosive purposes by the Chinese during the ninth century. Its introduction into European warfare is due to the Moors, for mention is made of artillery at Cordova in 1280. Ferdinand IV. of Castile took Gibraltar with artillery in 1309, and cannon were used at the sieges of Baza, Martos, and Alicante. This arm soon became known throughout Europe. The French availed themselves of it at the siege of Puy Guillaume in 1338, and the English had three small guns at the battle of Crécy in 1346. In the French War of Independence against the English, artillery was much used; and in 1428 Joan of Arc is said to have pointed the guns herself. The guns of the fourteenth century were of the rudest design; in the fifteenth century Charles VIII. of France used an improved artillery in his Italian campaigns, and to this arm also Louis XII. largely owed his success in Italy. Henry VII. and Henry VIII. of England did much for its advancement. During the sixteenth century brass guns and cast-iron projectiles were adopted throughout Europe, while Tartaglia in Italy made great improvements in gunnery and invented the gunner's quadrant. During the latter part of this century case-shot, the German *hagelkugel*, was invented, and shells were fired from mortars. The first half of the seventeenth century forms an era in the history of artillery. Henry IV. of France was among the first to recognize its coming importance, and occupied himself diligently with its improvement. Maurice and Henry Frederick of Nassau made much advancement in it, but it was under the great Swedish warrior, Gustavus Adolphus, that artillery first began to take its true position on the battle-field. He attached two guns to each regiment, and may, therefore, be said to be the father of the battalion system of guns; he proved its utility in the celebrated Thirty Years' War. During his life he did much to forward the science of artillery, increasing its mobility and its rapidity of fire, and raising the proportion of guns to over six for 1000 men. In England the Laboratory at Woolwich was established in 1672, and a reorganization of the artillery took place in 1682 under the Master-General Lord Dartmouth. Louis XIV. established a special artillery force, raised in 1671 a regiment for artillery duty, and in 1690 founded the first artillery schools. The inventions of the elevating-screw, the prolonge, and the priming-tube filled with powder, were made during his reign. The Prussian artillery was very backward during the first part of the eighteenth century, and Frederick the Great did not at first place much value upon its services. Although it contributed much to Frederick's victory at Rossbach, it was usually no match for the well-handled Austrian guns, which fact impressed him with the importance of giving more attention to this branch. He therefore raised the proportion of guns, and established horse-artillery in 1759.

After the Seven Years' War the Austrians recognized the importance of the artillery in modern warfare, and Prince Lichtenstein was commissioned to reorganize it. The experience of Frederick's wars was best utilized by France, and under Gribeauval, in 1765, great reforms in the French artillery were commenced. This officer had been sent to Austria during the Seven Years' War, and had held command under Prince Lichtenstein. Struck with the improvements effected in Austria, he strove on his return to build up a complete system, as to both persons and matériel, making a separate provision for field, siege, garrison, and coast artillery. At first his reforms met great opposition, but in 1776 he became First Inspector-General of Artillery, and was able to carry through his improvements. The French horse-artillery dates from 1791, and the last step in the complete organization of the field-artillery was made in 1800, when the establishment of a Driver's Corps (of soldiers) put an end to the old system of horsing by contract. Napoleon, who was a great artillery officer, introduced the tactical combination with brilliant success. To his wars we first look for instances of the important effects produced by this arm in that concentration of fire which in those days was produced only by massing guns. Napoleon III. made artillery a special subject of study; and the great treatise upon it, commenced and mainly written by him, is a standard work on the subject. Since the war of 1870–71, in which the French artillery proved itself far inferior to the German, the French have been actively engaged in experiments with a view to the introduction of superior guns, and have increased their force of artillery by 120 batteries. Similar progress has been made by the other great European Powers during this century. The British artillery had greatly deteriorated during the eighteenth century, and was not up to the standard of other countries, but horse-artillery was formed in 1793, and a Driver's Corps introduced the following year. At the commencement of the nineteenth century the Prussian artillery was powerful rather than mobile; but after the disasters of 1806–7 this defect was remedied, and in 1816 further improvement was made. In 1872 the German artillery was reorganized, the field-artillery of each army corps being augmented to 17 batteries, and divided into two regiments. The Austrian artillery has always been pre-eminent both in the excellence of its matériel and in tactical handling on the field. In 1859 rifled guns were introduced, and in 1861 gun-cotton was substituted for gunpowder, but was soon afterwards abandoned. Russia won special distinction in the Napoleonic wars by the power and good service of its artillery, and has continued to give great attention to this arm. Having adopted the breech-loading system of Prussia, Russia has increased its field-artillery from three to four batteries per division, with thirty-eight batteries of mitrailleuses added.

General William F. Barry was the organizer of the artillery of the Union armies during the Rebellion. The aggregate of field-guns was about 15,000, with 40,000 horses and 48,000 men. The number of guns of position used in field-works or intrenched lines during that war was 1200, served by about 22,000 men. There are at present in the Regular Army of the United States 5 regiments of artillery, with 284 officers and 2321 enlisted men. The personal armament of an artilleryman of the mounted batteries, whether field or siege, is a pistol and saber for the sergeants, trumpeters, and drivers; and a saber only for each cannoneer. Those serving in the sea-coast fortifications have a rifle-musket and the full equipment of an infantry soldier. The matériel of a mounted battery of the U. S. field-artillery when on a war-footing is 6 guns, 6 caissons, 1 battery-wagon, 1 traveling-forge, and 112 horses; on a peace-footing it is 6 guns, 6 caissons, and 80 horses. The ammunition of a field-battery for active service in war is 400 rounds per gun. The organization of a siege-battery in the U. S. service is 4 guns, 1 battery-wagon, 1 traveling-forge, and 60 horses. The ammunition for the siege-battery is 250 rounds per gun. The breech-loading principle was adopted in a clumsy way at the very outset of cannon construction. John Owen first cast brass cannon in England in 1535, and a year or two later they were manufactured in Scotland; but no long guns for firing hollow projectiles at long range by direct fire were known until Colonel Bomford, of the U. S. Ordnance Department, invented a cannon in 1812 called a "Columbiad," which proved very successful. Iron in some form is the sole metal in use for heavy artillery; cast-iron is used for smooth-bore guns and for rifled guns in the United States. Palliser invented a gun with a steel interior tube, strengthened by an exterior casting of iron; and his system became very popular in England; but the inventions of Sir William Armstrong, improved by those of Fraser, proved far superior, and have been generally adopted. Russia, Germany, and other nations have adopted the Krupp system with heavy forgings of steel ingots.

The defense of war-ships with iron armor has caused an increase in the size, weight, and calibers of sea-coast and naval cannon, and the whole method of gun-construction has been altered. Armstrong was the first in England to see the necessity of a change, and his method was improved by Whitworth, Fraser, Palliser, Blakely, and others. Francis Krupp of Essen, Prussia, is the inventor of a new method which proved so successful that it has been introduced in Germany, Russia, Austria, Belgium, and Spain. The body of the gun is fabricated from a solid ingot of low steel worked under heavy steel hammers, and is strengthened by three or more steel tubes shrunk upon the central tube of the gun, the last ring, or tube inclosing the breech, being forged in one piece with the trunnions, without a weld. The rings have various lengths, and the gun is diminished in thickness towards the muzzle, not by tapering, but by being turned with concentric steps of diminished heights. Krupp makes all his projectiles and gun-carriages of steel. In the United States, Rodman, Dahlgren, and Parrott have devoted themselves to the art of gun-construction. The Rodman gun is of cast-iron; it is cast hollow and cooled from the inside, the exterior being in the mean time kept from rapid cooling by fires built around the gun in the casting-pit. The Dahlgren gun is of iron cast solid, and cooled from the exterior, very thick at the breech up to the trunnions, then diminishing in thickness to the muzzle. The Parrott gun, like the Rodman, is of cast-iron, cast hollow, cooled from the inside, and strengthened about the chamber by an exterior tube of wrought-iron bars spirally coiled and shrunk on. It has been suggested that a Rodman gun lined with wrought-iron on Palliser's system would prove a highly effective weapon.

The manner of placing artillery and its employment must be regulated by its relative importance, under given circumstances, with respect to the action of the other arms. In the defensive, the principal part is usually assigned to the artillery; and the positions taken up by the other arms will, therefore, be subordinate to those of this arm. In offensive movements the reverse generally obtains. In defensive positions the security of the batteries is of the last importance. Unless the batteries are on points which are inaccessible to the enemy's cavalry and infantry, they must be placed under the protection of the other troops, and be outflanked by them. As in the defensive, we should be prepared to receive the enemy on every point; the batteries must be distributed along the entire front of the position occupied, and on those points from which they can obtain a good sweep over the avenues of approach to it; the guns being masked, when the ground favors, from the enemy's view, until the proper moment arrives for opening their fire. The distance between the batteries should not be much over 600 paces; so that by their fire they may cover well the ground intervening between them, and afford mutual support; the light guns being placed on the more salient points of the front, from their shorter range and greater facility of maneuvering; the heavier guns on the more retired points. Guns of various caliber should not be placed in the same battery. A sufficient interval should also be left between batteries of different caliber, to prevent the enemy from judging, by the variations in the effect of the shot, of the weight of metal of the batteries. Those positions for batteries should be avoided from which the shot must pass over other troops to attain the enemy. And those should be sought for from which a fire can be maintained until the enemy has approached even within good musket-range of them. Where the wings of a position are weak, batteries of the heaviest caliber should be placed to secure them. A sufficient number of pieces—selecting for the object in view horse-artillery in preference to any other—should be held in reserve for a moment of need; to be thrown upon any point where the enemy's progress threatens danger; or to be used in covering the retreat. The collection of a large number of pieces in a single battery is a dangerous arrangement, particularly at the outset of an engagement. The exposure of so many guns together might present a strong inducement to the enemy to make an effort to carry the battery; a feat the more likely to succeed, as it is difficult either to withdraw the guns or change their position promptly after their fire is opened; and one which, if successful, might entail a fatal disaster on the assailed, from the loss of so many pieces at once. In the outset of offensive movements, good positions should be selected for the heaviest pieces, from which they can maintain a strong fire on the enemy until the lighter pieces and the columns of attack are brought into action. These positions should be taken on the flanks of the ground occupied by the assailant, or on the center if more favorable to the end to be attained. In all cases, wide intervals should be left between the heavy batteries and the other troops, in order that the latter may not suffer from the return-fire which the assailed will probably open on the batteries. For the same reason, care should be taken not to place other troops behind a point occupied by a battery, where they would be exposed to the return-fire of the assailed; when this cannot be avoided, the troops should be so placed as to be covered by any undulation of the ground, or else be deployed in line to lessen the effects of the shot. The artillery which moves with the columns of attack should be divided into several strong batteries, as the object in this case is to produce a decisive impression upon a few points of the enemy's line by bringing an overwhelming fire to bear upon these points. These batteries should keep near enough to the other troops to be in safety from any attempts of the assailed to capture them. Their usual positions will be on the flanks and near the heads of the columns of attack; the intervals between the batteries being sufficient for the free maneuvers of the other troops, in large bodies. The maneuvers of these batteries should be made with promptitude, so that no time may be lost for the action of their fire. They should get rapidly over unfavorable ground to good positions for firing, and maintain these as long as possible; detaching, in such cases, a few pieces to accompany the columns of attack. In all the movements of the batteries, great care should be taken not to place them so that they shall in the least impede the operations of the other troops. See *System of Artillery.*

ARTILLERY COLORS.—In the United States army each regiment of Artillery has two silken Colors. The first, or the National Color, of stars and stripes, as described for the garrison flag. The number and name of the regiment are embroidered with gold on the center stripe. The second, or Regimental Color, is yellow, of the same dimensions as the first, bearing in the center two cannon crossing, with the letters U. S. above and the number of the regiment below; fringe, yellow. Each Color is six feet six inches fly, and six feet deep on the pike. The pike, including the spear and ferrule, is nine feet ten inches in length. Cords and tassels, red and yellow silk intermixed. See *Colors.*

ARTILLERY CORPS.—The larger weapons, before the invention of gunpowder, were sometimes called *engines of war*, sometimes *artillery*, and were worked by strong and rough soldiers, who needed no particular apprenticeship to that art. When, however, large balls of iron came to be propelled by the irresistible force of gunpowder, a great revolution gradually took place, though garrison-guns and siege-guns were improved more rapidly than field-guns. Nevertheless, field-guns changed the whole aspect of military tactics; for it became necessary that an army should form in order of battle at a much greater distance from the enemy than in older times. And when the cannon were made more rapidly movable, so did tactics vary. Gradually a body of men were set apart to study the force and action of gunpowder, the flight and range of projectiles, the weight and strength of cannon, and the maneuvering of heavy masses. The French were the first to make these researches; after them, the English; and still later, the Germans. During the Thirty Years' War an important step was taken in Germany—that of including the artillerymen, who were till then a sort of guild, as a component in the Regular Army. Gustavus Adolphus in Sweden, Frederick II. in Prussia, and Napoleon I. in France, all attached a very high degree of importance to the artillery as an arm of the service. After the great wars in the beginning of the present century nearly all the States of Europe formally recognized the artillery as the third great branch of military service (next after the infantry and cavalry); indeed, some of them, including Russia and Sardinia, have shown a tendency to elevate it to the first rank.

Artillery Corps, or artillerymen, are divided into land-artillery and marine-artillery. The land-artillery is divided into field, coast, garrison, and siege artillery. The field-artillery is subdivided into horse and foot. There are also the special appellation of reserve, light, and heavy artillery. In most European States the artillerymen are divided into regiments, battalions, brigades, and companies; but, in Britain the whole form one enormous regiment, which is expanded or contracted according to the exigencies of the service. When military men speak of *the* field-artillery they usually include cannon, carriages, horses, ammunition, and stores of every description, as well as the artillerymen. The distinction between heavy and light artillery depends on the size of the cannon and the weight of the shot and shell propelled from them. For obvious reasons the construction of very large field-guns is avoided. Military men are not quite agreed as to the precise figures; but there is a general concurrence in opinion that a well-appointed field-force should have two or three artillery guns to every 1000 infantry, and five or six horse-artillery guns to every 1000 cavalry. The proportion is necessarily affected by the kind of country and the amount of available transport. During the Peninsular War, Wellington had seldom more than 1 gun to every 1000 soldiers; when he entered France he had 3 to the 1000. Napoleon preferred 2 per 1000, with a larger supply of ammunition than had before been deemed necessary; and many foreign governments followed his example. Experienced officers in the British artillery have laid it down as a useful rule that an army of 60,000 men, comprising 50,000 infantry, 7500 cavalry, and 2500 artillery, should have 100 pieces of ordnance—viz., 30 for horse-artillery, 54 for foot-artillery, and 16 in reserve. See *Honorable Artillery Company*.

ARTILLERY HORSES.—Horses for artillery service should be not less than nine hundred nor more than twelve hundred pounds; age not less than five nor more than eight years; forehead wide; shoulders broad enough to support the collar, but not too heavy; forelegs short, straight, and well under the horse; chest broad and deep, barrel large and increasing from girth to flank; withers elevated, back short and straight, loins and haunches broad and muscular; hind-legs short, hocks well bent and under the horse; feet rather large. Special care must be taken that the withers are not too sharp, and that the horse is neither sway-backed nor roach-backed. In time of war horses should not be accepted under six nor over ten years of age; young animals, as a rule, are not able to stand the exposure of a campaign. Each horse must be well broken to harness; and in each battery horses of the minimum size and weight should never exceed one third of the whole number. The load allotted to an artillery horse is less than that usually drawn by a horse of commerce, for the reason that allowance must be made for bad roads, bad forage, rapid movements, and forced marches. They are as follows: Light-artillery horse, 700 lbs., including carriage; heavy field-artillery, 850 lbs.; siege-artillery, 1000 lbs. The above is based on the rapidity of movement required in the different services. An ordinary draught-horse can draw 1600 lbs. 23 miles in a day. Usually a horse can draw seven times as much as he can carry; hence all material of war should be transported on carriages if practicable. The average march for artillery on good roads is from fifteen to twenty miles per day. With rare exceptions the walk is the invariable gait. Long marches or expeditions should be begun moderately, particularly with horses new to the service. Ten or twelve miles a day is enough for the first marches, which over good roads may be increased to twenty or twenty-five miles when necessary, after the horses are inured to their work. The care of horses on the march is one of the most important duties of an artillery officer; by *constant attention* many horses may be kept in serviceable condition which would otherwise be disabled for months. Reveille, ordinarily, should not be sounded on the march before daylight, as horses rest better from midnight until dawn than at other times. A halt of from five to ten minutes is made at the end of every hour, for the purpose of adjusting harness, tightening girths, etc. When troops march for the greater part of the day, a halt of from twenty to forty-five minutes should be made about noon. The march is usually in column of sections; when practicable it will be in column of platoons at closed intervals; but the front of the column must not be frequently diminished or increased, as this unavoidably adds to the fatigue of the horses, particularly of those in rear. When distances are lost in column, they must never be regained by taking the *trot;* no practice is more fatiguing to horses and more injurious to their shoulders than the alternate trotting and walking so often seen at the rear of artillery columns. The walk will be quickened as much as possible by such carriages as have lost distance, and it is the duty of the Captain to have the gait of the leading guide slackened, or the column halted, so that they can close up. See *Draught Animals*.

ARTILLERY LEVEL.—An instrument adapted to stand on a piece of ordnance and indicate by a pendulous pointer the angle which the axis of the piece bears to the horizontal plane. By its means any required angle of elevation is given to the piece.

ARTILLERY MASS.—A concentration of artillery with mobility. It should combine with great mobility a powerful fire, which can be concentrated on some definite point of an enemy's line to be broken through. *Masses of Artillery* are usually employed after troops have been engaged for some time and the weak points of the enemy's lines have been ascertained.

ARTILLERY PARK.—A collective name given to the whole of the guns, carriages, ammunition, and other appurtenances essential to the working of siege or field-artillery. Besides reserve guns and carriages, there belong to it the ammunition-wagons, as well for the infantry and cavalry as for the artillery, the implements and materials necessary for repairing and completing equipments, harness-stores, field-forges, laboratories, and (in some armies) transport and provision wagons. The *personnel* of a park of artillery consists of artillery officers, non-commissioned officers, and artillerymen; besides a large number of smiths, wheelwrights, saddlers, armorers, drivers, and other mechanics and laborers. Sometimes the term is applied to the place selected, as well as to the vast military stores collected there.

ARTILLERY PRACTICE.—Siege-artillery is generally used against fixed objects on land; the target should therefore be placed on land. The range for the 4.5-inch gun should be about 2000 yards, and for this distance a target 12 feet square would be suitable. It is made of canvas, or of light boards nailed to uprights planted in the ground, and is whitewashed. A circular bull's-eye 4 feet in diameter is painted in black in the center of the target. About 100 feet diagonally in front of the target a pit of suitable size for the marker is dug, the earth being thrown upon the side towards the piece. It adds greatly to the security of the marker to have splinter-proof covering for the pit. The marker is provided with a disk, about a foot in diameter, made of sheet-iron or thin board, one side of which is painted black, the other white, and provided with a staff sufficiently long to enable him to point the disk to any part of the target. The marker should be accompanied by a flagman skilled in signaling, and provided with a white or red flag, such as are supplied by the Signal Bureau. At the piece is another flagman similarly provided. Where it is possible, a hill, situated two or three hundred yards beyond the target, is advantageous for arresting the projectiles. Cleared space beyond the target is preferable to woods.

Firm ground is selected for the gun-platform, which is laid with care and precision. The distance to the target is ascertained either by direct measurement, with the telemeter, or by triangulation. Previous to going out to fire, the Instructor should prepare a memorandum-table of elevations for each kind of projectile to be used, and the time to which fuses are to be cut for shells. The time of flight is determined by means of a stop-watch, and the distance at which shells burst by the Boulongé telemeter. Care and deliberation are exercised in loading and pointing. When the piece is ready to be fired, a signal is made by the flagman at the piece to the marker and flagman at the target, who then screen themselves in the pit. As soon as the projectile strikes, the flagman at the pit raises his flag and the marker proceeds, in case it has struck the target, to cover the hole with his disk; when a shell has been fired, the flagman signals whether it has burst short of or beyond the target. An observer at the piece, with a glass, or even with the naked eye, can see upon which side of the target the projectile passes, and can form an approximate estimate of the distance to the right or left.

From the data thus obtained, errors of pointing and of cutting the fuse may be corrected for succeeding shots. A complete record of each fire is kept and entered on a blank form furnished by the Ordnance Department. This record, besides giving a description of the piece, contains the kind and weight of the projectile, the kind of powder and the weight of charge, the elevation and the time of flight, the kind and length of fuse, and the position of the piece, whether above or below the level of the target. In the column of remarks is entered whether the projectile struck the target, and if so, where; or if it missed, to which side, and how far; whether it fell short or went beyond; whether the shell exploded short, beyond, or did not explode. The direction of the wind, with reference to the line of fire, and its strength are noted. Those engaged in the firing, particularly the officers, should examine and study the ground about the target, observing the effect produced by the striking of the shot; whether they penetrated or ricocheted; the depth of penetration, the character of the craters formed by bursting shells, and of the furrows made by glancing projectiles. This information is useful when constructing works of shelter against an enemy, and in the attack upon and demolition of his works.

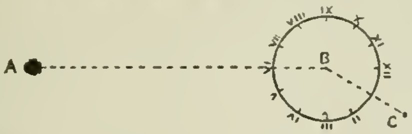
When the allowance of ammunition that may be expended admits of it, firing at a horizontal target should be practiced. The object of this kind of firing is to group the shots as closely as possible on the ground about the target. The rectangular space inclosed by the shots is called the polygon of fire. In actual service, the purpose of such fire is to reach an enemy sheltered behind works or some intervening object, as hills or woods. This is accomplished by the *drop* of projectiles fired at long range, or at short range by reducing the charge and giving high elevation. Skill in this, the most difficult kind of firing, can be acquired only by practice. To obtain the *center of impact*, the target, if an upright one, is divided into four parts by a horizontal and a vertical line passing through the center of the bull's-eye; if the target is horizontal, as for mortar-firing, one line is drawn as the trace of the plane of fire, and the other throught the center of the target at right angles to it. The distance in feet of each shot is measured from these lines as co-ordinates, and recorded in a table; as, *above* or *below* the horizontal line, and to the *right* or *left* of the vertical line. The table is of the following form:

No. of Shot.	Distance from Co-ordinates.				Distance from Center of Impact.			
	Vertical.		Horizontal.		Vertical.		Horizontal.	
	Above	Below.	Right.	Left.	Above	Below.	Right.	Left.
1....	3	..	2	..	4	..	1.6	...
2....	..	4	..	5	..	3	...	5.4
3....	.	6	4	..	..	5	3.6	...
4 ...	4	.	..	2	5	..	...	2.4
5....	..	2	3	.	..	1	2.6	...
	7	12	9	7	9	9	7.8	7.8
	5 + 5 = 1		2 + 5 = 0.4		18 + 5 = 3.6		15.6 + 5 = 3.12	

The algebraic sum of the distances in each direction, divided by the number of shots, gives the position of the center of impact in this direction. In the above example, the position of the center of impact is 1 foot below and 0.4 foot to the right of the center of the target. To obtain the mean deviation it is necessary to refer each shot-hole to the center of impact as a new origin of co-ordinates; and this is done by subtracting the tabular distance from the distance of the center of impact if both be on the same side of the center of the target, and adding them if on different sides. The sum of all the distances thus obtained in one direction, divided by the number of shots, gives the mean deviation in that direction; which in the present case is 3.6 feet vertically and 3.12 feet horizontally. The foregoing affords a measure for the accuracy of fire of the piece and projectile, but it does not afford so good a test of marksmanship as the *string*, or sum of the distances of the shots from the point aimed at. Target-practice with the 8-inch siege-howitzer is conducted in the same manner as for siege-guns, but the distance should not exceed 1200 yards, and the target need not be over 10 feet square. Direct, ricochet, and rolling fire should each be practiced with this piece. To observe the flight of canister, it is best to fire it over smooth water, with an elevation not exceeding two degrees.

The target for the 10-inch siege mortar should be about 1500 yards from the piece. The best form for the target is that of a square, inclosing the general trace of a field-work. The sides of the square should be about 100 yards, and the trace marked by stakes driven at distances of about 10 feet apart. A large empty cask or box, placed upon a post in the center of the figure, and whitewashed, serves as a point to aim at. At a distance of not less than 150 yards to the right or left of the target is constructed a strong bomb-proof for the marker and flagman. The marker is provided with a number of small stakes which, to make them more conspicuous, have attached to them a piece of white or red stuff. When a shell strikes the ground, the marker notes the place with a stake, marking it with a number corresponding to the number of the shot. The rules governing the flagman at the bomb-proof and at the piece are the same as those already given for the siege-gun. A convenient method of notifying those at the mortar as to the points at which the shells strike is to describe around the center of the target a circle with a radius of about twenty-five yards. Divide this circle into twelve equal parts, which mark conspicuously with stakes, being careful to place one of the divisions on the prolongation of the line passing through the mortar and the center of the target. Call this point XII, and number the others around to the right similar to the dial of a clock.

Suppose the shell falls at the point C (see figure), on the line passing through the center B and I, and at a distance of, say, twenty yards from the center. The marker steps or otherwise measures this distance, and signals to the piece "*One*"—"20." Those at the piece, referring to a similar diagram made upon *diagram* paper, ascertain at a glance the approx-



imate point at which the shell struck the ground. Firm ground is selected for the platform, and the distance to the target is determined as for siege-guns, as is likewise the time of flight of shells and the distance at which they explode. In order to economize shells, charges sufficient only to blow out the fuse are used, and the shells are afterwards collected. After the firing is completed, the distance from each point where a shell fell to the center of the target is measured, and, if desirable, a diagram made of the target, showing the position of each shot.

Previous to going out to fire, the Instructor should prepare a memorandum range-table, so that the first shots may be approximately accurate. Subsequent shots should be rectified with care; the tendency is always to overdo the correction; as, for instance, when the shell falls short, the addition given to the charge will most likely send it far beyond; or, should it fall to one side, the correction given to the direction will probably be so great as to cause it to fall a still greater distance to the other side. Under the most favorable circumstances, mortar-firing, as compared with firing from other kinds of cannon, possesses, inherently, a considerable degree of inaccuracy, and in making corrections care should be observed to discriminate between this and faulty gunnery. When practicable, the charges of powder should be weighed; if *measured*, uniformity should be observed as to the manner of doing it, so that all shall be shaken down in the measure, or all measured loosely. The platform should be tested frequently, to see that it does not settle unevenly. The shells should be weighed and marked with chalk, and in firing them care should be observed to commence with the lightest and go up to the heaviest, or *vice versa*. This enables the corresponding variation of the charge to be made with a greater degree of certainty. Target-practice with the 8-inch mortar is conducted as just explained for the 10-inch.

Target-practice with the Coehorn mortar is similar to the foregoing; but the distance to the target should not exceed 1000 yards, and the target may be smaller. As this piece can be moved from place to place with ease, and requires nothing more than level and firm ground for a platform, the distance to the target should be varied, thus affording practice such as frequently occurs in war-service. Sea-coast mortars are chiefly used against shipping in the defense of harbors; a floating target should therefore be used. Any floating object, as an empty cask or a spar, anchored to mark the spot, suffices. The distance to the target should be about 3000 yards. The practice is conducted in the same manner as for the 10-inch siege-mortar, except that for the purpose of determining the points of fall, or of explosion of the shells, plane-tables are employed in the manner hereafter explained. As the shells are not recovered after being fired, bursting-charges may be used.

Sea-coast guns are chiefly used against ships, and are fired over water; hence the target should be floating. For the 15-inch smooth-bore and the 8-inch and Parrott rifles it should be moored at a distance of about 3000 yards; for the 10-inch smooth-bore the distance should be about 2000 yards. Plane-tables are employed for the purpose of recording the striking-points of shots or the bursting-distance of shells. The tables are stationed one at each extremity of a line, the length of which is accurately determined either by actual measurement or by triangulation from a base-line, the measurement of which has been made with care and precision. At every post mounting heavy artillery a base-line should be so determined and permanently marked, to be used for the various requirements of artillery-firing. About 1000 yards is a suitable length for it. The plane-tables are placed so as to have a clear view of the target, of each other, and of the guns. They should, furthermore, be so placed that the lines joining them with the target will intersect at as near a right angle as possible This enables the position of the shot to be determined and plotted with greater accuracy than would be the case did the lines intersect with a very acute angle. The direction of the wind is determined by a vane at the piece. The most convenient and reliable method of noting it is by referring it to the dial of a watch held in such a position that the line passing through VI and XII will be parallel to the line of fire with the XII towards the target. The *direction* is that from which the wind comes. When coming directly from the front, it is noted as "*twelve o'clock*"; when from the rear, as "*six o'clock*"; when from the right, as "*three o'clock*"; when from the left, as "*nine o'clock*"; and when from intermediate points, in a similar manner. The velocity of the wind is determined by an anemometer. When it is practicable to establish telegraphic communication, all of the foregoing operations, so far as signaling is concerned, are greatly facilitated.

The target for the Gatling gun is made of light canvas or ordinary muslin, and is in four or more sections, each section being 8 feet long by 6 feet high. The canvas is nailed to a strong light frame, the uprights of which extend about 12 inches below the canvas in order that they may be set in the ground. Practice should commence at 200 yards and the distance be increased up to 1000 yards, or more. At the first distance a single section of the target is sufficient, and as the distance increases other sections will be added. Smooth, level, and firm ground should be selected for the gun to stand upon. See *Floating Target* and *Target*.

ARTILLERY SCHOOL.—A special school for instruction and training in artillery. The first school for artillery instruction was established by the Venetians in the beginning of the sixteenth century. Soon afterwards Charles V. established similar schools at Burgos and in Sicily. The French founded a school of practical artillery in 1675; and in 1679 they added to it a theoretical school at Douai. At present France has no fewer than seven such establishments. Saxony had an artillery school in 1766; but the other German States were more tardy in this work. In Prussia the artillery and engineer schools are combined, but in most of the European States a separation between these two arms of the science is made. In most schools of artillery the officers' studies comprise mathematics, as much of physics and chemistry as is necessary to the duties of the artillerist, field and permanent fortification, garrison warfare, field-tactics, military history and topography, military surveying and sketching, drawing from the model, etc. The practical exercises include the serving and firing of guns and mortars, the laying out and constructing of field-batteries, and the operations of the laboratory and artillery workshop.

The headquarters for artillery instruction in England are at Woolwich. A *Royal Military Academy* was established there in 1741, to impart professional instruction to the Artillerists and Engineers belonging to the Royal Army. The East India Company sent their Artillery Cadets to this academy from the year 1798 to 1810; but afterwards, until 1861, they maintained a separate establishment at Addiscombe (which, however, was not wholly for artillery). At the present day the students in the academy are recruited by fair open competition. They enter between the ages of seventeen and twenty; and they remain two years, or such longer time as may fit them to pass an examination for the Royal Artillery or Engineers. The sons of military officers are admitted on lower terms than those of other persons. The financial control is under the Secretary of State for War; but the Commander-in-Chief regulates the discipline and internal arrangements. There are twenty-two Professors and Instructors of various kinds. Besides this Royal Military Academy, there is at Woolwich a *Department of Artillery Studies*, for the instruction of junior officers of artillery, and for facilitating their visits to the fortifications and public works of foreign countries. There is also a *Select Committee*, whose duties are not so much educational as experimental; it is a small establishment for examining and reporting on the numerous inventions relating to artillery brought before the War Office. The School of Gunnery at *Shoeburyness*, subordinate to the headquarters of the artillery at Woolwich, is for experiments upon ordnance, gunpowder, and projectiles, and to exercise young artillery officers in the practical and mechanical duties of their profession.

An Artillery School was established in the United States in 1823 at Fortress Monroe, but discontinued six years later. The School was re-established in 1858, and was again closed when the war began in 1861. Near the close of 1867 it was again established. It is commanded by a Colonel of Artillery, assisted by a Lieutenant-Colonel and a Major. The instruction is both theoretical and practical; and each of the Artillery Regiments in the Regular Army has one foot-battery at the School, the officers of the several batteries being the Instructors. The term of instruction at present is two years for officers and one year for enlisted men. The course of studies for enlisted men comprises mathematics, geography, history, tactics, and penmanship. The course of practical exercises comprises as much of that appointed for the school for officers as is essential for enlisted men.

The following is a summary of the Course of Instruction pursued at the United States Artillery School:

ARTILLERY TRAIN.—The guns which accompany an army are assembled into an *Artillery Train*, containing pieces of different weights and calibers, to meet the various requirements of a campaign; and a certain number of men with officers are attached to the train, some to serve the guns, others to move and mount them and effect repairs.

ART OF WAR.—War, as usually defined, is a contest between Nations, States, or parts of States, carried on by force. Wars, from the causes for which they are waged, or which have produced them, are called Wars of Opinion, Wars of Conquest, Civil Wars, Wars of Rebellion or Insurrection, etc. In a military point view wars are usually classed as defensive or offensive wars. The Armies of a Nation entering the domains of another for the purpose of making war upon it carry on an offensive war, while for the latter nation the war is defensive. To the Science of War belongs a study of those principles which govern all the operations of war, and which are deduced from a study of the history of wars conducted by great Military Commanders. The Art of War is the practical application of these principles by a General in command of an army. The Art of War is divided into branches, which by most military authorities are classed as follows: (*a*) Statesmanship in relation to war; (*b*) Strategy; (*c*) Grand Tactics; (*d*) Logistics; (*e*) Engineering; (*f*) Minor Tactics. The first subject belongs purely to the political questions involved in the war, which clearly do not come within the scope of a military work. There is a subject which most clearly is a branch of the Art of War, and which of late years has become of the first importance, owing to the short duration of recent wars, viz., the Organization of Armies. We have lately seen that power which has developed the system of organization to the greatest extent and most highly perfected it conquer in two wars of great magnitude in a wonderfully short period. That Nation which adopts the most perfect plan of organizing its Armies will have a great advantage in future wars; for, as time is the most important element in military operations, the

country which first places a superior number of disciplined troops in the field is enabled to assume the offensive at once, and to advance against an enemy unprepared to meet it. It is, therefore, a subject which will in future demand the first consideration and the most thorough study; for, owing to the facility with which armies are now moved to the place of contest, that nation which is more fully prepared has great odds in its favor at the beginning of the war, and a few decisive actions at this time will usually be favorable to it and go far toward ending the conflict.

For these reasons, then, the Art of War should more properly be subdivided into the following branches, viz.: (*a*) The Organization of Armies; (*b*) Logistics; (*c*) Strategy; (*d*) Engineering; (*e*) Tactics. The Organization of Armies is the building up necessary for the application of the principles of strategy to them. Logistics is the art of moving and supplying armies. Strategy is the art of directing armies upon the theater of war. Engineering is the art of disposing troops and making arrangements of obstacles by means of which an inferior force may successfully resist the attacks of a superior force; and also the art of overcoming and removing all obstacles placed in the way by an opposing force. The following are the duties of Engineers of an army: the construction and maintenance of field-telegraphs, the construction of fortifications, the conduct of engineering operations at sieges, mining, bridging, surveying, reconnoitering, opening and making roads, choosing positions, sketching ground, etc. The details of these duties will be found in the different Manuals and Text-books of Engineering. Tactics is the art of putting into execution the projects of Strategy. An intimate knowledge of all these branches is absolutely necessary in order to be a great and successful General. The formation of a plan, that is, deciding the nature of the war that will be waged; determining the objects to be attained, and the best manner and means of attaining them; or, in other words, outlining the general features of a campaign, belong to Strategy. The execution of the plan decided upon belongs to Tactics. The country in which the opposing armies can come into collision is the province of Strategy. The province of Tactics is the field of battle. The principles of war cannot be violated with impunity. These principles are fixed and are determined from the narrative of operations conducted by successful Generals. A study of military history is then necessary for a proper understanding of the principles of war; and as in all other professions, so in war, he who is most proficient in the lessons as taught by the masters of the art will be most successful.

The duties of each arm of the service overlap and blend into one another, and the higher the grade an officer attains, the more requisite it is that he should be acquainted generally with the duties of those arms of the service to which he himself does not belong. By this means alone can we hope to obtain that intelligent co-operation, that harmonious working of all branches of the service together, which makes a perfect machine out of the various elements comprising an army, and at the same time gives the surest guarantee of success. In armies, as elsewhere, there is a tendency for every one to think his own branch, that which he has studied most and knows best, the most important. Such feelings are very natural, and in the lower grades often do much good; but as men rise in the service it is desirable that they should know something of the duties of other branches, and the difficulties others have to contend with. Such knowledge tends to produce cordiality and forbearance. Cavalry officers falling into command of mixed forces will not then expect their infantry to gallop, infantry officers will not seek to bind the cavalry to the pace of their infantry. A knowledge of the capabilities of other arms will enable officers to use those arms to the best advantage as occasion offers. It should, however, be borne in mind that it is impossible to lay down fixed rules of action. Nearly every military regulation should be followed by the words "according to the ground and according to circumstances." Rules are but guides, which must be intelligently, not blindly, followed. Practice and experience alone can decide many points; practice and experience alone can give the power of applying rules; but theory, by which is really meant the experience obtained by others, is not the less important and valuable. Principles are but guides, which must be revised, examined, and verified after each war, after each discovery that may be brought to bear on the military art. The great success of Gustavus Adolphus, Frederick, Marlborough, Napoleon, Wellington, Von Moltke, are but due to careful consideration and appreciation of the effects of various discoveries on the Art of War. There is no finality in the Art of War.

ARX.—In the ancient military art, a fort, castle, etc., for the defense of a place.

ARZEGAGES.—Batons or canes with iron at both ends. They were carried by the Estradiots, or Albanian cavaliers, who served in France under Charles VIII. and Louis XII.

ASAPES.—An inferior class of Turkish soldiers employed in sieges to work in intrenchments and perform other pioneer duty.

ASHLAR—ASHLER.—Building-stone squared and hewn, as distinguished from rubble, or rough stones which are used as they come from the quarry without being dressed. Ashlar is laid in regular courses in fortification, and is of various kinds, according to the style of working that side of the stone which is to form the facing of the wall. Thus there are *tooled ashlar*—the marks of the tooling being either *random* or in *grooves*; *polished ashlar*, in which the face of the stone is rubbed smooth; and *rustic ashlar*, in which only the joints are accurately hewn, the face of the stone being left projecting irregularly. Quarriers apply the term ashlar to squared stones before being hewn. In old documents the term appears under a variety of forms, such as *achlere*, *ashelar*, *asture*, and *estlar*.

ASKERI MOHAMMEDIZE.—A name given to the Turkish regular troops organized according to modern tactics.

ASPECT.—An army is said to hold a menacing aspect when by advanced movements or positions it gives the opposing enemy cause to apprehend an attack. A country is said to have a military aspect when its general situation presents appropriate obstacles or facilities for an army acting on the offensive or defensive. An army is said to have an imposing aspect when it appears stronger than it really is. This appearance is often assumed for the purpose of deceiving an enemy, and may not improperly be considered as a principal *ruse de guerre*.

ASPHALT—ASPHALTUM.—The name given to a bituminous substance of a solid consistence. It probably owes its origin to vegetable matter which has been subjected to a slow process of decomposition or decay, resulting in the production of a bituminous coal, from which, by volcanic agency, the asphalt has been distilled and diffused over the neighboring district. The largest natural deposit of asphalt is in the Island of Trinidad, where the plain known as the *Pitch Lake* is found. The asphalt from Trinidad is largely used for ships' bottoms, and is reputed to kill the teredo or borer, which proves itself so very destructive to the wood of ships in tropical regions. Asphalt is also found on the shores of the Dead Sea in large quantity, and is known to the Arabs by the name or *Hajar Mousa*, or *Moses' Stone*. It likewise occurs in South America at Coxitambo near Cuenca, in Alsace and other parts of the European Continent, in East Lothian and Fifeshire (Scotland), in Shropshire, etc. During the manufacture of coal-gas much tarry matter is evolved from the retort, and is received in the coolers or condensers. If this tar be subjected to partial distillation, naphtha and other volatile matters escape, and an artificial asphalt is left behind, which possesses the principal properties and can be employed for the majority of purposes to which native asphalt is applied. The various kinds of asphalt have a pitchy odor, are of a black or dark-brown color, but do not soil the fingers; are insoluble in water, sparingly soluble in alcohol; but are in great part dissolved by ether, oil of turpentine, and naphtha. *Petroleum*, or *rock-oil*, is a native liquid bitumen, which largely exudes from crevices in rocks in many districts, and is essentially asphalt dissolved in naphtha. The specific gravity of asphalt is very near that of water, ranging from 1000 to 1100. When set fire to, it burns readily with a smoky flame, and is often used in the smaller gas-works as fuel, by being allowed to run very slowly into the furnace-fires. Asphalt, besides being employed for coating the exterior of ships' bottoms, is also used, in a heated condition, for saturating timber which is intended for piles in the construction of breakwaters, river-bridges, and other situations where the combined action of the air, water, and minute animals would soon render ordinary wood rotten and useless. Wooden houses may be preserved in the same manner by a coating of asphalt applied externally; and ground-flooring placed in damp situations is much the better for the spaces between the planks being filled up with asphalt. About 1840 asphalt began to be generally used for foot-pavements, and also for floors of cellars and outhouses. For purposes of this nature it is heated in portable boilers, into which, at a certain stage of the preparation, there is poured a quantity of thoroughly dried sand, gravel, or powdered limestone, which is well mixed with the liquid asphalt. The mixture is then spread on the spot prepared for it, and when cool forms a hard kind of pavement. Of this method of forming footways high expectations were at first formed; but latterly the process of asphalting has gone out of use in England, as it is found not to be so durable as stone, and therefore, in ordinary circumstances, more costly. In Paris, however, asphalting is still extensively practiced in the more spacious thoroughfares. The better kinds of asphalt are used in the manufacture of the black varnish which is employed in forming the enamel which coats the variety of leather known as *patent leather*.

ASPIC.—An ancient piece of ordnance which carried a 12-pound shot; the piece itself was 11 feet long, and weighed 4250 pounds.

ASPIS.—A large round or oblong shield which was used by the heavy infantry of the ancient Grecians.

ASSAS-BACHI.—A superior officer of Janissaries, who was also Administrator of the Police Department in Constantinople, and presided over public executions.

ASSASSINATION.—The law of war does not allow proclaiming either an individual belonging to the hostile army, or a citizen, or a subject of the hostile government, an outlaw, who may be slain without trial by any captor, any more than the modern law of peace allows such international outlawry; on the contrary, it abhors such outrage. The sternest retaliation should follow the murder committed in consequence of such proclamation, made by whatever authority. Civilized nations look with horror upon offers of rewards for the assassination of enemies as relapses into barbarism.

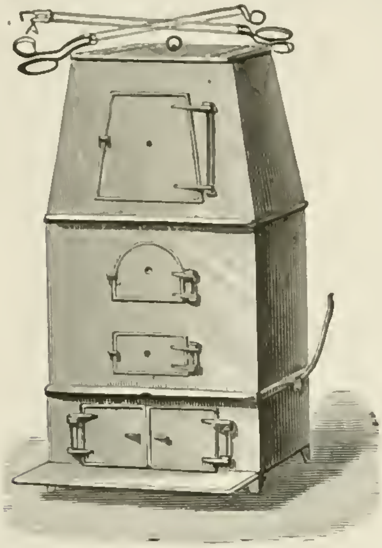
ASSASSINS.—A military order, a branch of the secret sect of the Ismaelites. The secret doctrines of these Ismaelites, who had their headquarters in Cairo, declared the descendants of *Ismael*, the last of the seven so-called Imaums, to be alone entitled to the califate; and gave an allegorical interpretation to the precepts of Islam, which led, as their adversaries asserted, to considering all positive religions equally right, and all actions morally indifferent. The atrocious career of the Assassins was but a natural sequence of such teaching. The founder of these last, Hassan-ben-Sabbah-el-Homairi, of Persian descent, and imbued with the free-thinking tendencies of his country, had, about the middle of the eleventh century, studied at Nishpur, under the celebrated Mowasek, and had subsequently obtained from Ismaelite *Dais*, or religious leaders, a partial insight into their secret doctrines, and a partial consecration to the rank of Dai. But on betaking himself to the central lodge at Cairo, he quarreled with the heads of the sect, and was doomed to banishment. He succeeded, however, in making his escape from the ship, and reaching the Syrian coast, after which he returned to Persia, everywhere collecting adherents, with the view of founding, upon the Ismaelite model, a secret order of his own, a species of organized society which should be a terror to his most powerful neighbors. In 1090 Hassan conquered the Fortress of Alamut, in the Persian district of Rudbar; and continued to increase in strength, intimidating Princes and Governors by a series of secret murders, and gaining possession of several fortified Castles, with their surrounding territories, both in the mountain-range south of the Caspian, in Kuhistan, and in the mountains of Syria (Massiat). The internal constitution of the order, which had some resemblance to the orders of Christian Knighthood, was as follows: First, as supreme and absolute ruler, came the Sheikh-al-jebal, the Prince or Old Man of the Mountain. His vicegerents in Jebal, Kuhistan, and Syria were the three *Dai-al-kebir*, or Grand-Priors of the order. Next came the Dais and Refiks, which last were not, however, initiated, like the former, into every stage of the secret doctrines, and had no authority as teachers. To the uninitiated belonged first of all the Fedavies or Fedais, i.e., the devoted: a band of resolute youths, the ever-ready and blindly obedient executioners of the Old Man of the Mountain. Before he assigned to them their bloody tasks he used to have them thrown into a state of ecstasy by the intoxicating influence of the *hashish* (the hemp-plant), which circumstance led to the order being called Hashishim, or hemp-eaters. The word was changed by Europeans into Assassins, and transplanted into the languages of the West with the signification of murderers. The Lasiks, or novices, formed the sixth division of the order, and the laborers and mechanics the seventh. Upon these the most rigid observance of the Koran was enjoined; while the initiated, on the contrary, looked upon all positive religion as null. The catechism of the order, placed by Hassan in the hands of his Dais, consisted of seven parts, of which the second treated, among other things, of the art of worming themselves into the confidence of men. It is easy to conceive the terror which so unscrupulous a sect must have inspired. Several Princes secretly paid tribute to the Old Man of the Mountain. Hassan, who died at the age of 70 (1124 A.D.), appointed as his successor, Kia-Busurg-Omid, one of his Grand-Priors. Kia-Busurg-Omid was succeeded in 1138 by his son Mohammed, who knew how to maintain his power against Nureddin and Jussuf-Salaheddin. In 1163, Hassan II. was rash enough to extend the secret privilege of the initiated—exemption, namely, from the positive precepts of religion—to the people generally, and to abolish Islam in the Assassin State, which led to his falling a victim to his brother-in-law's dagger. Under the rule of his son, Mohammed II., who acted in his father's spirit, the Syrian Dai-al-kebir, Sinan, became independent and entered into negotiations with the Christian King of Jerusalem for coming over, on certain conditions, to the Christian faith; but the Templars killed his envoys, and rejected his overtures, that they might not lose the yearly tribute which they drew from him. Mohammed was poisoned by his son Hassan III., who reinstated Islamism, and thence obtained the surname of the New Moslem. Hassan was succeeded by Mohammed III., a boy of nine years old, who, by his effeminate rule, led to the overthrow of the order, and was eventually murdered by the command of his son, Rokn-eddin, the seventh and last Old Man of the Mountain. In 1256 the Mongolian Prince Hulagu burst with his hordes upon the hill-forts of Persia held by the Assassins, which amounted to about a hundred, capturing and destroying them. The Syrian branch was also put down about the end of the thirteenth century, but remnants of the sect still lingered for some time longer in Kuhistan. In 1352 the Assassins reappeared in Syria, and indeed they are still reported to exist as a heretical sect both there and in Persia. The Persian Ismaelites have an Imaum, or Superintendent, in the district of Kum, and still inhabit the neighborhood of Alamoot under the name of Hosseinis. The Syrian Ismaelites live in the district of Massiat or Massvad. Their Castle was taken from them in 1809 by the Nossaries, but afterwards restored.

ASSAULT.—Assaults are of two kinds; open assaults and those made with great secrecy. Whatever be the kind of assatilt, it should be preceded by reconnoissances, made as full as possible, for the purpose of ascertaining the best and easiest approaches to the work, the nature and position of the obstacles, the numbers and kinds of troops composing the garrison, and the strength and positions of the reserves exterior to the work, but near enough to take part in its defense. Particular attention should also be paid to the positions for the artillery of the attack. These positions should be such that the guns can bring enfilading fires on the principal faces of the work, strong cross fires upon the point of attack, and if possible a sweeping fire on the approaches to the work in rear. An important point to be observed in this matter is to select, if possible, positions from which the guns will not have to be removed during the attack.

In any assault, it is necessary that the Officer Commanding and responsible for the whole operation should be in immediate communication with the troops during the assault, and be present with the reserve or supporting party. The troops destined for this duty should be divided into two portions, *each* equal in strength to three fourths of the garrison attacked: one portion being the attacking party, and the osher half the reserve or supporting party. Each column of the attacking party will also be subdivided into advance, main body, and support, whatever may be the number of these columns. The disposition of the attacking party, as it reaches the point of attack, will be regulated by the Engineer Officer, under the orders of the Officer Commanding—they having made the necessary reconnoissances; the party must be furnished with tools, ladders, and proper implements, adapted to the circumstances of the moment, and accompanied by a detachment of sappers. The disposition of the reserve, equal, as before observed, to the whole attacking force, should be regulated by the officer intrusted with the execution of the assault; and this reserve should be accompanied or not, according to circumstances, by cavalry and field-artillery. When these descriptions of force are present, the former should be placed under cover or out of gun-shot, about 1500 yards distant; the artillery should be kept in hand until the attacking party is engaged, when the guns should be spread out on the flanks and open a vigorous fire upon the works; the infantry, brought immediately in rear of the leading attack, should be placed under cover, if possible, from fire of grape and musketry, and halted until the issue of the first assault is seen. It is impossible to regulate an assault by any minute suggestions for the advance, except to observe that it is usual for each column to attack the salient points of the works and least defended portions; to throw out skirmishers and firing-parties under any cover available, and keep up a rapid and compact fire upon the defenders; to follow with the sappers and grenadiers to force all obstructions; and then to advance the main body, the supports of each column being judiciously planted in the rear. Eventually, as success occurs and the whole move on, points of security should be taken up, such as the reverse, or the exterior slope of the works; buildings, walls, as well as gorges and flanks, which frequently give cover. Men should be planted under an officer, with instructions to take no notice of the pell-mell, but to keep up a heavy firing in front; employing the sappers in intrenching the position taken up by the supporting party, or in collecting wagons, carts, carriages, etc., capable of being made into a barricade. Either on the supposition that the success of the assault is doubtful, or that there is a check or repulse, the reserve, in case of doubtful success, to render the attack doubly sure, should move forward under the Officer Commanding the whole assaulting force, and relieve the assailants, who take their places as the reserve as soon as order can be restored; the artillery brought into position in the openings, between the advancing columns, would be directed upon the retreating or resisting forces; and if success is finally complete, the cavalry, in the event of their being employed, will move forward, either through the openings cleared, or by a detour, if a fortified town, in pursuit.

In the second case—that of a check—the reserve, on the reconnoissance of the Officer Commanding, will either march forward in support of the attack, or to cover the retreat, if further perseverance in the assault is deemed impracticable—the artillery and cavalry being warned as to the intention. In the event of the assault being repulsed, the reserve, which should be in echelon, having advanced-guards in front, will allow the retreating party to move through the intervals, and the advanced-guard will endeavor to check the pursuit; if overpowered, they will fall back on the reserve, and the whole may in that manner retreat until beyond gun-shot, endeavoring to make a stand, repulse the garrison, and if possible convert failure into success, if the pursuit has been badly conducted and without due caution. As an important rule in all assaults, except in partial attacks, as an outwork, or any particular work in which a lodgment is to be made, the composition of the forces should be by regiments and corps, and not by detachments; and each non-commissioned officer should be provided with the means of spiking a gun, for which purpose even an old nail is sufficient. *Assaults*, if *feasible*, would seldom fail with these precautions, and there are few posts not open to assault, by taking the proper opportunity. An officer intrusted with the defense of a place should therefore exercise the most unremitting vigilance. See *Attack*.

ASSAY FURNACE.—A furnace with a chamber or muffle in which the metallic ore or alloy to be tested is exposed to heat. Assaying is more generally followed in the examination of compounds of silver and gold, but is likewise resorted to in the investigation of ores of iron, copper, tin, zinc, bismuth, antimony, mercury, and lead. In manufactured articles, also, some foreign metal (generally copper) is present, to impart hardness to the metal; and in Great Britain each article is assayed at the Goldsmiths' Hall, previously to being sold, so as to determine the exact richness of the metal whereof it is made. In the assay of compounds containing silver, the apparatus employed is a *cupel*, a small basin-shaped vessel made of bone-ash; and a *muffle*, composed of fire-clay, about eight inches in length and three to four inches in diameter, shaped like a miniature railway-tunnel, open at one end, closed at the other end, and having numerous slits or air-holes along the side. The drawing shows the Judson Assay Furnace, much used in Ordnance Laboratories. It is constructed in three sections, whereby the following advantages are secured: the risk of cracking, by unequal expansion and contraction, is much diminished; without sacrificing anything in strength, the gross weight is considerably reduced; and the furnace is rendered very portable. The grate is a revolving one. The convenience of this in removing ashes and clinkers is too evident to need comment. The muffle-doors and the door for feeding and crucible operations are large. There is a muffle-door in both front and back in order to use a muffle open at both ends. The advantages of this style of muffle are the greater convenience in working the charge, the diminished risk of cracking by unequal expansion and contraction, and the better



circulation of air over the contents. The ordinary muffle, closed at the back, can also be used as with any other furnace. The doors have small holes in them through which the reactions going on within the muffle may be watched without injury either to the operation or the operator.

ASSEGAI.—A light projectile spear employed by the Kaffirs. Also written *Assagai.*

ASSEGUAY.—A kind of knife-dagger, used very commonly in the Levant.

ASSEMBLING.—The act of putting in their respective places and fastening together the component parts of an article composed of a number of distinct pieces, so as to form a complete and perfect whole; as the cheeks and stock of a gun-carriage, with their connected parts; the lock, stock, and barrel of a musket, etc. The term is more peculiarly applicable to the fitting together of parts which are made strictly to fixed shapes and dimensions so as to be promiscuously interchangeable. The system of interchangeability of parts was first introduced into the French Artillery service by General Gribeauval, about the year 1765. This system was further simplified and extended, and was finally applied in the United States Arsenals and Armories to all articles made up of pieces, the improvements in machinery enabling most articles to be made accurately to pattern without depending on the eye and hand of the workman. This has been carried to a very high pitch of improvement by means of the machinery at the Springfield Armory and other manufactories of small-arms in this country; and the beauty and utility of the system, by which exact equality of dimensions is insured in every one among thousands of almost microscopic screws and other small parts, are particularly exemplified in the work of the American watch and sewing-machine companies. This system of interchangeability and assemblage, which by enabling a large proportion of perfect and serviceable articles to be made up from the parts of similar articles which have been broken or injured in use, instead of permitting them to be cast into the scrap-heap, is one of the most beautiful triumphs of modern mechanism. It has proved itself capable of adaptation to large as well as small machinery, and is now applied to the locomotives of the Pennsylvania Railroad.

ASSEMBLING-BOLT.—A bolt used for holding together two or more removable pieces, as the cheeks and stock of a field gun-carriage.

ASSEMBLY.—In the conduct of an army, the second beating of the drum or sounding of the bugle before a march, at which the soldiers strike their tents if encamped, roll them up, and stand to arms.

ASSER.—An instrument of warfare used by the Romans on their war-ships; it consisted of a heavy pole with an iron head, and was used as a battering-ram against hostile ships. Other authorities assert that it was used to destroy the rigging only.

ASSESSMENT OF DAMAGES.—In the English army, the determination by a Committee of Officers of the value of the injury done to the barracks each month, in order that stoppages in liquidation may be made from men who have committed the damage.

ASSIDUI MILITES.—Roman soldiers who, for the love of arms, served in the army without receiving pay or emoluments.

ASSIGNMENT OF PAY.—The assignment of pay by a non-commissioned officer or private previous to discharge is invalid. A transfer subsequent to discharge is valid.

ASSINAIRES — ASSINARIES. — Festivals which were instituted at Syracuse in commemoration of the destruction of the Athenian fleet commanded by Nicias and Demosthenes.

ASSISTANT. — In the English army, the third grade in any particular branch of the Staff, such as the Quartermaster-General's or Adjutant-General's. After the Principal comes the Deputy and then the Assistant. In the United States it is the second grade in the Staff of the Army.

ASSISTANT ADJUTANT-GENERAL.—In the English army, a Field-Officer and a subordinate member of the Adjutant-General's Department. An officer of this rank is attached to each division of the army. His duties include the submission of reports on discipline, military duties, training, and efficiency, to the General Officer Commanding the Division. Through his Department the bulk of the correspondence on arms, accouterments, ammunition, etc., passes before being sent on to the Control Department. The Adjutant-General of the United States army has similar Assistants.

ASSISTANT SURGEONS.—All candidates for appointment as Assistant Surgeons must apply to the Hon. Secretary of War for an invitation to appear before the Medical Examining Board. The application must be in the handwriting of the Candidate, stating age and birthplace, and be accompanied by testimonials from Professors of the College in which he graduated, or from other Physicians in good repute. Candidates must be between twenty-one and twenty-eight years of age (without any exceptions), and graduates of a regular Medical College, evidence of which must be submitted to the Board before examination. The morals, habits, physical and mental qualifications, and general aptitude for the service of each Candidate are subjects for careful examination by the Board, and a favorable report is not made in any case in which there is a reasonable doubt.

The following is the general plan of the examination: 1. A short essay, either autobiographical or upon some professional subject—to be indicated by the Board. 2. Physical examination. This will be rigid, and each Candidate will, in addition, be required to certify "*that he labors under no mental or physical infirmity, nor disability of any kind, which can in any way interfere with the most efficient discharge of his duties in any climate.*" 3. Oral examinations on subjects of preliminary education, general literature, and general science. The Candidate must satisfy the Board in this examination that he possesses a thorough knowledge of the branches taught in the Primary Schools, and a failure to show this will end his examination. Oral examination on scientific subjects will include chemistry and natural philosophy; and that on literary subjects will include English literature, history of the United States, and general history—ancient and modern. Candidates possessing a knowledge of the higher mathematics, the ancient and modern languages, will be examined therein, and due credit given for a proficiency in any or all of these subjects. 4. Written examination on anatomy, physiology, surgery, practice of medicine and general pathology, obstetrics, and diseases of women and children. Oral examination on these subjects, and also on medical jurisprudence, materia medica, therapeutics, pharmacy, toxicology, and hygiene. Few Candidates pay the attention to hygiene which it deserves; it is made an important subject in this examination. 5. Clinical examination, medical and surgical, at a hospital. 6. Performance of surgical operations on the cadaver. The Board deviate from this general plan whenever necessary, in such manner as they deem best to secure the interests of the service. An applicant failing one examination may be allowed a second after one year, but not a third. No allowance is made for the expenses of persons undergoing examination. See *Medical Department.*

ASSIZE OF ARMS.—A law enacted in the reign of Henry II. which enjoined every able-bodied man in the realm to maintain arms, suitable to his rank and condition of life, at his own expense. Of this law our militia is the modern offspring, and there can be no doubt that it is incumbent on every British subject now, as it was in earlier times, to give his service when required in defense of his Sovereign and Country. The enforcement therefore of the ballot in the militia would be no hardship.

ASSOCIATION OF GRADUATES OF THE MILITARY ACADEMY.—An Association of all Graduates of West Point who comply with the provisions of its Constitution. The Association was organized in 1869. Its object is "to cherish the memories of our Alma Mater and to promote the social intercourse and fraternal fellowship of its Graduates." The meetings of the Association are held annually at West Point, about the time that the graduating exercises take place. The oldest Graduate belonging to the Association is its President. The other officers are appointed annually by the President. At the present time (April, 1884) the Association has 531 members on its rolls. The oldest living Graduate is John T. Pratt, of the class of 1818, living at Georgetown, Ky. The Association endeavors to keep a record of all Graduates of the Academy. After the annual meeting in June, a report is published by the Secretary containing obituary notices of deceased Graduates, together with other matters of interest relating to the Military Academy.

ASTIGMATISM.—An anomaly in the refraction of the eye which, by law, disqualifies a recruit for enlistment in the army. Although this defect is very common, yet not until the last few years were its fre-

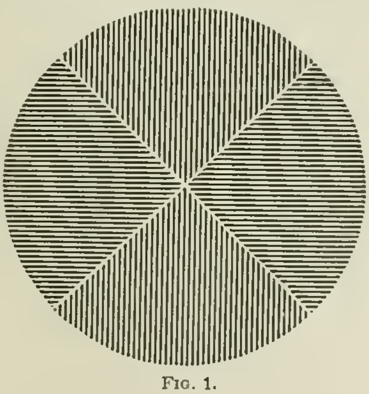


Fig. 1.

quency and importance fully recognized. Astigmatism is a condition in which the curvature of the cornea varies in the different meridians (Fig. 1). On examining an ordinary lens we find that all parts of its surface have an equal curvature (Fig. 2), and so it should be in a normal cornea; but in an astigmatic eye it is not so, since the vertical curvature differs from the horizontal, thus producing asymmetry of the refractive part of the eye, and, as a result, rays falling on such an eye are not all brought to a single focus, but those in one meridian fall either before or behind the retina, or focal point of the other meridian,

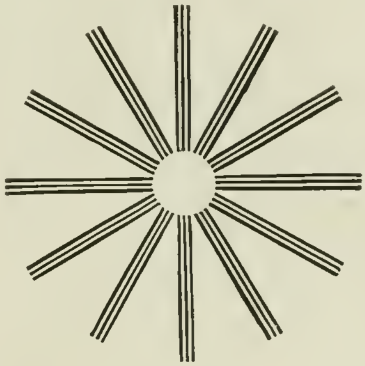

Fig. 2.

thus causing a confused and indistinct picture of the object viewed. Astigmatism is either Myopic or Hypermetropic; it may also be "mixed"—the eye being Myopic in one and Hypermetropic in another of its meridians.

Vision in astigmatic eyes is usually impaired both for distant and near objects, since at no point can a

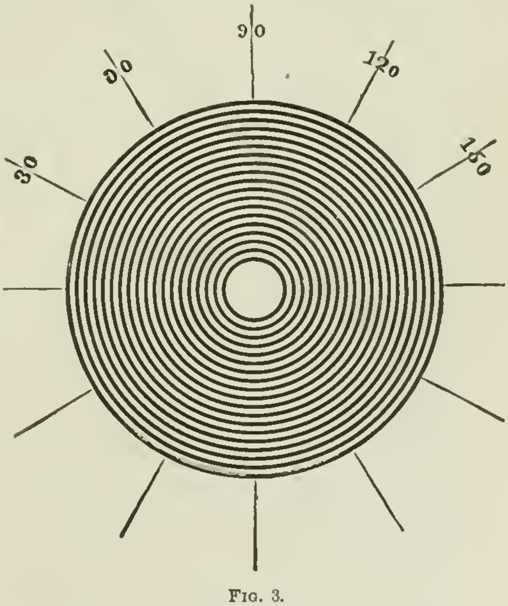

Fig. 3.

distinct image be obtained; but the distinguishing feature of this defect is the fact that certain groups in a series of lines and circles are seen with more distinctness and blackness than any others. (Fig. 3.) Astigmatism has frequently been discovered by looking at a clock, it being noticed that when the hands were at certain figures, say III and IX, they were seen with difficulty, while when at VI or XII they were distinctly seen.

In the treatment of Astigmatism, recourse must be had to *cylindrical lenses,* as the ordinary lenses would not correct the defect. Since the correcting glasses for Astigmatic eyes are frequently combinations, these lenses are always ground according to formula to correct the defect of each individual eye, which can only be determined after careful measurement. See *Recruits*.

ASTRAGAL.—A small convex molding used in the ornamental work of ordnance, and usually connected with a flat molding or *fillet*.

ASTROLABE.—The name given by the Greeks to any circular instrument for observing the stars. Circular rings, arranged as in the armillary sphere, were used for this purpose. A projection of the sphere upon a plane, with a graduated rim and sights for taking altitudes, was known as an astrolabe in the palmy days of astrology, and was the badge of the astrologer. The astrolabe has been superseded by the more perfect instruments of modern astronomy.

ASTYLLEN.—A small dam in an adit or mine to prevent the full passage of the water.

ASYLUM.—The persons entitled to the benefits of the Asylum, or Soldier's Home as it is now called, located in the District of Columbia, are: 1. All soldiers, and discharged soldiers of the army of the United States, who may have served honestly and faithfully for twenty years. 2. All soldiers, and discharged soldiers of the Regular Army, and of the Volunteers, who served in the war with Mexico, and were disabled by disease or wounds contracted in that service and in the line of their duty, and who are, by their disability, incapable of further military service. This class includes the portion of the Marine Corps that served with the army in Mexico. 3. Every soldier, and discharged soldier, who may have contributed to the funds of the Soldier's Home since the passage of the Act to found the same, March 3, 1851, according to the restrictions and provisions thereof, and who may have been disabled by disease or wounds incurred in the service and in the line of his duty, rendering him incapable of military service. 4. Every pensioner on account of wounds or disability incurred in the military service—though not a contributor to the funds of the Institution—who shall transfer his pension to the Soldier's Home during the period he voluntarily continues to receive its benefits. No provision is made for the wives and children of those admitted.

No mutineer, deserter, or habitual drunkard, or person convicted of felony or other disgraceful crime of a civil nature, while in the army or after his discharge, is admitted into the Asylum without satisfactory evidence being shown to the Commissioners of the Soldier's Home of subsequent service, good conduct, and reformation of character. The Commissioners are the Adjutant-General, the Commissary-General of Subsistence, and the Surgeon-General. The Soldier's Home has its Governor, Secretary, and Treasurer appointed from the army. See *Royal Military Asylum*.

AS YOU WERE.—A word of command corresponding to the French *remettez vous*, frequently used by drill-masters to cause a resumption of the previous position when any motion of the musket or movement of the body has been improperly made.

ATCHEVEMENT.—A term nearly equivalent to armorial bearings, and often used when speaking of the arms of a deceased person as displayed at his funeral or elsewhere. In this sense it is more commonly used in its abbreviated form of *hatchment*.

ATEGAR.—The old English hand-dart, named from the Saxon *aeton*, "to fling," and *gar*, "a weapon."

ATHANATI.—A corps of picked soldiers belonging to the ancient Persian army, 10,000 strong, which were called the "Immortals," for the reason that as soon as one of the corps died another was put in his place.

ATHLETE.—The name given to a combatant, pugilist, wrestler, or runner, in ancient Greece. Athletics were studied in Greece as a branch of art, and led to several useful rules of diet, exercise, etc., applicable to ordinary modes of life. Bodily strength and activity were so highly honored by the Greeks that the athlete held a position in society totally different from that of the modern pugilist. When he proposed to enter the lists at the Olympic or other public games, he was examined with regard to his birth, social position, and moral character. A Herald then stepped forth and called upon any one, if he knew aught disgraceful to the Candidate, to state it. Even men of genius contended for the palm in athletic exercises. Chrysippus and Cleanthes, the famous philosophers, were victorious athletes, or, at least, *agonista*, i.e., persons who pursued gymnastic exercises, not as a profession, but for the sake of exercise, just as at the present day we have gentlemen-cricketers, amateur-pugilists, etc. The profound and eloquent Plato appeared among the wrestlers in the Isthmian games at Corinth, and also in the Pythian games at Sicyon. Even the meditative Pythagoras is said to have gained a prize at Elis, and gave instructions for athletic training to Eurymenes, who afterwards gained a prize at the same place. So great was the honor of an Olympian victor that his native city was regarded as ennobled by his success, and he himself considered sacred. He entered the city through a special breach made in the walls; he was supported at the public expense; and when he died was honored with a public funeral. Euthymus, of Locri in Italy, who had, with only one exception, been regularly victorious at Elis, was honored with a statue, to which, even during his lifetime, homage was paid by command of an oracle. Athletic sports were first witnessed at Rome 186 B.C. They were introduced by M. Fulvius, at the end of the Ætolian War, and became excessively popular in the time of the Emperors. At Rome the athletes formed a corporation.

ATILT.—In the manner of a tilter; in the position or with the action of a man making a thrust. "To run atilt at men."

ATLAS METAL.—The metal used in the manufacture of the cases of Hale's rockets and Boxer's life-saving rockets. It is a mild steel produced by the Bessemer process.

ATLAS POWDER.—A nitro-glycerine compound of great explosive power, uniting that element in a marked degree with safety. When not confined it burns quite harmlessly; but when fired by a blasting-cap it explodes with enormous force. In cold weather it hardens and freezes, but resumes its soft, pasty condition when warmed. To secure its full explosive power it must never be used even in a semi-frozen state. As the tendency of all nitro-glycerine compounds is to decompose when exposed for any length of time to the direct rays of the sun, whatever the temperature of the air may be, great care should be taken not to expose this powder, or any other compound of a similar nature, to a test of that kind.

As an industrial agent this powder is stronger, cheaper, and safer than most other blasting-compounds. No invariable rule can be laid down as to the diameter and length of cartridges to be used under any and all circumstances, nor the amount nor grade of powder required for all kinds of work. Much will have to depend upon the good sense and judgment of the persons using the powder. As a general rule it throws rock less and breaks it more, and extends its effects much deeper than ordinary blasting powder; and those who use it soon learn not to judge of a blast by first appearances. It frequently happens that a blast which seems to have had no effect proves to have done remarkable execution in cracking and loosening the rock, and preparing the way for subsequent blasts. This is especially the case in tunnels and shafts.

The powder is put up in cartridges of either 6 or 8 inches in length, and from ¾ inch to 2 inches in diameter, is packed in 25-lb. and 50-lb. boxes, and is branded as follows:

F+,	Powder	containing	15	p.	c.	of Nitro-Glycerine.
E,	"	"	20	"	"	"
E+,	"	"	25	"	"	"
D,	"	"	30	"	"	"
D+,	"	"	35	"	"	"

C,	Powder containing	40 p. c.	of Nitro-Glycerine.
C+,	"	45 "	"
B,	"	50 "	"
B+,	"	60 "	"
A,	"	75 "	"

See *High Explosives*.

ATMIDOMETER. — An instrument used in the English Medical Corps for measuring the rate of evaporation. Also written *Admometer*.

ATMOSPHERIC HAMMER. — A power-hammer driven by the force of compressed air. In some cases the air is employed merely to lift the hammer; in other cases air is also employed as an adjunct in the effective stroke. In the latter case the operation is much like that of the steam-hammer, the main difference being in the substitution of air for steam.

ATTACH.—To place or appoint. Officers and Non-commissioned Officers are said to be attached to the respective army, regiment, battalion, troop, or company with which they are appointed to act.

ATTACHE.—The seal and signature of the Colonel-General in the old French service, which were affixed to commissions of officers after they had been duly examined.

ATTACK.—An advance upon the enemy, with a view of driving him from his position. It may either be an attack in the open field or an attack upon a fortress. In an attack in the open field, the General first ascertains the strength and position of the enemy, by means of a reconnoissance or of spies. He then seeks to discover at what point the enemy can make the least resistance; which is generally on one or other flank. He next arranges to concentrate his chief strength upon this particular point, and to mask his real intention by feigned operations in other places. He then attacks with energy and force, his troops advancing without halt till near enough to use their weapons with the greatest effect. The more the attack has the character of a "surprise," the greater the probability of its success. In order to make this success as much felt as possible, and to be provided also against unforeseen disaster, the attacking body should be followed at a distance by a reserve; a neglect of this precaution has frequently caused the entire failure of an attack. Various forms have been devised for the attack; but generally the *parallel* or *frontal* is the one made use of. Frederick the Great, however, won most of his battles by the oblique attack, in which one wing is more advanced than the other. The first Napoleon preferred, by means of his heavy columns, to penetrate and break up the enemy's center. Another mode combines an attack on one flank as well as in front, by two separate corps, so as either to get into the enemy's rear, or to perplex him as to his retreat. A skillful General will be guided by circumstances in his selection among these several modes of operating. An attack by night might act most signally as a surprise; but as this requires a very exact knowledge of the ground, an attack at early dawn is generally preferred.

The different arms of the service render each its own kind of aid during an attack. First come the skirmishers, or perhaps whole battalions of light and active troops, whose rifles or long-range guns commence the firing. Then come the main body of infantry in heavy column; they halt within musket-shot, fire, and charge with the bayonet—the skirmishers meanwhile deploying round to the rear of the column, but holding themselves in readiness to harass the enemy's flanks. English troops especially excel in the attack by bayonet in line; but other armies, for the most part, rely more upon the momentum of a compact and heavy column in an attack. There are positions in which the cavalry attack, with its shock and the use of the sword, is more efficacious than that of the infantry. The troopers approach at a trot, break into a gallop at a distance of one or two hundred paces from the enemy, and endeavor by their weight and impetuosity to force the enemy's line. There are many forms of cavalry attack, according to the nature of the ground and the position of the enemy. The artillery, working at a distance, often begin an attack long before the infantry and cavalry can come up, harassing and confusing the enemy. At 800 to 1200 yards' distance, the artillery pour out shot and shell, and try to silence the enemy's guns, so as to make way for the attack of the infantry; while the bayonet-charge is being made, the artillery keep in check the enemy's cavalry. If the attack succeeds, the infantry and artillery take up the ground recently occupied by the enemy, leaving the cavalry and riflemen to maintain a pursuit; but if it fail, the artillery and cavalry take up such positions as will cover the retreat of the infantry.

In an attack upon a fortress, the operation is a part of that of besieging; but very often intrenchments are attacked in the open field. Such an attack has the character of a surprise, when the works are approached under cover of night, and an attempt is made to break into them on all sides. In such case, there is a reserve corps, which is rapidly brought up when wanted; but the attacking corps retire behind the reserve, if repulsed. The artillery post themselves on the prolongation of the line of works, and try to dislodge the enemy's guns and gunners; or pour a concentric fire sufficient to breach the works. The infantry advance as close as will enable them to fire upon the gunners. When the enemy's fire is silenced, the engineers (under cover of the artillery) proceed to remove palisades and all other obstacles, and to bridge over ditches and openings. Then follow the operations of the storming-party, analogous to those noticed under *Assault*.

ATTACK OF TEMPORARY FORTIFICATIONS.—The subject of the attack admits of two natural divisions; the first of which comprehends all the preliminary steps taken before the troops are brought into action; the second, all the subsequent operations of the troops. An attack is made either by *surprise* or *openly*. In both cases exact information should be obtained of the approaches to the works; their strength; the number and character of the garrison; and also the character of the Commander. This information may be obtained through spies, deserters, prisoners, and others who have access to the works; but implicit faith ought not to be placed in the relations of such persons, as they may be in the interests of the garrison; and in all cases they should be strictly cross-examined and their different representations be carefully compared with each other. The best source of information is an examination, or *reconnoissance*, made by one or more intelligent officers. This reconnoissance should, if possible, be made secretly; but as this will not be practicable if the garrison show even ordinary vigilance, it will be necessary to protect the reconnoitering officer by small detachments, who drive in the outposts of the garrison. The object to be attained by the reconnoissance is an accurate knowledge of the natural features of the ground exterior to the works; the obstacles it presents, and the shelters it affords to troops advancing; the obstacles in front of the counterscarp and in the ditches; the weak and strong points of the works, and the interior arrangements for the defense. If the work is an isolated post, information should be obtained as to the probability of its being succored in case of an attack; the length of time it must hold out to receive succor; and the means it possesses of holding out.

A surprise is an *unexpected attack*, for which the assailed are not prepared. It is, perhaps, the best method of assailing an undisciplined and careless garrison, for its suddenness will disconcert and cause irremediable confusion. Secrecy is the soul of an enterprise of this nature. To insure it, the garrison, if aware of the presence of the troops, should be deceived and lulled into security by false maneuvers. The troops that form the expedition should be kept in profound ignorance of its object until they are all assembled at the point from which they are to proceed to the attack. The winter season is the most favorable for a surprise, which should be made about two hours before day, as this is the moment when the sentries are generally least vigilant, and the garrison is in profound sleep; and the attempt, if at first successful, will be facilitated by the approach of day, and if unsuccessful, the troops can withdraw with safety under the obscurity of night. Should there be danger, from succors arriving in a short time, the attack should be made soon after midnight, when the garrison is asleep, so that the troops may retire before daylight, after having attained their object. As a general rule, the troops for the attack should consist of a storming party, divided into an advanced party and its support, and be followed by a reserve of picked men. The advance of the storming party will open the way, and be closely followed by the support in the assault of the parapet, and a reserve of picked men. There should be two guides, one in front of the storming party, with the detachment of workmen under the command of an engineer officer; the other in the rear, under charge of a guard, to supply the place of the first, if killed. The workmen should be furnished with axes, crowbars, pickaxes, etc., and several bags of powder, of about thirty pounds each, to be attached to palisadings, fraises, and barriers, to blow them down, if the alarm should be given whilst they are opening a way through them by other means. All the operations should be carried on with dispatch and in silence. Should the sentries challenge, they must be secured or bayoneted. Circumstances alone can determine whether it will be advisable to make false attacks with the true one. They will distract the attention of the garrison, if the alarm is given, from the true attack; and a false attack has sometimes succeeded when the true one has failed. When made, one should be directed against the strongest point of the work, as the strong points are usually guarded with less vigilance than the others; and they should all be made at some distance from the true attack; and orders be given to the detachments making them to proceed to the point of the true attack, should they succeed in making their way into the work. If the attack succeed, immediate measures should be taken to place the works in a state of defense, if the position is to be maintained; or else they should be destroyed, as far as practicable, before retreating from them.

The general arrangements for an open assault comprehend the operations to gain possession of the works; the measures for maintaining possession of them, and following up the first advantage; and, finally, the precautions to be observed in the event of a repulse. An open assault may be made either with the bayonet alone, or with the combined action of artillery and the bayonet. The first is the most expeditious method, but it is attended with great destruction of life; it should therefore only be resorted to against works of a weak character, which are feebly guarded; or against isolated posts within reach of speedy succor. When tried it will usually be best to make the attack just before day. If it is made by daylight it will, in most cases, be well to scour the environs with a few squadrons of cavalry, to pick up patrols and stragglers who might give the alarm, and then push forward rapidly the assaulting columns. If the assailed seem prepared, light troops should precede the columns of attack, with orders to display in front of the counterscarp and open a brisk fire on the assailed, for the purpose of diverting their attention from the columns of attack. In an attack with artillery, the troops are drawn up in a sheltered position, or beyond the range of the guns of the assailed; batteries are then established within twelve to six hundred yards of the works, in the most favorable positions to enfilade the faces, and destroy all visible obstacles. The batteries keep up an incessant fire of ball and hollow projectiles, in order to dismount the cannon and create confusion among the assailed. When the fire of the works is silenced, the troops are thrown forward, and demonstrations are made on several points, to divert the attention of the assailed from the true point of attack, and prevent him from concentrating his strength on that point. Several false attacks should be made at the same moment with the real one, and each of them should be sufficiently formidable, in point of numbers, to enable the troops to profit by any success they may obtain. The number and disposition of the troops making the assault will depend, in so great a degree, on local circumstances, and the arrangements of the assailed, that nothing more can be laid down under this head than some general rules. The attack should be led by a storming party, composed of picked troops, or of volunteers for the occasion; this party is preceded by a detachment of engineer troops, provided with the necessary means to make their way through all obstacles, to enable the storming party to assault with the bayonet. If the detachment is arrested at the crest of the counterscarp, by obstacles which must be destroyed before further progress can be made, the leading files of the storming party may open a fire on the assailed to divert their fire from the workmen; but this operation should only be resorted to from necessity, as it breaks in on that unity so essential in an operation of this character, and impairs the confidence of the soldier in the bayonet, on which his sole reliance, in such cases, should be placed. The storming party should be provided with light scaling-ladders, planks, fascines, strong hurdles, etc., for the purpose of descending into the ditch; to mount the scarp; to cover trous-de-loup, small pickets, etc., etc. Another detachment of engineer troops follows in the rear of the storming party; its duties consist in rendering the passages, opened by the first detachment, more accessible to the troops, who immediately follow it to sustain the storming party. This second detachment is also charged with the care of placing the work from which the assailed has been driven in a defensive attitude, in order to frustrate his attempt to repossess himself of it. The first detachment should be charged with this duty; for, independently of having handsomely acquitted itself in bearing the brunt of the action, it may be required to precede the storming party in the pursuit of the assailed to his interior works. The troops destined to support and, if necessary, reinforce the storming party, advance in one or two lines, with cavalry, and some pieces of artillery on the wings, to repel sorties. The remainder of the troops follow in order of battle, to improve the first successes, or to cover the retreat of the assaulting columns, if repulsed.

The salients are generally the points on which the storming party advances, unless some natural feature of the ground should present greater facilities for advancing on a re-entering, or in front of a face. When the ditch is gained, shelter is sought in a dead angle; and if the work is fraised, or resolutely defended with the bayonet, a breach must be made, either by firing beforehand hollow loaded projectiles into the parapet, or by undermining the scarp with the pick. If the intrenchments consist of detached lunettes, an attack should be made on their gorge at the same moment with the one in front. When the assailed are driven from their main works, the storming party should press hotly on their rear, and endeavor to enter pell-mell with them into their interior works, leaving to the troops which follow them the care of retaining possession of the works gained; but if the intrenchments are supported by other troops drawn up in order of battle, the storming party should halt in the works until it is reinforced by the troops in its rear. There is no danger to be apprehended, in case of a retreat, after an unsuccessful attack on an isolated work. But in an attack on intrenchments, supported by an army, the retreat of the storming party should be covered by cavalry and artillery until it can find safety behind the main body of the troops drawn up in order of battle to protect it, and to receive the assault of the assailed should he attempt offensive operations. In conducting the attack, preparations should be made beforehand for removing all the artificial obstacles that the assailed may have placed before their works to impede the progress of the storming party. This duty is usually intrusted to the detachment of engineer troops, who are provided with axes, picks, and other suitable tools for this purpose. When the obstacles are of a nature to be easily destroyed by artillery, it should always be resorted to. Abattis, palisades, fraises, and entanglements, when exposed, may be readily torn to pieces by opening an enfilading ricochet fire on them. When cannon cannot be brought to bear on these obstacles, an abattis may sometimes be set fire to, and palisades, etc., be blown in by attaching bags of powder to them. Trous-de-loup may be passed, either by covering them with plank or strong hurdles, or else by directing the men to pass cautiously between them in extended order; small pickets may be broken down, or else fascines may be spread over them so as to form a tolerably stable roadway; fascines may also be used to cover the points of spikes.

The passage of the ditch and the assault of the parapet are the most difficult operations. If the ditch is not more than six feet deep, it can be leaped into without danger, and the men can mount the scarp readily with a very little assistance from each other. When the width is not greater than twelve feet, the ditch may be crossed by laying thick plank or small scantling over it. When the depth is over six feet, the storming party is usually provided either with small scaling-ladders for descending into, or with fascines, sand-bags, or other means to fill the ditch partly up; or if these means cannot be procured, the detachment dig away the counterscarp into steps, throwing the earth into the ditch, and thus in a short time form an easy entrance to it. Wet ditches may be filled up either with sand-bags alone, or more expeditiously by attaching sand-bags to large fascines or to trusses of hay or straw. The assault of the parapet is made by the aid of scaling-ladders, or by effecting a breach by firing loaded hollow projectiles into the scarp and parapet, which by their explosion crumble the earth down so as to form an accessible ramp; or else the foot of the scarp is undermined with the pick, and the mass of the parapet tumbled into the ditch. See *Assault* and *Defense*.

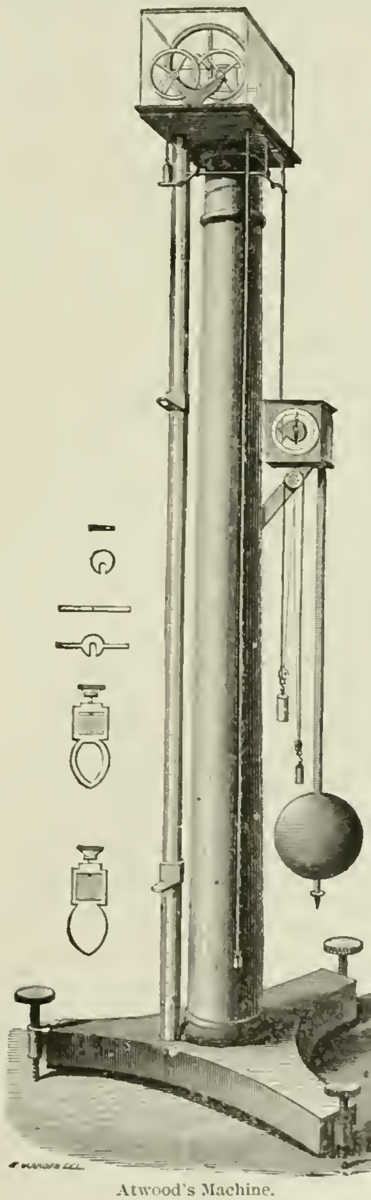
ATTENTION.—A cautionary command addressed to troops preparatory to a particular exercise or maneuver. *Gare-a-vous* has the same signification in the French service.

ATTESTATION.—In the English service, a certificate which is granted by a Justice of the Peace within four days after the enlistment of a recruit. This certificate bears testimony that the recruit has been brought before the Justice in conformity to the Mutiny Act, and has declared his assent or dissent to such enlistment, and that (if according to the said Act he shall have been duly enlisted) the proper oaths have been administered to him by the Magistrate, and the sections of the Articles of War against mutiny and desertion read to the said recruit.

ATTICK BRONZE REINFORCE.—The exact material of this *hoop* reinforce was never made public, inasmuch as it was supposed to have a great tensile strength. This method of reinforce was tested on the Naugatuck. An old cast-iron 42-pdr. had a hoop of this *Bronze Composition* forced on by hydrostatic pressure. The gun was first tried with 100-lb. projectiles (James') and 16-lb. charges. The endurance for a while appeared satisfactory, but the gun subsequently burst after a short service.

ATWATER GUN.—A 5.85-inch (80-pdr.) hooped gun, experimented with at the Washington Navy Yard. It is a cast-iron gun, 21 inches in diameter at the breech, with a tier of six wrought-iron hoops, 6×2 inches each, shrunk on, and a second tier of five similar hoops over the first tier. Length of bore, 12 feet; weight, 11,625 pounds. This gun is remarkable in its rifling. It has 12 grooves $\frac{1}{10}$ inch deep, and 12 lands of equal width at the breech. At 12 calibers from the bottom of the chamber the lands are cut away in alternate pairs to $\frac{1}{4}$ inch below the bottom of the original grooves. Other conditions remaining the same, the range of projectiles from this bore is considerably increased. This result is ascribed to various causes. Decrease of friction would be better promoted by cutting off the chase altogether. The more perfect combustion of the powder by the air entering at the side of the shot would also follow, leaving an air-space in the chamber of the gun; in fact, to the sudden and perfect combustion thus promoted some authorities attribute the bursting of guns. The inventor reasons from the experiments of Rodman that the air-pressure in front of the shot is greater than the gas-pressure behind it, at the point where he cuts the lands away.

ATWOOD'S MACHINE.—An instrument for illustrating the relations of time, space, and velocity in the



Atwood's Machine.

motion of a body falling under the action of gravity. It was invented by George Atwood (or Attwood), a mathematician of some eminence, who was born in

1745, educated at Cambridge, became Fellow and Tutor of Trinity College in that university, published a few treatises on mechanics and engineering, and died in 1807. It is found that a body falling freely passes through 16 feet in the first second, 64 feet in the first two seconds, 144 feet in the first three seconds, and so on. Now, as these spaces are so large, we should require a machine of impracticable size to illustrate the relations just mentioned. The object of Atwood's Machine is to reduce the scale on which gravity acts without in any way altering its essential features as an accelerating force. The machine consists essentially of a pulley, moving on its axis with very little friction, with a fine silk cord passing over it, sustaining two equal cylindrical weights at its extremities. The pulley rests on a square wooden pillar, graduated on one side in feet and inches, which can be placed in a vertical position by the leveling-screws of the sole on which it stands. A pendulum usually accompanies the machine, to beat seconds of time. The weight of the cylinders being equal, they have no tendency to rise or fall, but are reduced, as it were, to masses without weight. When a weight is placed on one of the cylinders, the motion that ensues is due only to the action of gravity upon it, so that the motion of the whole must be considerably slower than that of the weight falling freely. Suppose, for instance, that the cylinders are each $7\frac{1}{2}$ ozs. in weight, and that the weight is 1 oz.: the force acting on the system—leaving the friction and inertia of the pulley out of account—would be $\frac{1}{16}$ of gravity, or the whole would move only 1 foot in the first second, instead of 16. If the weight be left free to fall, its weight or moving force would bring its own mass through 16 feet the first second; but when placed on the cylinder, this force is exerted not only on the mass of the bar, but on that of both cylinders, which is 15 times greater, so that it has altogether 16 times more matter in the second case to move than in the first, and must, in consequence, move it 16 times more slowly. By a proper adjustment of weights, the rate of motion may be made as small as we please, or we can reduce the accelerating force to any fraction of gravity. The drawing represents the latest pattern of the machine, made by Queen & Co., and employed in experiments to establish the laws that regulate the motion of falling bodies and to illustrate various principles in gunnery. See *Falling Bodies*.

AUDITOR.—The name given to certain officers appointed to examine accounts in behalf either of the government, of courts of law, of corporations, or of private persons. In 1785 Public Auditors were appointed in England under the title of "Commissioners for Auditing the Public Accounts," by which the patents of Lord Sondes and Lord Mountstuart, as *Auditors of the Imprests*, were vacated, the sum of £7000 per annum being made payable to each of them for life, in lieu of a percentage which had been paid them on the amount of expenditure audited. Many subsequent statutes have been passed for the purpose of extending and defining the duties of these Commissioners, and regulating the business of the Audit Office. The Commissioners of Audit are empowered to call on all Public Accountants to account for moneys or stores intrusted to them; and should they fail to do so, are required to certify their names to the Remembrancer of the Exchequer, and the Attorney-General of England or Ireland, or the Lord Advocate of Scotland, in order that they may be proceeded against as defaulters. These proceedings, however, may be stayed for a time by the Lords of the Treasury, by whom the whole arrangements of the Audit Office are controlled, on the application of the accused. The accounts of the Ordnance, of the Army and Navy, and the Land Revenue are now subjected to examination in the Audit Office. In the United States, the Second and Third Auditors are officials connected with the Treasury Department, whose duties consist in examining all accounts relating to the pay and clothing of the army, the subsistence of officers, bounties, premiums, military and hospital stores, and generally all accounts of the War Department other than those provided for; also all claims for compensation for loss of horses and equipments of officers and enlisted men in the military service of the United States, pensions, etc.

AUGET—AUGETTE.—A kind of small trough used in mining, in which the saucisson or train-hose is laid in straw to prevent the powder from contracting any dampness.

AUGUSTAN SYSTEM OF FORTIFICATION.—In this system, the gorge of the tenailles is occupied by two parallel defensive barracks and by casemated redoubts. Many of the casemates here traced bear a close resemblance to the plan of Haxo. This system is so complicated as to be impracticable. See *Fortification*.

AUGUSTICUM.—A bounty that was given by the Roman Emperors to their soldiers upon the latter taking the oath of allegiance for the first time, or upon a renewal of the oath.

AULIC COUNCIL.—One of the two highest Courts of the old German Empire, co-ordinate with the Imperial Chamber. It came into existence in 1495, and seems to have been at first employed principally in preparing business matters regarding the Crown-lands and the Empire generally, in order to expedite the decisions of the Imperial Chamber. It soon, however, began to assume or acquire higher functions. After 1502, the States submitted important grievances to its independent consideration; but it did not receive a fixed Constitution before 1559. In 1654 it was formally recognized as the second of the two Supreme Courts, and equal in dignity to the Imperial Chamber. It was composed of a President, a Vice-President, a Vice-Chancellor, and eighteen Councilors, who were all chosen and paid by the Emperor, with the exception of the Vice-Chancellor, who was appointed by the Elector of Mainz. Of the eighteen Councilors, six were Protestants, whose votes, when they were unanimous, could not be set aside by those of the others, so that a religious parity was to some extent preserved. The Councilors were divided into three classes—Counts, Barons, and Men of Learning—all of whom were on a footing of equality, except that the last mentioned received a higher salary, and were usually advanced into the ranks of the nobility. The Council held aloof from politics, but under its jurisdiction were placed: (1) all matters of feudality in which the Emperor was immediately concerned; (2) all questions of appeal on the part of the States from decisions in favor of the Emperor in Minor Courts; (3) whatever concerned the imperial jurisdiction in Italy. On the death of the Emperor, the Council was dissolved, and had to be reconstructed by his successor. It finally ceased to exist on the extinction of the old German Empire in 1806.

AUMACOR.—A title similar to General-in-Chief, which was given to the Chief of the Saracens during the Crusades.

AUSEN.—A name given by the Goths to their victorious Generals. This word in their language signifies "more than mortal," i.e., demi-gods.

AUSTRIAN ARMY.—One of the four great continental armies of Europe. In December, 1868, the imperial signature was affixed to the law introducing the system of obligatory personal service for every male subject of the Austrian Empire. At present the military force of Austria is composed of the Standing Army, the Reserve, the Landwehr, and the Landsturm. The latter element means simply a *levée en masse* of the entire male population for the defense of the country in case of invasion. The total liability to military service extends over twelve years, this period being thus apportioned: three years to the Standing Army, seven years to the Reserve, and two years to the Landwehr. In countries that have adopted the compulsory service, exemptions are obtainable under the following social conditions: 1. Being the only son and support of a helpless father or widowed mother; 2. After the death of a father, being the only grandson and support of an infirm grandfather or widowed grandmother; 3. Being the only support of helpless relations. All service of a substitute or exemption by purchase is abolished. As in Prussia and France, volunteers for one year are admitted. The effective numerical strength of the Standing Army, Reserve, and Landwehr amounts to about 1,100,000 men, of which about $\frac{5}{11}$ are contributed by the first two classes, the Standing Army and Reserve, to which Hungary furnishes a quota of nearly 330,000. Austria, inclusive of Hungary, is divided into 17 military districts. The Standing Army is composed of 24 divisions, containing 52 brigades of infantry and 19 of cavalry. The infantry of the line consists of 80 regiments; the cavalry of 41 regiments (14 of dragoons, 14 huzzars, and 13 lancers), giving about 36,000 cavalrymen. The artillery consists of 12 regiments of field and 12 battalions of garrison artillery, each field-artillery regiment consisting of four 4-pdr. foot-batteries, three 4-pdr. horse-batteries, and five 8-pdr. foot-batteries. In the Austrian army, to every 1000 combatant foot-soldiers there are 103 cavalry and 4 field-guns. There are 2 regiments, of 5 battalions each, of engineers, with 4 active and 8 reserve companies, and 1 depot battalion of 5 companies. The transport service of Austria is conducted by a Military Transport Corps, which consists of 36 field-squadrons, 22 of which on mobilization are assigned to the infantry divisions, 5 to the cavalry, 4 to army corps headquarters, and 2 to general headquarters. There are, besides, the Intendance and a Hospital Corps. The Emperor is the supreme head of the Austrian army, which he governs through a Minister of War and an Inspector-general. The mode of officering the Austrian army is as follows: 1. By passing, as a Cadet, through a Military College; 2. Rising from the ranks. (1) Cadets are trained at public cost, and remain ten years in active service from the date of their leaving the Academy. After the aspirant has practically learned every duty of the private and non-commissioned officer, he attends the school which is established at the headquarters of every division. He goes then through a course of eleven months, followed by an examination. If successful, he performs the duties of an officer, though still not commissioned, and receives his commission when a vacancy occurs. (2) The preparation for promotion is also regimental, and in this manner non-commissioned officers of good character and antecedents, and of sufficient attainments, may obtain a commission. Promotion goes right through, arm by arm and rank by rank. It is by seniority and non-seniority. The former depends on the confidential reports giving testimony of the individual's efficiency, and the latter is followed every sixth step below field-rank and every fourth step above it. There is an examination twice a year for promotion. See *Army*.

AUSTRIAN FIELD-GUN.—A muzzle-loading rifled gun made of bronze. There are two sizes, the 4-pdr. and the 8-pdr.; the former for horse-artillery, the latter for field-batteries. The projectiles are iron-ribbed, not studded, for taking the rifling. The Austrians are about to change their bronze guns for steel of their own design; the proof lately of one of their guns answered all that was required of it. The gun experimented on was an 8.7-centimeter steel cannon, and is said to be an improvement on the Prussian field-gun.

AUSTRIAN RIFLING.—This system is specially adapted to gun-cotton. The bore is spiral in cross-section, increasing in diameter from the point at the end of the land, which is the bearing-side going in; all the rest of the bore is the bearing-side which rotates the shot coming out. The cast-iron projectile is covered with a soft metal coating which enters the gun freely when a projection bears against the land mentioned; but which, as the shot comes out, is compressed by the spiral bore, and shuts off the windage. To prevent the shot jamming in the bore, three grooves are introduced to receive corresponding ribs on the shot. But, the shot is centered and rotated, coming out, by the whole circumference of the bore as well as by these three grooves.

AUTHORITY.—In a general acceptation of the term, a right to command, and a consequent right to be obeyed. The Articles of War provide that when any officer or soldier is accused of a capital crime, or of any offense against the person or property of any citizen of any of the United States, which is punishable by the laws of the land, the Commanding Officer, and the officers of the regiment, troop, battery, company, or detachment to which the person so accused belongs, are required, except in time of war, upon application duly made by or in behalf of the party injured, to use their utmost endeavors to deliver him over to the Civil Magistrate, and to aid the officers of justice in apprehending and securing him, in order to bring him to trial. If, upon such application, any officer refuses or willfully neglects, except in time of war, to deliver over such accused person to the civil magistrates, or to aid the officers of justice in apprehending him, he shall be dismissed from the service.

AUTOCRACY.—A term signifying that form of government in which the Sovereign unites in himself the legislative and the executive powers of the State, and thus rules uncontrolled. Such a Sovereign is therefore called an Autocrat. Nearly all Eastern governments are of this form. Among European rulers the Emperor of Russia alone bears the title of Autocrat, thus signifying his constitutional absoluteness.—Kant used the word Autocracy, in philosophy, to denote the mastery of the reason over the rebellious propensities.

AUTOGENIC PLUMBING APPARATUS.—This apparatus is a modification of the oxy-hydrogen blow-pipe. It has been in use for some years by manufacturing chemists, etc., in the construction and repair of leaden utensils. Its purpose is to provide, by means of the reaction between oil of vitriol, water, and zinc, a supply of hydrogen gas, and, after mixing it with air, to burn the mixture at the end of a blow-pipe nozzle, and by means of flexible rubber tubing apply the flame readily to the work in hand. By its aid lead sheets, pipes, etc., may be joined together by melting the points of junction, without the use of solder or flux. It can also be used for soldering, brazing, and annealing; in fact, for any purpose requiring an intense heat locally applied. It consists of a rectangular box divided into two closed compartments. The upper one is an acid-chamber, opening at the top, and a pipe connects it with the bottom of the lower compartment. The lower compartment is the zinc- and gas-chamber, having a pipe near its top to convey the gas generated into a purifier arranged in the space between the upper and lower compartments. This space also contains the opening into the lower compartment, through which the zinc is inserted The dilute acid runs down the pipe from the upper chamber into and up through the zinc in the lower chamber, in the upper part of which the gas collects and passes out by a bent pipe into the bottom of the purifier. The purifier is a box intended to collect any drips which may pass over with the gas. From its upper part a pipe conveys the gas to the bottom of a second purifier, filled with water, through which the gas rises and passes to the blow-pipe. The water removes any sulphurous-acid gas or other impurities that may pass over with the hydrogen gas. The rear end of the blow-pipe is divided into two branches. To one of these the tube conveying the hydrogen is attached, and to the other a tube conveying air driven in by a bellows. The hydrogen and air combine and mix in the blow-pipe and flow out of its nozzle when the mixture is ignited for application of the flame to the work. Lead sheets may be joined edge to edge or by a lap. In the former case lead straps are melted along the joint to perfect and strengthen it. The apparatus is much used in arsenals for lining pickling-vats, floors covered with lead, etc.; also for annealing the serrated wires for friction-primers, and for soldering and brazing.

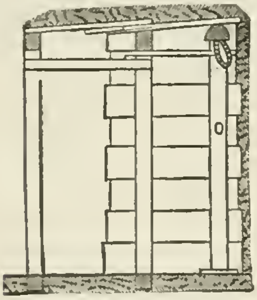
AUTOMATIC FIRE.—The automatic fire or explosive mixture of the Greeks was made from equal parts of sulphur, saltpeter, and sulphide of antimony, finely pulverized and mixed into a paste, with equal parts of the juice of black sycamore and liquid asphaltum, a little quick-lime being added. The rays of the sun would set it on fire.

AUTONOMY.—The arrangement by which the citizens of a State manage their own legislation and government; and this evidently may, with certain restrictions, be the case also within limited bodies of the same people, such as parishes, corporations, religious sects. The term Autonomy is used to designate the characteristic of the political condition of ancient Greece, where every city or town community claimed the right of independent sovereign action. The idea of two or more town communities sinking their individual independence, and forming the larger aggregate unity which we understand by a State, seems to have been intolerable to the Greek mind.

AUXILIARY FORCES.—The Militia, Yeomanry, and Volunteers of Great Britain. These forces aggregate as follows:

	Officers	Men.	Total.
1. *Yeomanry*, 40 regiments........	804	14,274	15,078
2. *Militia*:			
Artillery, 29 regiments.........	3497	16,422	139,619
Infantry, 131 battalions........		119,700	
Total...............	4301	150,396	154,697
3. *Volunteers*:			
Artillery..........................	Separate numbers are not given.		31,823
Cavalry: Light horse, 4 regiments.			366
Cavalry: Mounted rifles, 4 regiments			139
Engineers.......................			6,296
Infantry.................. ...			128,669
Permanent Staff...............			1,458
Total...........		......	168,751

AUXILIARY FRAME.—When mining in loose soils, besides the ordinary gallery-frame, there is re-



Auxiliary Frame.

quired, as for shafts in the same soils, an auxiliary gallery-frame. This frame, shown in position, in the vertical section of the gallery through the axis, in the drawing, is somewhat wider than the ordinary gallery-frame, and somewhat shorter also. Its cap-sill is rounded on top, and has two mortices on its lower side, to receive the tenons with which the two stanchions are finished. The mortices are a little longer than the tenons; the latter being confined in them by wedges when the frame is set up. To adjust the frame when set up, a pair of folding wedges is placed under each end of its ground-sill. By these contrivances the frame can be readily set up or taken apart. See *Gallery* and *Shaft*.

AUXILIARY TROOPS.—Foreign troops which are furnished to a belligerent power in consequence of a treaty of alliance, or for pecuniary considerations. Of the latter description may be considered the Hessians that were employed by Great Britain to enslave America.

AUXILIARY WAR.—A war in which a nation succors its neighbors, either in consequence of alliances or engagements entered into with them, or sometimes to prevent their falling under the power of an ambitious Prince.

AVANT-BRAS.—Guards for the lower arms, worn by knights and soldiers in the Middle Ages.

AVIS—AVIZ.—An order of knighthood in Portugal, instituted by Sancho, the first king of Portugal, in imitation of the Order of Calatrava, and having, like it, for its object the subjection of the Moors. By the present usage, the king of Portugal, who is grand-master of all of them, wears decorations of the first three orders of Portugal—those of Christ, St. James, and Aviz united in one medal, divided into three equal spaces.

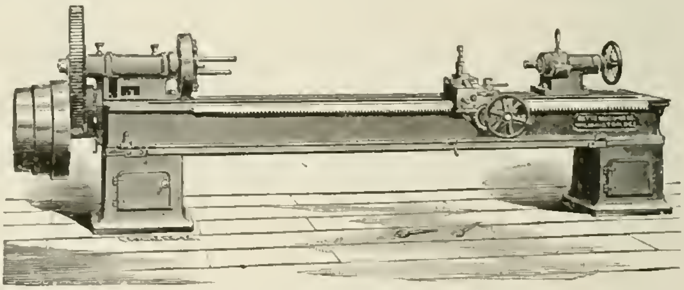
Badge of Order of Aviz.

AWARD.—A judgment, the result of arbitration. In a military sense, the decision or sentence of a Court-Martial.

AXIS.—A straight line, real or imaginary, about which a body revolves is called the axis of rotation. In gunnery, the axis of the piece is the central line of the bore of the gun.

AXLE-LATHE.—A lathe much used in arsenals for turning axles, shafting, and other relatively long articles which are liable to be swayed or bent by their flexibility or by the pressure of the cutter. Bearings are provided at points between the lathe-centers, and sometimes the cutters are duplicated so as to act upon opposite sides simultaneously. The axle or shafting is turned to form by suitably shaped cutters secured to two jaws, which approach each other by the rotation of a right- and left-hand screw in a fixed rest. Whitworth's famous lathe is of this character.

The drawing shows the form of lathe in general use. It swings 16 inches diameter over the shears, and 14 inches diameter over the rest-carriage; the



Axle-Lathe.

cone pulleys have three speeds for a 4-inch belt, which, with the two sets of fast and loose pulleys on the countershaft, give six changes on the face-plate; it has cast-steel spindles running in gun-metal boxes; the dead-spindle is secured by a patent conical binder; the rest-carriage has a hand-movement by a rack in the bed; its feed is by a screw and cut cog gearing with two changes, operated by a clutch and rod, for roughing and finishing; adjustment to dead-head for turning taper, and has Clement's driver. With 12-foot shears, to turn 8½ feet long, the weight is 5700 pounds. See *Lathe*.

AXLE-TREE.—A solid bar or beam, so shaped as to receive at each of its extremities a wheel, which revolves freely about it. Those parts about which the wheels revolve are called the *arms* or *axle-tree arms*. The part of the axle-tree between the arms is called the *body;* that portion of the body contiguous to the arm is the *shoulder;* and the extremity of the arm is its *point*.

AXLE-TREE ARM.—That portion of an axle-tree about which the wheel revolves. The *axle-tree arm* is circular in section, and near its outer extremity is a vertical hole to receive the linch-pin, which keeps the wheel on the arm.

AXLE-TREE BED.—A wooden beam or block intermediate between the axle-tree and the body of the carriage. In the usual constructions it is kept in contact with the body of the axle-tree along its entire length, the body being housed or let into it from end to end. In this connection side-thrusts exert hardly any injurious moment about the junction between axle-bed and body, the length of this connection being considerable as compared with the length of the lever-arm $R + d$ (R being the height of the axle-arm above the ground, and d the depth of the axle-tree bed); but any tractional moment, $Pd\frac{(2aR - a^2)}{R^2}$ (a being the height of the obstacle, and P the measure of blow upon the tire in direction parallel to the road), must be guarded against by bands, knees, or connecting stays.

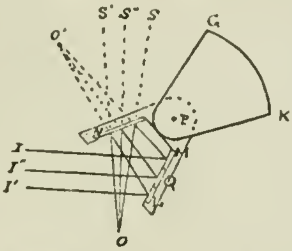
AYA-BASSI.—A non-commissioned grade in the corps of Janissaries, corresponding to that of Corporal in modern armies.

AYENEE.—A tree which grows in the forests of Southern India, Godavery, and Burmah; the wood is strong, tolerably close, even-grained, and of a light yellowish color. It is a wood that may be used for gun-carriage purposes.

AZAINE.—A name anciently applied to a trumpet in the French army; now obsolete.

AZAPES.—Auxiliary troops which were levied by the Turks among the Christians (under their dominion), whom they exposed to the first attack of the enemy.

AZEMAR TELEMETER.—Of the mirror-telemeters giving fixed angles, that of Azémar seems to be the simplest. This is made to give two angles, one acute and the other obtuse, supplements of each other. It is shown in the drawing with the addition of an additional fixed mirror for giving a right angle. If only two angles are used, an acute combined with a right angle would be better than the two supplementary angles, as the advantage of having a right angle would be secured without necessitating back-sights in observation.



The modified Azémar telemeter consists of a small frame, L M N, on which are placed four plane mirrors reaching from the top to the bottom of the frame; this frame swinging between two plates of brass, G K, it being pushed out and in by turning it about the pivot P. The mirrors L, Q, and M make with the mirror N angles less than, equal to, and greater than 90 respectively—the greatest and least angles being complements of each other. Such a telemeter commends itself by its cheapness, but a prism-telemeter gives far greater clearness to the image, while, unlike the mirror-telemeter, it is not subject to derangement. See *Telemeter*.

AZURE.—A French word technically used in Heraldry to signify blue. In engraving arms it is always represented by horizontal lines.

B

BABOOL.—A tree which is found in different parts of India. The wood is close-grained and tough, of a pale red color, inclining to brown. It is used in the gun-carriage agencies of Madras and Bombay for naves and felloes of wheels. This tree, which grows in abundance in the northwest of India, forms the staple food of the camel.

BACCHI.—Two ancient warlike machines; the one resembled a battering-ram, the other cast out fire.

BACHELIER.—A young squire, or knight, who has passed through his first campaign, and received the belt of the Order.

BACHEVALEUREUX.—A term which, in the old French language, signified warrior, brave, valiant, etc.

BACK.—A cast-iron plate forming the back wall of a forge, and through which the blast enters by a *tuyere*. When the back consists of an iron cistern, it is called a *water-back*. When it consists of a chamber in which the air-blast is heated, it is called a *heating-back*.

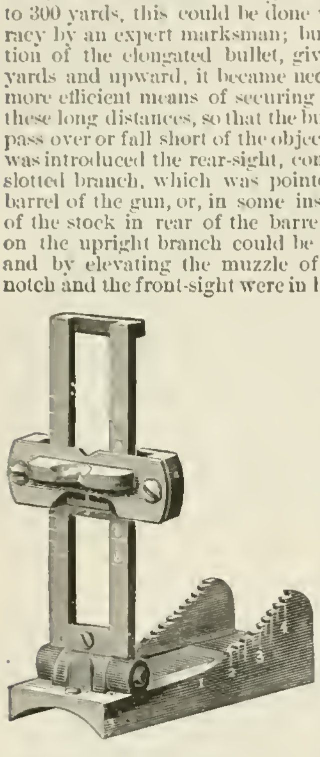
BACK-BAND.—The band or strap which passes over the back of the horse and meets the belly-band; the two unite to girth the horse.

BACKING.—Experiment has shown that wood-backing alone, unless combined with rigid horizontal angle-iron stringers, affords but little support to the armor-plate; that is to say, a projectile which is capable of penetrating a plate unbacked will also be capable of doing so if it be backed with wood alone. Wood-backing is, however, of great value because it distributes the blow; it deadens the vibrations and saves the fastenings; also it stops the splinters. The best form of backing appears to be that in which wood is combined with strong horizontal angle-iron attached to the inner skin, and extending to the armor-plates; this, by giving rigidity, very considerably assists the plate to resist penetration. An inner skin of iron is of the greatest possible advantage; it renders the backing more compact, and prevents the passage of many splinters. Oak and teak are the most suitable timbers for backing-plates, and are used as such on vessels. A yielding backing is found to occasion less strain on the fastenings than a very hard one. Where projectiles are made of the same material, and are similar in shape, their penetration into unbacked plates is nearly in proportion to their *living force, or their weight multiplied by the squares of the velocity of impact.*

The resistance which an unbacked plate offers to penetration is nearly in proportion to the *square of its thickness*, provided this thickness be confined within ordinary limits. In the case of oblique plates the penetration diminishes nearly with the *sine of the angle of incidence*. The most suitable material for shells to be used against iron plates is tempered steel. These projectiles should be made of cylindrical shape with thick sides and bottom to direct the explosive effect of the charge forward after penetration is effected. The most suitable material for solid shot is hard, tough cast-iron. Palliser's chilled shot are made of this material, and so are the shot made for our service. It follows from the preceding that the most suitable covering or shield for cannon is a conical-shaped turret made of wrought-iron plates, as large as it is practicable to make them, backed with oak or teak. To protect the men from the fragments of projectiles which may penetrate completely through this covering, there should be an "inner skin" of thick boiler-plate placed behind the wood. With our 15-inch cast-iron projectiles, made of the best charcoal-iron, poured and worked in a peculiar manner so as to obtain hard and solid masses, the penetration is quite as great and uniform as that obtained with *steel* shot of equal weights propelled by similar charges, the only difference being that the iron breaks after passing through, while the steel is only compressed or flattened, a result rather in favor of the iron shot, if entrance is made where men are exposed to its fragments.

BACK-PLATE.—A piece of armor for covering the back. See *Armor.*

BACK-SIGHT.—The rear-sight of a gun. It may be of various forms. In the old-fashioned arms intended for round balls, it was merely a notch in a knob or plate near the breech of the gun, the proper elevation to be given being estimated by the marksman. As the effective range scarcely exceeded 250 to 300 yards, this could be done with sufficient accuracy by an expert marksman; but with the introduction of the elongated bullet, giving ranges of 1000 yards and upward, it became necessary to seek some more efficient means of securing the proper range at these long distances, so that the bullet might not either pass over or fall short of the object. For this purpose was introduced the rear-sight, consisting of an upright slotted branch, which was pointed to a seat on the barrel of the gun, or, in some instances, on the small of the stock in rear of the barrel. A notched slider on the upright branch could be elevated as desired, and by elevating the muzzle of the gun until this notch and the front-sight were in line any range within the limit of projection of the piece could be attained. This sliding sight has, in the United States service, been superseded by the leaf-sight, which is more compact and less liable to derangement. Other back-sights, especially those first introduced in southern Germany, have been made of various patterns; one variety being permanently fixed perpendicularly to the barrel, and having notched holes at proper heights through which to sight; and another being segmental in shape, and moving circularly in a direction longitudinal to the barrel through a stud fixed thereon. Another form of back-sight vertically adjustable for range, and attached to the stock, has a graduated spring-piece slipping within a vertical slot in the small of the stock, and is adjusted as required. Its spring retains it in place, or it may be clamped by a set-screw or lowered below the line of the hind-sight on the barrel. The drawing shows the back-sight (with wind-gauge) used on the Winchester military rifle. See *Pointing.*



BACK-STEP.—The retrograde movement of a man, or a body of men, without changing front.

BACK-SWORD.—A sword with one sharp edge in contradistinction to one which has two edges throughout the whole or a portion of its length. In England, the *back-sword* is a stick with a basket-handle, used in rustic amusements; called also "Single Stick."

BACKWARDS.—A technical word made use of in the British service to express the retrograde movement of troops from line into column, and *vice versa.* Also, a word of command, in the United States service, to cause a man, or a body of men, to march to the rear without changing front.

BACULE.—A kind of porteullis or gate, made like a pitfall, with a counterpoise. See *Bascule Bridge.*

BADALEERS.—Musket-charges of powder in tin or copper tubes, worn dangling from a shoulder-belt, before the introduction of cartridges.

BADELAIRE.—A short, broad, curved, and double-edged pointed sword. Also written *Bandelaire.*

BADEN FUSE.—A modification of the Bormann fuse. The metal, form of the parts, etc., are the same as in the Bormann fuse, with the addition of a bronze stud and plate, used to confine a piece of quick-match in the recess shown at *b* (see Bormann fuse), and two pieces of common cartridge-paper, cut in the proper shape to fit the horseshoe-shaped opening, one of which goes above, the other below, the charge of composition, to prevent it, when burning, from melting the metal above and below it. The graduated scale is more extended than in the Bormann fuse, the numbers expressing, instead of seconds, the bursting-distances in hundreds of paces of 29½ inches in length. The *charge-cover* is cast in a mold; the plate to cover the priming is cut out with scissors, and the paper is stamped or cut out with a stamp or punch. The vent leading from the composition-channel to the magazine is closed, to prevent the entrance of composition when pressure is applied. One of the pieces of paper is now laid in the bottom of the channel, and on it is placed evenly a layer of mealed powder, weighing exactly 51 grains troy; on top of this is placed the second piece of paper, and then the charge-cover, which is pressed down to its place by machinery, having on its under surface the dies to impress the figures of the graduating scale on the metal. The amount of pressure exerted is about 5000 lbs.; which forces the top of the charge-cover slightly below the surface of the fuse, forming thus a shallow annular hollow, in which is poured some of the melted metallic mixture, but at as low a temperature as possible, in order that the heat of this solder may not act on the sulphur in the fuse. When cool, the fuse is placed in a turning-lathe, dressed off smooth, and any irregularities in the thread of the screw corrected. The vent is then unstopped, the magazine filled with fine powder, the cover placed on, fastened, and pierced.

This fuse, like the original Bormann, was designed for use with Shrapnell shot, and is always used with what the French call an *obturateur,* or stopper, which is made usually of wrought-iron. The eye of the shell is divided into two parts, the larger on the exterior (called the eye proper), and the contracted portion, next to the interior, called the *table.* Into this latter the obturateur is screwed, and serves, with the offset between the two, to prevent the soft metal of the fuse from being driven into the shell by the force of the charge. The obturateur is perforated through the center, to allow the passage of the flame into the charge. The weak point of this fuse, and all modifications of the Bormann fuse, is the difficulty of regulating them exactly and promptly on the field of battle, in a dense cloud of smoke, and especially at night. A remedy for this defect, however, has been found in the ingenious invention of Captain Breithaupt, of the Austrian service. See *Breithaupt Fuse.*

BADGE.—The term by which, in general, all honorary decorations and special cognizances are known. Badges are either conferred by the State or Sovereign, or assumed by the individual for purposes of distinction, the former class having very frequently had their origin in the latter. Of badges conferred by public authority, for the purpose of inciting to exertion and gratifying honorable ambition, numerous instances are to be met with in every part of the world. The Garter of the English knight, the Golden Fleece of the Spanish grandee, and the Button of the Chinese mandarin will occur as familiar examples. To the same class belong not only the Stars and Crosses with which princes and other persons of rank are adorned in England, and to a far greater extent on the Continent, but the medal of the private soldier, and even those not less honorable decorations which are now frequently conferred by private societies for acts of voluntary daring, such as the medal given by the Humane Society for saving from drowning. Amongst the ancients, one of the most usual emblems of authority was a gold ring, which was worn generally on the fourth finger. A ring of this description was the mark of senatorial and magisterial dignity, and latterly of knighthood at Rome; iron rings, during the earlier period, at all events, having been used by private citizens. The right of wearing a gold ring (*jus annuli aurei*) was gradually extended, till at length Justinian conferred it on all the citizens of the Empire In the early times of the Republic, when Embassadors were sent to foreign States, they were furnished with gold rings, which they wore during their mission as badges of authority. From an early period, every freeman in Greece appears to have used a ring, though the custom, not being mentioned by Homer, can scarcely have belonged to the earliest period of the history of that people, and is commonly supposed to have been of Asiatic origin. Rings are often mentioned in Scripture as badges of authority both amongst the Jews and other Oriental nations. We read of Pharaoh taking off his ring and putting it on Joseph's hand, as a token of the power which he committed to him (Gen. xli. 42); and still earlier (Gen. xxxviii. 18) Judah left his signet with Tamar as a pledge. In the New Testament, rings are spoken of rather as marks of wealth and luxury than as badges of official rank; e.g., James ii. 2, and Luke xv. 22, where, on the return of the prodigal son, the father ordered that a ring should be put on his finger. Of badges assumed for the purpose of distinction, none are more famous than the white and red roses of York and Lancaster. Henry VII. combined these two emblems, first carrying a rose per pale, white and red, and afterwards placing the white rose within the red one. One of Queen Elizabeth's badges was a golden falcon perched on the stump of a tree between two growing branches of white and red roses, a badge which is said to have been given to her mother. Anne Boleyn, by Henry VIII. The *bear and ragged staff*, which still exists as a sign in London, was the badge of the great Earl of Warwick. The *white hart* and *silver swan*, which are frequently met with as signs to inns, have a similar origin, the first having been the badge of Richard II., and the second having belonged to the House of Lancaster. The *garb and sickle*, the badge of the Hungerfords, is another very

Garb and Sickle.

Fleur-de-lis of Louis VII.

beautiful and less common example of the same class of badges. Different countries have also distinctive badges, generally connected with the history either of the actual ruling or of some former dynasty. Of these, the *fleur-de-lis* of France, and the other badges. for which it from time to time makes way—viz., the cap of liberty and other emblems of republicanism, the eagles of the Empire, borrowed from Rome, and the bees and other insignia which the Bonaparte family have assumed—may all be taken as examples.

For the badges of the different Orders of Knighthood, see their respective titles.

BAGGAGE.—No question is more important in giving efficiency to an army than the regulation of its baggage. Nothing so seriously impairs the mobility of an army in the field as its baggage-train, but this baggage is necessary to its existence; and the important question therefore arises, How shall the army be sustained with least baggage? Sufficient attention is not paid by Government to this subject in time of peace, and in war the Commander of the troops finds himself therefore obliged to use the *unstudied* means which his Government hastily furnishes. In respect to artillery and artillery equipments, the minutest details are regulated. It should be the same with other supplies. In the United States Army, the Quartermaster's Department has charge of transports, and some steps have been taken to regulate the subject; but legislation is required for the necessary military organization of Conductors and Drivers of wagons, and perhaps, also, unless our arsenals may be so used, for the establishment of depots, where a studied examination of field-transportation may be made, which will recommend rules, regulating the kinds of wagons or carts to be used in different circumstances; prescribing the construction of the wagon and its various parts in a uniform manner so that the corresponding part of one wagon will answer for another, giving the greatest possible mobility to these wagons consistent with strength; prescribing the harness, equipment, valises of officers, blacksmith-forges, tool-chests, chests for uniforms, bales of clothing, packing of provisions, and, generally, the proportion, form, substance, and dimensions of articles of supply,; what should be the maximum weight of packages; the means to be taken for preventing damage to the articles; the grade, duties, and pay of the Quartermasters, Wagon-masters, and Drivers should be properly regulated; rules for loading should be given; and, finally, a complete system of marks, or modes of recognition, should be systematized. With such rules, and the adoption of a *kitchen-cart*, together with small cooking-utensils for field-service which may be carried by the men, an army would no longer always be tied to a baggage-train, and great results might be accomplished by the disconnection.

In the marching arrangements of the British Army the baggage is placed under strict rules, in order that accumulation of weight may not impede the movement of the troops; and rules of an analogous kind are enforced in troop-ships, when soldiers are on a voyage. The term itself is made to apply chiefly to articles of clothing, and to small personal effects. A private soldier is allowed to carry nothing except that which his knapsack and other accouterments can hold; but those who are married with their officers' consent —a small number in every regiment—are allowed one small chest each, of definite size, which may be carried on a march, but at the men's own expense. Staff-sergeants and Pay-sergeants have similar permission. The baggage-wagons are not expected to receive packages weighing more than 400 lbs. each, or as much as four men can lift. Officers' baggage is, of course, much more considerable in amount than that of the non-commissioned officers and privates. On board troop-ships, the weight to be carried for each person is strictly defined—from 18 cwt. for a Field-officer, down to 1 cwt. for a married private soldier, with his wife and children. In encampments, whether permanent or temporary, and in armies on field-service, the utmost care is taken to preserve the baggage from the enemy, by surrounding it as much as possible with defensive troops.

BAGGAGE - MASTER.—An officer, in the English Army, appointed to take charge of the baggage of each brigade and division of an army in the field. He is selected from the Line if the Senior Officer of the Army Service Corps is not suited for the work. During the march he is the Staff-officer of the Field-officer of the Day, who, commanding the rear-guard, can give him orders if necessary. The Queen's Regulations of 1873 state that each regiment on a march is to furnish its own baggage-guard, under the care of an officer of the regiment.

BAGGONET.—The ancient term for bayonet. It is seldom used at present.

BAGPIPE.—A wind-instrument, very popular in the Highlands of Scotland. This instrument, the performers of which are called "pipers," is played by the bandsmen of Highland regiments. Up to the eighteenth century, the bagpipe was a very common instrument over the greater part of Europe. It is supposed to be of Grecian origin, and the Romans in all probability took it from the Greeks. The natives of India have an instrument very similar to the bagpipe. The bagpipe has long been a favorite instrument with the Scots, inspiring them with great enthusiasm and valor in the day of battle.

BAGS.—Articles used in field-fortifications, and in works to cover a besieging army. *Sand-bags*, which are generally 16 inches in diameter and 30 high, are filled with earth or sand, to repair breaches and embrasures of batteries, when damaged by the enemy's fire or by the blast of the guns. They are also placed on parapets, so arranged as to form a covering for men to fire through. *Earth-bags*, holding a cubical foot of earth, are used to raise a parapet in haste, or to repair one that is beaten down. They are only employed where the ground is rocky, or too hard for the pickaxe and spade, and does not afford ready material for a temporary parapet. See *Blowing-bags*, *Bursting-bags*, *Calico-bags*, *Cartridge-bags*, *Gunny-bags*, and *Gunpowder-bags*.

BAGS OF POWDER.—Powder in bags used to blow down gates, stockades, and slight obstructions. In future wars the higher explosives will doubtless be used for such purposes.

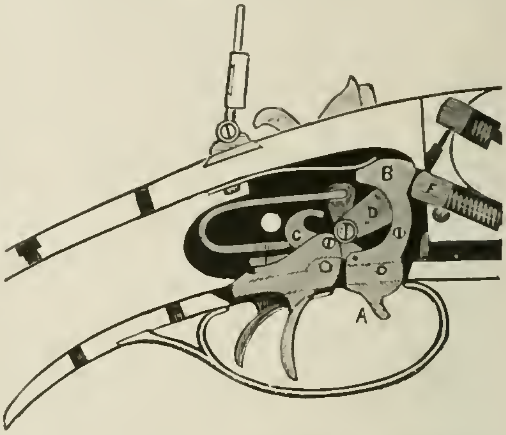
BAICLAKLAR.—The name given to a Color-bearer in the Turkish Army.

BAIKY.—The ballium, or inclosed plot of ground in an ancient fort.

BAIL.—A stout iron yoke placed over heavy guns and fitting closely over the ends of the trunnions, to which it is attached by pins in the axis of the trunnions; used to raise or lower the gun by means of the gin.

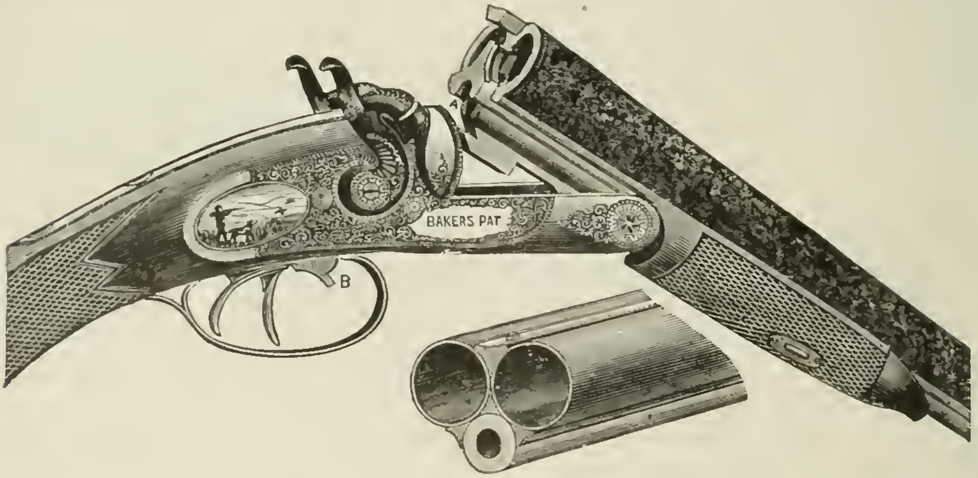
BAILLE.—A term formerly used to designate a work or fortification which served as an outpost or exterior defense.

though the same weight of metal was put in one barrel, which may be accounted for by the fact that the same weight of metal in a hollow tube is much stiffer than though it was in a solid bar; and, also, each barrel forms a brace to help support the other, and especially in regard to the rifle-barrel, in which



are used the heaviest charges that are manufactured for a sporting-gun.

The drawings show the form of the gun and the manner of operating the mechanism. In the smaller drawing, A is the rifle hammer which, being hung in the trigger-plate and extending up its side between the two shotgun locks, strikes the rifle firing-pin at



A, Rifle Barrel; B, Thumb-piece of the Rifle Hammer.

BAIONNIER.—A name formerly given to soldiers who were armed with a bayonet.

BAKER GUN.—A three-barrel breech-loading gun recently introduced and received with much favor. As happens to every hunter or sportsman, unexpected opportunities offer themselves to shoot at a class of game that a shot-gun will either not reach at all, or fail to kill. This gun gives confidence to those hunting in localities where there are dangerous animals, or where an enemy might be lurking and unexpectedly encountered at any moment. It is a most useful and suitable weapon for the hunters attached to scouting columns in the field, who are charged with supplying the messes with game. The weight, not over nine pounds, is sufficient to prevent an unpleasant recoil, and permits the gun to be carried with the same case as does an ordinary rifle, containing metal enough to do satisfactory work.

It is demonstrated by actual use that there is less spring or recoil in a gun with three barrels than

B. To operate it, cock the left-hand shot-gun lock and then push forward the thumb-piece, A, of rifle hammer, which will cause the hook, C, to engage with the pin, E, which is attached to the tumbler of the left-hand lock; then by pulling the back trigger the rifle hammer will be caused to strike the firing-pin at B, and stop, thus not allowing the left-hand hammer to go quite far enough to reach its firing-pin. After firing the rifle, cocking the left-hand hammer throws the rifle lock out of gear, then the shotgun locks are entirely independent of the rifle lock. The rifle barrel is chambered to use the Winchester 44-caliber cartridge.

The gun has a hinge-sight on the stock which turns down entirely out of the way while shooting the shot-barrels, and when turned up has a slide with a common notch in the top for open or quick shooting, and when raised has a fine hole or peep-sight for close or target shooting. A buckhorn sight can be placed on the rib when desired, but in most cases is unadvisable, as the rear-sight answers all practical purposes.

The lock is so constructed that while it retains the identical form of the best forward-action locks, making the gun the same shape, and having the same appearance outside of the finest standard work, the mainspring, instead of running forward into the breech, is inclosed within the lock-plate, which leaves the breech to retain the entire strength of the metal which has to be removed to make room for the ordinary lock, and which weakens it most precisely where it is subject to the greatest strain. While the lock thus allows of absolutely the strongest breech possible to get on a gun, it also admits of obtaining the easiest access to the entire working-parts of the gun, and is of such construction that with ordinary usage it will not get out of order, or become clogged with dirt or oil so as to prevent its successful working.

It will be seen, by referring to the description of the action, that while it is composed of the fewest pieces that is possible to use in a snap-action, it at the same time possesses every quality that is desirable, or that has been found essential to strength, durability, and safety. It is impossible to fire the gun unless the bolt is securely in its place, and the act of pulling the trigger holds it there while the gun is being discharged. It is also manifest that as soon as the gun is fired the hand is in place to open it without any change of position, insuring easy manipulation and rapid firing, it being entirely practicable to open it ready to receive the cartridge while bringing it down from the shoulder.

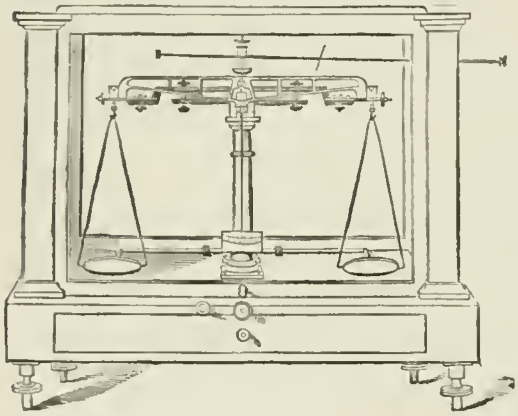
BAKERIES.—Armies have generally the means of obtaining soft or loaf bread, though not till recently could this be said of the British Army. The French, ever since the time of Louis XIV., have been accustomed to take portable ovens with their armies; those now used will each bake 450 rations at once. Outside Sebastopol, in the winter of 1854, the British soldiers sometimes willingly exchanged with the French 3 or 4 lbs. of biscuit for 1 lb. of soft bread. The efforts since made to improve the sanitary condition of the army have included the establishment of traveling-bakeries for field-service. Under the Commissaries, the troops now rarely fail to obtain their daily rations of fresh-baked bread. The English were the last among the greater nations to make this obvious improvement; but the French depend more on bread and less on meat than the English; and this may partly account for the difference. The French soldiers are taught to construct field-ovens, and to bake their bread in camp, while government bakeries are established all over France, entirely conducted by soldiers. Among other lessons afforded by the Siege of Sebastopol was one relating to an improved supply of army-bread. Two screw-steamers, the *Bruiser* and the *Abundance*, were sent out to Balaklava, one provided with machinery for grinding corn, and the other with machinery and ovens for making and baking bread. In each case the ship and the machinery were propelled by the same steam-engine. When quietly anchored in the harbor, the mill ground 24,000 lbs. of flour per day—better in quality and cheaper than could have been obtained by contract. The bakery-ship *Abundance* had four ovens of 14 bushels' capacity each; it baked in an excellent manner 6000 loaves of 3 lbs. each per day, which loaves were sent up to the siege-army as soon as cooled. The ships and machinery were sold when the war was over—a proceeding which the Commissariat Officers much regretted; but the experience thence obtained will not be lost. The improved arrangements suggested for meat-rations are noticed under *Cookery*.

BAKER RIFLE.—In 1800, the 95th Regiment, now the Rifle Brigade of England, was armed with this rifle, which weighed 9½ pounds. The barrel was 2½ feet in length and had 7 grooves, making a quarter turn in the length of the barrel, and its caliber was a 20 bore. A small wooden mallet was supplied with this rifle, to force the ball into the barrel; this mallet remained in use for a short time, when it was withdrawn. The great difficulty experienced in loading the rifle led to the remedy of M. Delvigne in 1826.

BALANCE.—An instrument for ascertaining the weight of bodies in grains, ounces, pounds, or any other units of weight. The ordinary balance consists of a lever called a beam, whose point of support is in the middle of its length, and having dishes or scales suspended from either extremity. As it is of importance that the beam should move easily round its point of support, it rests on polished agate or steel planes, by means of knife-edges of tempered steel, which project transversely from its sides, and serve as the axis of rotation. By this arrangement the surface of contact is reduced to a mere line, and the friction of the axis of the beam on its support almost entirely obviated. The scales are hung by means of chains attached to steel hooks, which rest also on knife-edges, but turned upwards instead of downwards as in the first case. The essential requirements of a balance of this description are: 1st, That the beam shall remain in a horizontal position when no weights are in either scale; and 2d, That the beam shall be a lever of equal arms, or have the distances between the central knife-edge and those at either end exactly the same. To insure the first of these conditions, it is necessary that the center of gravity of the beam lie vertically below the point of support, when the beam is horizontal. When such is the case, the center of gravity at which the weight of the beam may be considered to act oscillates as in a pendulum round the point of support, and always comes to rest right under that point, thus restoring to the beam its horizontal position when it has been tilted out of it. If the center of gravity were above the point of support, the beam would topple over; and if it coincided with that point, there being no restoring force, the beam would occupy indifferently any position into which it was thrown, the balance in both cases being useless. That a balance possesses the second of the above conditions is ascertained by putting weights into the scales which keep the beam horizontal, and then transposing them, when, if it still remains so, the lengths of the arms are equal. Should the arms be of different lengths, a less weight at the end of the longer arm will balance a larger weight at the end of the shorter arm; but when transposed, the larger weight having the longer arm, and the smaller weight the shorter, the beam can no longer remain horizontal, but will incline towards the larger weight. A balance with unequal arms is called a *false balance*, as distinguished from an equal-armed or just balance. When weighing with a false balance, it is usual to weigh a body in both scales, and take the arithmetical mean—that is, half the sum of the apparent weights for the true weight. This is near enough to the truth when the apparent weights differ little from each other; but when it is otherwise, the geometrical mean must be taken, which gives the exact weight in all cases.

Although the preceding conditions are of essential importance, they do not supply all that we look for in a good balance. It is necessary, in addition, that the beam should turn visibly from its horizontal position when there is a slight excess of weight in the one scale as compared with the other. This tendency is termed *sensibility*, and depends upon the weight of the beam, the position of its center of gravity, and the length of its arms.

There is another form of delicate balance employed in the arsenal and laboratory. The beam is constructed so as to combine lightness with strength, and rests by a fine knife-edge on an agate plane. It is surmounted by a weight moving on a screw, so that the sensibility may be increased or diminished, according as the weight is raised or depressed. In order that the knife-edge may not become blunted by constant contact with the supporting plane, a cross-bar, with two projecting pins, is made to lift the beam from the plane, and sustain its weight when the balance is not in play. The beam is divided by lines marked upon it into ten equal parts, and a small weight made of fine wire bent into the form of a fork, called a rider, is made to slide along to any of the divisions. If the rider be, for instance, $\frac{1}{10}$ of a grain, and if, after the weight of a body is very nearly ascertained, it brings the beam, when placed at the first division next the center, exactly to its horizontal position, an additional weight of $\frac{1}{100}$ of a grain will be indicated. The use of inconveniently small weights is, by this arrangement, to a large extent obviated. As the beam takes some time before it comes to rest, it would be tedious to wait in each case till it did so, and for this reason a long pointed index is fixed to the beam below the point of suspension, the lower extremity of which moves backward and forward on a graduated ivory scale, so that when the index moves to equal distances on either side of the zero-point we are quite certain, without waiting till it finally settles, that the beam will be horizontal. The same is seen in ordinary balances, only the tongue or index is above the beam; and according to its deviation on each side of the fork or cheeks by which the whole is suspended is the future position of the beam ascertained. The finer balances are never loaded to more than a pound in each scale, and when so charged will deflect with $\frac{1}{100}$ of a grain of



additional weight in one of the scales, or will turn, as it is technically called, with $\frac{1}{115200}$ of the load. The finest balances turn with $\frac{1}{1000000}$ of the load, and some have been constructed which turn with much less. Even with the best achievements of mechanical skill, no balance can be made whose arms are absolutely equal; and to remedy this defect, the method of double-weighing is resorted to when the utmost accuracy is demanded. This consists in placing the body to be weighed into one scale, and sand, or the like, into the other, until exact equilibrium is obtained, then removing the body, and putting weights or another body in its place which exactly counterbalance the sand. Both being thus weighed in precisely similar circumstances, must weigh precisely the same.

The balance employed in the process of determining density is a simple beam-scale, constructed with great accuracy. The great convenience of a decimal system of weights has led to the adoption of the scale of grams in ascertaining the density of powder. The set of weights used is of 5000 grams; approximately 11 pounds. The heaviest, 1 kilogram, 2.204 pounds; the lightest, 5 centigrams, 0.75 grain. The powder to be tested, if of mammoth size, will require breaking up to a smaller granulation; for in its natural state it will not readily enter the vase, which is of but one half-inch interior diameter at the neck. This is readily and safely done by using a light steel hammer, the powder resting on a table of wood. For convenience of computation, it is advisable to use samples of 100 grams; or, if employing grain weights, of 1543.3 grains. To take the density, weigh out the sample with great accuracy, taking 100 grams, if practicable. The vase being mounted, with the nozzle screwed in place and well immersed in the mercury, close the lower cock, opening both the others, and exhaust the air from the tube and vase. When the gauge shows nearly a perfect vacuum, open the lower cock. The mercury from the dish will then enter and fill the vase, rising in the tube nearly to the barometric height, the vacuum meanwhile being kept up by continuous pumping. As soon as the column becomes stationary, close the lower stop-cock, and re-admit the air to the top of the tube by unscrewing the casing of the vacuum-gauge; close the other cocks and unscrew the nozzle; dismount the vase, jar out the mercury from the tubular spaces outside the cocks, brush the outside clean, and then place the vase on its rest and weigh it. Call this weight of vase and mercury $VM = W$. Empty the vase by opening the cocks, and allow the mercury to return to the dish; also let the mercury run out of the barometer-tube. If the inside of the vase is coated, unscrew both plugs and wipe it out with a cloth; or, if necessary, wash it with aqua regia. With clean mercury, washing is rarely required. In general practice, after having emptied the vase, one plug is unscrewed, and the sample of powder previously weighed out is poured in. The plug being again securely in place, the vase is mounted and the mercury pumped into it, passing up through the powder, filling its interstices, driving out the air, and rising to the same height in the tube as before. When this point is reached, close the cocks, admit the air, unscrew and weigh the vase as before, calling the weight of powder, vase, and mercury $PVM = W'$. From these two weights, together with that of the powder sample, the density is calculated by the proportion: Density of mercury is to density of powder as weight of mercury displaced by powder is to weight of powder; or, if

W = weight of vase and mercury,
W' = weight of powder, vase, and mercury,
w = weight of powder,
D = density of mercury,
d = density of powder,

then $W' - w$ = weight of mercury, vase, and powder, less the weight of powder, and $W - (W' - w)$ = weight of mercury displaced by the powder, and the proportion becomes

$$D : d = W - W' + w : w,$$

or

$$d = \frac{D \times w}{W - W' + w}.$$

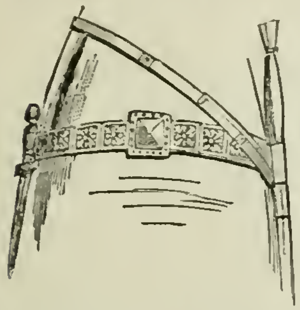
The weight of W should be determined at the beginning and end of each set of trials, and the mean be used to correct the result of the whole series. The mercury used should be of specific gravity $= 13.55055$ at 66° Fahrenheit. Its purity can be tested by comparison with distilled water by the following process: Clean the vase and its connections thoroughly, and weigh it. Call this weight a. Mount the vase and fill it with mercury, and again weigh it, calling the result b. Empty, clean, and connect it again, substituting a dish of distilled water for that of mercury ordinarily used. Fill the vase by pumping slowly to avoid overflowing. Detach and weigh it again, calling this last weight c; then

$$\frac{b - a}{c - a} = D,$$

the density of the mercury, which, if up to the standard, will correspond to that given in the table for the temperature at the time of trial. The mercury used with the densimeter should frequently be strained through chamois-leather to remove impurities which are accidentally introduced into it in experimenting. See *Weighing-machine.*

BALANCE-STEP.—An exercise in squad-drill which is much practiced as a preliminary to marching.

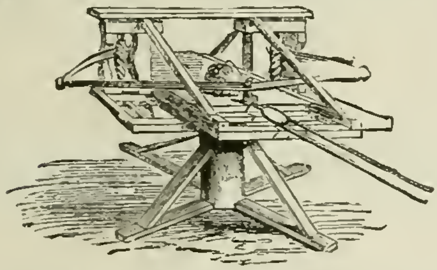
BALDRICK—BAUDRICK.—A band or sash worn partly as a military and partly as a heraldic symbol.



It passes round the waist as a girdle, or passes over the left shoulder, whence it is brought downward obliquely under the right arm, or is suspended from the right shoulder in such a way as to sustain a sword. Many of the effigies of knights contain representations of the baldrick, more frequently as a belt than a shoulder-sash. Queen Victoria frequently wears a blue silken baldrick on state occasions. The name is derived from the *balteus* of the Roman soldier.

BALESTRE.—The *cross-bow à galet*, so called by the Germans, from its being somewhat large in size. Also written *Ballestre.*

BALISTA—BALLISTA.—A large military weapon in use before the invention of gunpowder. The *balista*, the *catapulta*, the *scorpion*, and the *onager* propelled large and heavy missiles, chiefly through the reaction of a tightly-twisted rope of hemp, flax, catgut, sinew, or hair; or else by a violent movement of levers. The scorpion was a kind of large crowbar: the balista threw stones; the catapulta threw heavy darts or arrows, and was somewhat smaller than the balista. One man could manage the scorpion, but two or more were needed for the balista or the catapulta. There was a good deal of mechanism necessary to bring about the propulsive force. The



makers of those machines were very particular in the choice of women's hair, the sinews of a bull's neck, and the tendons of the deer, wherewith to fashion the elastic cord. The onager was a kind of balista, which threw a stone by the agency of a sling instead of a stretched cord. The early chroniclers tell of catapultas that would throw an arrow half a mile, or hurl a javelin across the Danube; and of a balista which threw a stone weighing 360 lbs. Numerous other weapons of an analogous character were known in the Middle Ages—such as the *mangonel;* the *trebuchet*, which threw a large stone by the action of a lever and a sling; the *petrary*, which, as its name implies, threw a stone; the *robinet*, which threw darts as well as stones; the *mate-griffon* and *mate-funda*, both slinging-machines; the *tricolle*, which hurled quarrels, or square-headed arrows; the *espringal* or *springal*, which threw darts; the *ribaudequin*, a large kind of cross-bow; the *war-wolf*, a stone-throwing machine, etc. The arbalest may be regarded as a small portable arrow-throwing balista.

BALISTA FULMINATRIX.—A peculiar war-engine of the Middle Ages. This engine is interesting on account of the men inside the wheels who form its motive power.

BALISTARIUM.—A store-room or arsenal in which the Romans stored their balistas.

BALISTER.—A term applied in ancient times to the cross-bow, carried by the *Balistriers*, or cross-bowmen.

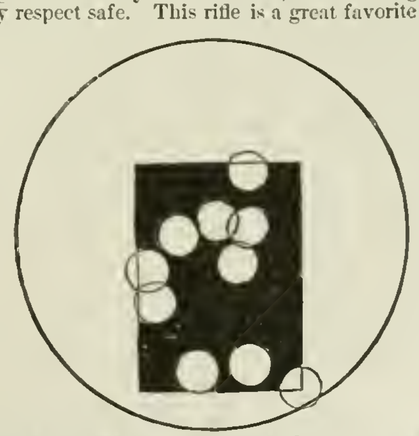
BALISTRARIA.—One of the names given to those narrow apertures so often seen in the walls of old castles, and through which the cross-bowmen discharged their arrows. Balistraria do not seem to have come into use till the thirteenth century. The lower terminations of balistraria are generally circular, sometimes in the form of a shovel. This term, frequently written *ballistraria*, also signified a projecting turret, otherwise called a bartizan, such as is commonly seen in old castles.

BALKS.—Joist-shaped spars, which rest between the cleats upon the saddles of two pontons, to support the chess or flooring.

BALL.—In the somewhat indefinite language of the military and naval arts, all kinds of shot and bullets are occasionally called by the collective name of *ball.* This was especially the case when nearly all such projectiles were solid and spherical, before the era of hollow and spheroidal shells. At present, when the varieties are so numerous, it is more usual to employ the terms *bullet* and *shot.* These, together with *shell*, are subdivided into numerous kinds, the most important of which will be found noticed under their proper designations. A particular class of spherical combustibles is described under *balls.*

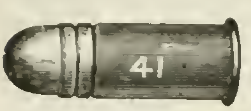
BALL À CULOT.—As no two soldiers would probably use the same number of blows, or the same force, when ramming the ball into the grooves, various degrees of expansion would take place. With a view to expanding the ball regularly and independently of the soldier, a ball with a wedge (culot) was invented. The shape of the cavity in this ball was that of the frustum of a cone, and in this cavity was inserted a piece of iron to act as a wedge. This culot was driven before the powder into the cavity, and by expanding the softer metal of the ball forced it to take the grooves.

BALLARD RIFLE.—An American rifle having a very simple and effective breech mechanism. The extractor is positive and cannot fail to work, as it acts on the same pin with the lever; when the lever is thrown down it withdraws the breech-block, at the same time throwing the hammer to the half-cock notch; after inserting the cartridge, pushing up the lever causes the lock to move forward and upward, closing tightly on the head of the cartridge. There is no possibility of an explosion, as the hammer is at half cock, and there is nothing which might slip through careless handling. Nothing short of firing the gun voluntarily can set it off, thus making it in every respect safe. This rifle is a great favorite with



the Indians of North America, and seems to possess shooting and non-fouling properties not possessed by many other rifles. The Target represented was made after 40 rounds at fifty yards, with this rifle. The wind was from the left rear, light, but the atmosphere was damp, and consequently favorable from the fouling point of view. In no case was there the slightest evidence of any increase of fouling up to 100 shots. The rifle is approved and recommended by the best shots in the leading clubs in the United States, Great Britain, France, and Germany.

BALL-CALIBER.—A ring-gauge for testing the diameter of gun-shot, usually used on board ship.



BALL-CARTRIDGE.—A cartridge for small-arms; the ball and powder being in an envelope or shell. In contradistinction to *blank-cartridge*. See *Cartridge*.

BALLING-FURNACE.—A furnace in which *piles* or *fagots* of iron are heated so as to form balls for rolling. In the *puddling-furnace*, pig-iron is boiled to drive off certain impurities, and the iron therein is formed into balls by the *rabble* or *paddle* of the puddler, so as to be ready for the shingling-hammer or the squeezer which drives the slag from the bloom. At the same heat the iron may be rolled and become a merchantable article of bar-iron; but with some qualities of iron, and for the production of the finer varieties of bar and sheet iron, the bar from the first rolling is cut up by the shears and made into *piles* or *fagots*, which are reheated to form *balls* for re-rolling. The furnace resembles a puddling-furnace, with the exception that it is not designed for stirring and puddling; but the *piles* or *fagots* are laid upon the floor of the reverberating chamber, and are there heated without running together, each being withdrawn as it attains the required condition. The bottom is made up from time to time with sand. It is not a *mere* reheating, but the action of the fire and the admission of regulated quantities of air remove certain impurities which have resisted the previous operations.

BALLING-TOOL.—A tool for aggregating the iron in a puddling-furnace, to fit it for conveyance to the tilt or squeezer.

BALLISTEA.—In antiquity, songs accompanied by dancing, used on occasions of victory.

BALLISTIC MACHINE.—A machine designed to determine by electricity the initial velocity of a projectile. These machines are made in great variety. The Benton velocimeter, devised for use at the Military Academy, and usually known as the West Point ballistic machine, will serve to illustrate their general purpose and construction.

BALLISTIC PENDULUM.—The ballistic pendulum invented by Robins, who is justly held to be the pioneer of modern gunnery, was first used in 1740, with the object of measuring the velocity of projectiles and the resistance of the air. If such a pendulum, being at rest, is struck by a body of known weight, and the vibration which it makes after the blow is known, the velocity of the striking body may thence be determined. The quantity of motion of the body before impact is equal to that of the pendulum and body after impact. It consists essentially of a strong, large pendulum, which has its axis of suspension secured, and a core or block at its lower part. The projectile is fired into this core and remains there, causing the pendulum at the same time to swing through a certain angle α with the vertical; this is measured by a slider which is pushed along a fixed arc.

Before using the pendulum certain adjustments as to symmetry and level are necessary, and it is important to arrange that the pendulum may be struck at such a point that no impulse shall be given to the axis of suspension; in other words, the center of percussion should be hit. It is an established fact that the centers of percussion and oscillation are coincident, and the center of oscillation is readily found by causing the pendulum to vibrate through a small arc; and observing the period (T) taken to perform a number of vibrations (n), then $\frac{T}{n}$ gives the time (t) of a single vibration with considerably accuracy. The length of the corresponding simple pendulum (l), the distance of the center of oscillation or percussion from the axis of suspension, is then known from the formula $t = \pi \sqrt{\frac{l}{g}}$. If the distance of the center of the core from the axis of suspension is exactly equal to l, the instrument is in adjustment; but if this is not the case, weights must be pushed up or down the pendulum by trial and error, till the time of oscillation is found to be correct.

The weight of the pendulum being known, the distance (h) of its center of gravity from the axis of suspension is then found experimentally (if not already determined). A cord, with a known heavy weight at the end of it, is passed over a pulley (in the plane of oscillation), and attached to the lower part of the pendulum, which it pulls through a certain angle β, which is measured. The distance of the point of attachment of the cord from the axis of suspension is also measured; and from these data the position of the center of gravity of the pendulum is easily found.

Let W be the weight of the pendulum in pounds; w, the weight of the projectile in pounds; v, the velocity of the projectile in feet per second; d, the distance of center of percussion from axis in feet; h, the distance of center of gravity from axis in feet; ε, the angular velocity of the pendulum at the instant of impact. Then

$d\varepsilon$ = linear velocity, in feet per second, of the center of percussion at the instant of impact, and

$h\varepsilon$ = linear velocity of center of gravity at the instant of impact.

The projectile is fired into the middle of the core, and the pendulum swings through the angle 2α.

Since the center of oscillation moves as though it were isolated, its velocity $d\varepsilon$ at the instant of impact must be the same as that of a body falling freely under the influence of gravity from the height to which it will rise at the end of its swing, or

$$d^2\varepsilon^2 = 2gd\,(1 - \cos\alpha);$$

whence
$$\varepsilon = 2\,\frac{\sqrt{gd}}{l}\,\sin\frac{\alpha}{2}.$$

As the shot buries itself in the core, rebound is prevented, and we have a case of impact of inelastic bodies, when the momentum of the projectile *before* striking must be equal to that of the pendulum and of the projectile *after* striking, or

$$wv = Wh\varepsilon + wd\varepsilon;$$

whence
$$v = \frac{\varepsilon}{w}\,(Wh + wd).$$

Substituting the value of ε from above, we obtain

$$v = 2\sin\frac{\alpha}{2}\,\frac{Wh + wd}{wd}\,\sqrt{gd}.$$

If the center of percussion is not exactly struck, the velocity of the projectile can still be found by suitable modifications in the calculations; this often had to be done, when firing from a considerable distance, to find the loss of velocity due to the resistance of the air, as it was difficult to hit the exact spot aimed at.

BALLISTICS.—That branch of the science of gunnery which treats of the motion of projectiles. Ancient artillerists considered that the trajectory, or path described by a projectile after it left its piece, was composed of three distinct parts: 1st. The *violent*, which approached a straight line; 2d. The *middle*, or *mixed*, which was a circle; 3d. The last, or *natural*, which was also a right line.

Tartaglia, an Italian engineer, invented the quadrant for measuring elevations, which he divided into twelve parts, and by which he was able to compare the ranges of different cannon, fired under the same or different degrees of elevation. He demonstrated that no portion of the trajectory was a right line, and that the angle which gave the greatest range was 45°.

About 1638, Galileo discovered the laws which

BALLOONS. 1. Montgolfière (first balloon). 2. Pilâtre de Rozier's balloon (first ascent). 3. Blanchard's balloon (first aerial navigation). 4. Coutelle's balloon (first employed in war, at the battle of Fleurus; later first employed for scientific purposes at Hamburg). 5. Green's balloon. 6. Nadar's balloon "Le Géant" (disastrous fall at Hanover). 7. Duruof's balloon "Le Neptun" (exploded). 8. Aeronaut's marine balloon. 9. Parachute closed. 10. Parachute open. 11. "Captive ballon," at London. 12. Rufus Porter's guidable aerial ship. 13. Dupuy de Lôme's guidable aerial ship. 14. Kaufmann's flying machine. 15. Filling a balloon. Gasometers.

II—150.

govern the fall of bodies, and from these he demonstrated that the curve described by a projectile, thrown in a direction oblique to the horizon, is a parabola, the axis of which is vertical. He did not consider that the air offered any material resistance to the motion of artillery projectiles.

About 1723, Newton demonstrated that the curve described by a spherical projectile in the air was far from being a parabola; that the two branches were dissimilar, and that the descending branch would become vertical if sufficiently prolonged. While he considered the resistance of the air proportioned to the square of the velocity, he did not conceal the fact that this was but an approximation to the true relation, which remained to be determined by experiment.

About 1765, Robins invented an instrument for determining the initial velocity of a projectile, called the ballistic pendulum, by which he was able to show that the range in vacuo was much greater than in air. He also discovered that the rotary motion which spherical projectiles generally assume around their centers of gravity will cause them to deviate from their true direction.

Hutton, who lived about the beginning of the present century, improved the ballistic pendulum, and applied it to determine the true law of the resistance of the air, as exemplified in projectiles of small caliber. At Metz, in 1839 and '40, further experiments were made on the resistance of the air to projectiles of large size, moving with high velocities, and the law of variation was determined with great accuracy.

The subject of ballistics presents two fundamental questions: 1st. To determine the initial velocity of a projectile for a known piece and charge of powder. 2d. Knowing the initial velocity and angle of projection, to determine the range, time of flight, remaining velocity, and, in fact, all the circumstances of the projectile's motion.

BALLIUM.—A term used in ancient military art, and probably a corruption of Vallium. In towns, the appellation "ballium" was given to a work fenced with palisades, and sometimes to masonry covering the suburbs; but in castles, it was the space immediately within the outer wall.

BALLOON.—The art of traversing the air by means of balloons, generally called aëronautics, and sometimes aërostation, is of comparatively recent date. The germ of the invention of balloons is to be found in the discovery by Cavendish, in 1766, of the remarkable lightness of hydrogen gas, then called inflammable air. Prof. Black, of Edinburgh, seems to have been the first who conceived the idea that a light envelope, containing this gas, would rise of itself. He requested Dr. Monro, the Professor of Anatomy, to give him some thin animal membrane for the experiment, but for some reason or other it was never made. The first practical attempts were made by Cavallo, who, in 1772, filled swine's bladders and paper bags with the gas, but found the former too heavy and the latter too porous; and he only succeeded in raising soap-bubbles inflated with the gas. The invention of the balloon is due to the two brothers Stephen and Joseph Montgolfier, paper-makers at Annonay, in France, whose names are as distinguished in the development of their own branch of manufacture as in the history of aëronautics. It immediately struck these brothers, on reading Cavendish's *Different Kinds of Air*, that the air could be rendered navigable by inclosing a light gas within a covering of inconsiderable weight. Led by their avocation, they fixed upon paper as the most fitting material for the purpose, and first attempted to make balloons of paper filled with inflammable air. Finding that these emptied themselves almost as soon as they were filled, instead of abandoning the paper as an unsuitable covering for the gas, they sought after another gas more suited to the paper. By a chain of false reasoning which need not here be detailed, they thought they found such in the gas which resulted from the combustion of slightly moistened straw and wool, which had, as they imagined, an upward tendency, not only from its being heated, but from its electrical properties, which caused it to be repelled from the ground. It is hardly necessary to say that this so-called Montgolfier gas possessed no advantages for raising balloons other than that possessed by heated air of any kind; in fact, the abundant smoke with which it was mixed, by adding to its weight, rather detracted from its merits. At Avignon, in November, 1782, Stephen Montgolfier first succeeded in causing a silk parallelopiped, of about 50 cubic feet, to rise to the roof of a room. Encouraged by this success, the brothers made experiments on a larger scale at Annonay with an equally happy result; and finally, in June, 1783, in the presence of the States of Vivarais, and of an immense multitude, they raised a balloon, 35 feet in diameter, to a height of 1500 feet. This last, nearly spherical in shape, was made of packcloth, covered with paper, and was heated by an iron choffer placed beneath it, in which 10 pounds of moist straw and wool were burned.

Balloons are useful in warfare for purposes of reconnoitering, and in the case of a beleagured city, for keeping up communication with the outside world. The Prussians are said to have reconnoitered the French position before Metz in the war of 1870 by means of a balloon with telegraph attached, and it is further said that the survey, made with great care, was most successful, and conveyed instantaneously to General von Moltke the true position of the French army at all points, and its movements. From an account given of the first balloons used for war purposes, it appears that the proposal for employing what were then termed captive balloons was made by the Committee of Public Safety in 1793. After some preliminary experiments at Meudon, a small Corps of Aërostats, skilled in precarious crafts, was formed on the model of an Engineer Company, and dispatched to Manberg, then besieged by the Dutch and Austrian troops. The balloon used was 30 feet in diameter, and rose 1800 feet with two observers and 130 pounds of ballast. It was managed by two ropes attached to the net, and was filled with hydrogen, obtained with much difficulty and expense from water. The immediate moral effect upon the enemy of the use of this balloon by the besieged was extraordinary. They imagined, which was far from being the case, that their every movement was at once made patent to the French, and it was this that in a great measure caused the demoralized Austrians to abandon the siege. The balloon, passing from a defensive to an offensive position, was then transported while inflated to Charleroi, which the French were attacking. Its apparition at once deprived the besieged of all confidence in their strength, and hastened the surrender of the town while still efficient for defense. The balloon was subsequently used at Fleurus, where much is attributed to it; then at Brussels, Liége, Aix-la-Chapelle, on the Rhine, and on the Danube. A Corps of Aërostats accompanied the French army to Egypt, but did nothing, as the apparatus was damaged on the way. In 1800 both corps were suppressed. The Prussians used ballooning against the French in 1812, but the results were not encouraging. At Solferino, one of the brothers Godard ascended in a montgolfier; but he was much too late, and the ascent was all but useless. In the American war, balloons were used from time to time, but were attended with no advantage.

The following are the results of experiments made at Woolwich a few years ago in reference to war or captive balloons, inflated at the Royal Arsenal gas-works. They are thus described in one of the public journals of the day: It has been found that a height of 100 fathoms, at a horizontal distance of 600 fathoms from the enemy, would enable the observers to secure the widest expanse of view. With captive balloons it has been found that they attain stability, and remain like a kite, at rest, when the horizontal resultant of the ascensional force and the tension of the cord are equal to the force of the wind; and this enables a second diversion of science to come in and lend its aid in the time of war. The war-balloon having, by a mathematical rule, taken a stationary position, eight cameras and lenses, spread round the balloon at equal distances, enables a complete view of the surrounding country to be photographed, and subsequently examined at leisure. The inclination and length of the cord to keep the balloon in the same stratum of air was found to be easily calculable, subject to the inequality of gales of wind and their change of direction. The Woolwich balloons were held by two new cords, fastened to the network, and terminating at two different points on the ground, which gave greater stability to the balloon, and provided against one cord snapping or being cut by the enemy's fire. Under the old plan, aëronautic correspondence was carried on by the explorers in the balloon-car being provided with white pasteboard tubes, formed like cartridges open at both ends, to which a bullet was securely fastened. Each piece of intelligence was written in pencil in large characters along the major axis of the paper tube or cartridge, which was immediately dispatched by passing the end of the small cord through it, and it was thus precipitated by the gravitation of the bullet into the hands of the expectant General. This plan has just been abrogated by a third diversion of science being brought to bear in the time of war. By the new system of military telegraphy for field-service, and by means of the wagons at present being placed in store for military service, lines of telegraph can be carried through the air from *terra firma* to a balloon several miles distant. The wire can be paid out as fast as the balloon travels, so that if a captive balloon should break or soar away communication could be kept up with it for six miles, or two or more balloons can be sent.

BALLOTING.—A bounding movement of a spherical projectile in the bore of a cannon.

BALL-PROOF.—Incapable of being penetrated by balls from fire-arms or other engines.

BALL-SCREW.—An implement for extracting bullets from the barrel of a gun in cases where it would be dangerous or impossible to expel them by firing. It is screwed on the end of the ramrod, which, being turned, causes the screw-threaded pointed end of the ball-screw to enter the bullet, which is then withdrawn by pulling the ramrod. Witzleben's ball-screw has two jaws with sharp-edged interior shoulders, constituting a portion of a concave screw-thread, which enters the bullet to prevent it from slipping from the grasp of the jaws.

BALL-TRAIN.—In the foundry, a set of rolls for rolling *puddler's* balls into bars. The word *train* signifies that more than one pair is used, the first being *crushing* rolls, and the second *finishing*. The result of the action of the two is *bar*-iron.

BALOTS.—Sacks or bales of wool, made use of in cases of great emergency, to form parapets or places of arms. They are likewise adapted for the defense of trenches, to cover the workmen in saps, and in all instances where promptitude is required.

BALUSTRADE.—A range of balusters, together with the cornice or coping which they support.

The balustrade is often used as a parapet over bridges, for the roofs of large edifices, etc., or as a mere termination to the structure. It is also used to inclose stairs, altars, balconies, etc. Balustrades are made of stone, metal, or wood. See *Fortification.*

BAMBOO.—A genus of grasses, of which it is the most gigantic; it is well known for its great economical importance. It is found in all tropical climates, and the purposes to which it is applied are so numerous that it would be difficult to point out an object where strength and elasticity being requisite, and lightness no objection, to which the stems are not adapted in the countries where it grows. When ripe and hard, it is converted into bows, arrows, quivers, lance-shafts, poles of palanquins, poles for tents, fire and escalading ladders, and used in the flooring and supports of rustic bridges. In an artillery park in India, wherever the bamboo can be procured, it is made use of in carrying heavy weights, such as ammunition-boxes, shot or shell when carried in slings, and for a variety of other purposes.

BAN.—1. Formerly, a title given to some of the military chiefs who guarded the eastern boundaries of the Hungarian kingdom, and was therefore synonymous with the German *markgraf.* The ban, who was appointed by the Sovereign, but not for life, and whose appointment had to be ratified by the National Diet, had originally very extensive, in fact almost unlimited, powers. In political, judicial, and military affairs he was the supreme authority. Within his own territory he exercised an influence similar to that of the Palatine in Hungary, and only lower than a king. In time of war he headed the troops of his *banat*, and if the campaign occurred within its limits, it was his duty invariably to occupy the post of danger. He led the van to battle, or covered the rear in retreat. For these services he was recompensed partly in ready money and partly by a monopoly of salt. The most important banats were those of Dalmatia, Croatia, Slavonia, Bosnia, Machow, and Szorény, but their boundaries changed so frequently that at the present day it is impossible to ascertain what they originally were. The encroachments of the Turks in the sixteenth century rendered the union of the various banats necessary: and after some time the whole were formed into the double banat of Dalmatia and Croatia. A still more complete unity was subsequently obtained by centralizing the military power. In 1723 the authority of the ban was made entirely subordinate to that of the supreme government of Hungary. After numerous vicissitudes, his powers, rights, and titles were strictly defined during the reign of Maria Theresa. He was then acknowledged to be the third dignitary of the Hungarian kingdom, appointed a member of the Hungarian council of government, and president of the council of the banat, and at the coronation of the Hungarian king went before him, bearing the golden apple, the symbol of sovereignty. Such was the position of the ban until the 4th of March, 1849, when Croatia, Slavonia, and Dalmatia were transformed into Austrian crown-lands, and the ban made wholly independent of Hungary. In 1868 Croatia and Slavonia were reunited with Hungary. One of the Hungarian ministers superintends the affairs of the "Kingdoms of Croatia and Slavonia;" while there is a special local administration for internal affairs. The head of this administration is called the ban.

2. Besides the civil use of the word ban, as a proclamation or prohibition, there was a military application of the term in former days in France. When the feudal barons, who held their estates and honors from the king, were summoned to attend him in the time of war, they were called the *ban*, or the levy first called out; while the tenants, subordinate to these barons, formed the *arrière ban*, or secondary levy.

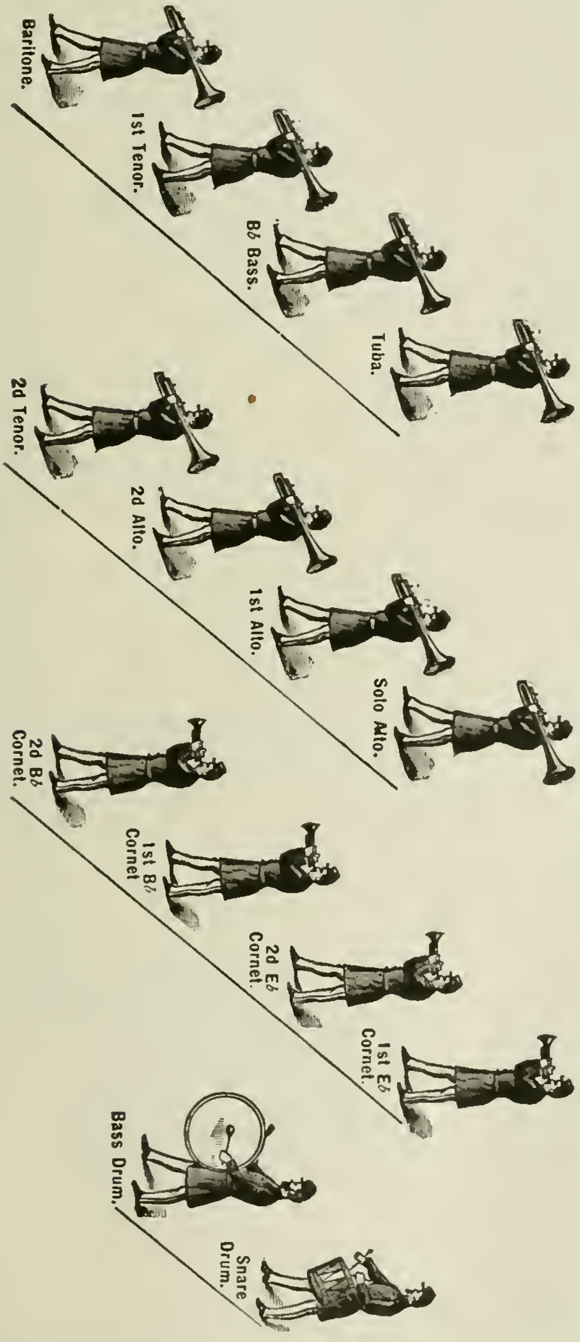
BANCAL.—A curved saber, which was used in France during the Republic and the Empire.

BANCA TIN.—A brand of English tin used to a great extent in gun-construction. The purest comes from the islands of Banca and Billotin, in the Malayan Archipelago, and is sold once or twice a year at Amsterdam and Rotterdam. In Whitney's *Metallic Wealth of the United States*, published in 1854, is given the following analysis of Banca tin:

Tin	99.961
Iron	.019
Lead	.014
Copper	.006
	100.000

English "refined" tin, from the Cornish mines, stands next as regards purity, and is followed by—1st. English tin (which includes "Lamb and Flag"); 2d. Straits tin, from the Malayan Peninsula; 3d. Australian tin.

BAND.—In the United States Army, when it is desired to have bands of music for regiments, there



Band of Fourteen.

are allowed, for each, sixteen privates to act as musicians, in addition to the chief musicians authorized by law, provided the total number of privates in the regiment, including the band, does not exceed the legal standard. Regimental Commanders designate the proportion to be subtracted from each company for a band. The musicians of the band are, for the time being, dropped from company muster-rolls, but they are instructed as soldiers, and liable to serve in the ranks on any occasion. They are mustered in a separate squad under the chief musician, with the Non-commissioned Staff, and are included in the aggregate in all regimental returns. When a regiment occupies several stations, the band is kept at the headquarters, *provided* troops (one or more companies) be serving there. The field-music belonging to companies not stationed at regimental headquarters are not separated from their respective companies. In addition to the regimental bands, there is enlisted in the Army one band, which consists of one Band-leader and not more than twenty-four musicians, ordinarily stationed at the Military Academy.

In the British service, according to military regulations, the only indispensable instruments are drums, fifes, bugles, and trumpets, all of which are employed to give signals on the march or in active service, either for infantry or for cavalry. To supplement this meager musical establishment, however, the officers of regiments organize, chiefly at their own cost, effective military bands, who use a variety of instruments—such as flutes, clarionets, bassoons, horns, ophicleides, big drums, cymbals, triangles, etc. This arrangement has assumed almost the force of a regulation; for officers above the rank of Subaltern are obliged to contribute a sum not exceeding 12 days' pay in the course of a year, and an extra sum when promoted, to the band-fund. The members of these bands are selected from the ranks; but the Band-master, though in uniform, is often a civilian who is hired for the purpose and who generally refuses to accompany the regiment abroad, except at an increased rate of remuneration. The musicians, generally, are in an anomalous position; for, whilst serving in the band, their pay and eventually their pensions are restricted to those of the private soldier. Good musicians have at all times a tendency to quit the band; their better prospects as teachers and players in orchestras and concerts induce them to obtain release by paying the amount of compensation prescribed by regulation. An attempt made by the Duke of Cambridge in 1856 to relieve the Commissioned Officers of part of the expense entailed upon them by the present system failed, except as regards Subalterns, and with that exception matters remained as they were. In most of the regiments of the Line the band consists of a Band-master and about 15 musicians; but in the choice corps the number is often much larger. The band plays on parade and at mess as a part of regular duty.

The success of a military band depends very much on the proper selection of instruments, and the assignment of the most suitable members to the various pieces. The band should have at least fourteen members, as follows: 1st and 2d E*b* Cornets, 1st and 2d B*b* Cornets, 1st and 2d Altos, 1st and 2d Tenor, Baritone, Tuba, B*b* Bass, Solo Alto, Snare Drum, and Bass Drum. When selecting the players for different instruments, let the best musicians take the 1st E♭ Cornet, 1st B♭ Cornet, and Baritone. Next select a large good-natured gentleman for the Tuba, and one with some ability for the 2d B♭ Cornet. The 1st and 2d Altos and 1st and 2d Tenors are about equally difficult. For the Bass Drum have some one who will keep good time, and for the small Drum it is well to have a man who has played before either in a martial or a brass band.

There is some diversity of opinion as to the best modes of holding some of the larger instruments, but it is considered proper and each member is directed to place the mouthpiece in the center of the mouth, after drawing the lips tightly across the teeth; then to relax the lips, leaving the part inside still tight, and to be careful not to push the lips or cheeks out when blowing. To produce high tones, it is necessary to press the instrument firmly against the lips; for low tones, press lightly, and relax the muscles. Begin the tone by pronouncing the syllable *Tu*. To take breath, open the mouth a little at either or both sides of the mouthpiece. The length of the passage to be executed should govern the amount of breath that is taken. If too much breath is taken in short passages, it is likely to produce *suffocation*. It is not advisable to change the position of the mouthpiece upon the lips after it has once been located.

In practicing, members should seat themselves either in a circle or about a long table; the Director at the end, where he may be seen by all. At his right, 2d E♭ Cornet, 1st B♭ Cornet, 2d B♭ Cornet, B♭ Bass, and Tuba. At his left, 1st and 2d Altos, 1st and 2d Tenors, and Baritone. The Drums at the extreme end. Always have the Drums near the Basses, and opposite the Leader. Let it be understood, from the beginning, that when the Conductor raps for attention, every member must obey him, and at once. It would add much interest to the practice if, a few days previously, each of the members would practice privately, getting the proper tones. At first, the exercise will make the lips quite sore, but they will soon become hardened, so that the unpleasantness will pass away. Having decided to attempt new music, the Director should familiarize himself with each part before assigning it, that he may see quickly what is required of every instrument. He should explain the first movement, and after it has been practiced, the harmony horns, consisting of 1st and 2d Altos, Tenors and Basses, should play their parts to the first strain. Then add the lead and other horns. Next play it through with full band. Do this with each strain until the entire number has been played. It is always well to take the water out of a horn as soon as the band stops playing, and then there will be no delays in commencing again.

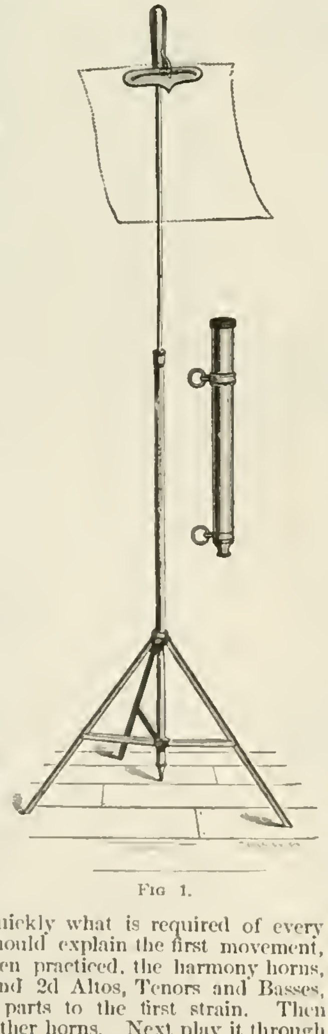


Fig 1.

When requested to play at a funeral, the band should march to a point near the remains, without music. While the body is being removed to the hearse, play something appropriate, *Pleyel's Hymn* or music of this order. After taking a position at the head of the column, funeral marches should be played until arriving at the cemetery entrance, when the band should open order, and cease playing until the procession passes through. At the conclusion of the services the band should resume their position at the head of the column, and immediately play some quick march. It is well to make selections of marches that are not very common, otherwise it would often seem incongruous. All commands should be given in a subdued tone, and the utmost respect and gentlemanly bearing should exist among the band-members.

The smaller Horns, such as E♭ and B♭ Cornets, should be kept in boxes; while the larger ones, such as Altos, Tenors, Baritone, Tuba, etc., should be kept in sacks made of soft flannel. It is well to keep a piece of chamois-skin to wipe each instrument before placing it in its sack or box. Should the valves, in piston-action, refuse to work freely, unscrew the cap, take them out, and wipe them carefully with a soft, dry cloth. Then moisten them slightly and put them back. Spittle, though seemingly vulgar, is the best antidote for a sticky valve. Sometimes it will be necessary to use a little alcohol or kerosene to cleanse them thoroughly. In rotary action, a little alcohol poured in the bell and run through the valves will make them work well. Always keep the slides in order by using a little fine oil several times a year, as the instruments are liable to be blown out of tune, and can be remedied by pulling the slide slightly.

Cornet-players should faithfully and frequently practice all the scales commonly used for the Cornet. It is a great mistake to allow the attention to be given too much, or too soon, to *triple-tonguing*, while simple melodies are neglected. It requires an artist of greater skill and better perception to interpret rightly the less showy class of music than to perform the most difficult strain in triple-tonguing. In the practice of *tonguing*, the syllables *tu, tu, ku*, with C on the staff, should be used. At first this should be done very slowly, while care should be taken to have the *ku* equal in power to the first two syllables. After this is accomplished, other letters on the staff should be used, both above and below C, while at the same time the *tempo* should be increased as much as possible. In the practice of the scales, each note should be commenced as softly as possible, then increased to *ff*, and diminished to *pp*. It is not well to practice immediately after eating. Sleep should be indulged in at regular hours. Total abstinence from stimulants is commendable, as the use of them counteracts the work of hardening the lips.

A want long felt by all bands, for a light and handsome stand that could be carried upon the march, at a serenade, or used in the band-room, has been fully supplied in the "Acme" stand shown in Fig. 1. It might with equal propriety be called the "Sword" stand, having, when not in use, the exact appearance of a handsome sword; and instead of any detraction, materially adds to the appearance of a military band. The drawing shows the stand set up and the extension drawn, ready for use, the dotted lines indicating where the music is placed. The music can be placed at any height from 30 to 60 inches. The holder remains upon the belt when the stand is in use. There are no set-screws to lose, and but one spring in the whole stand, making it simple and very durable. It weighs only 36 ounces, and is entirely nickel-plated, to prevent rusting or tarnishing.

Fig. 2. shows an improved band-lamp, made of brass, hand-spun, and having but one seam. These lamps are three inches deep, burn four hours, use a half-inch round wick with kerosene oil, or, what is better, equal parts of kerosene and lard oil, make a brilliant light, and being balanced in center, keep their equilibrium with the player in any position.

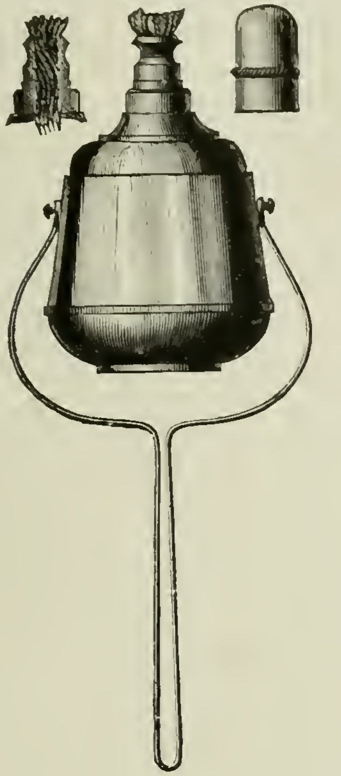

Fig. 2.

Bands will find these a great convenience for night-playing, and much superior to anything else for this purpose. They are readily affixed to the cap, merely taking the place of the pompon or plume, as shown in Fig. 3. The lamp has an improvement, which consists of a tight-fitting tube or cap which, when

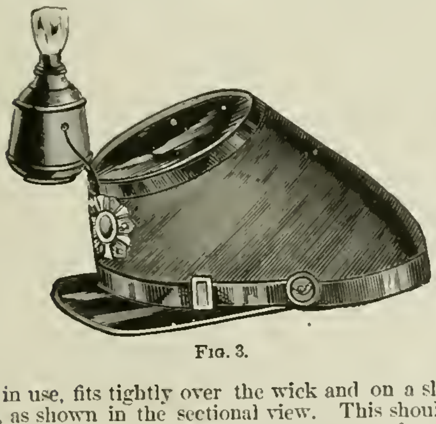

Fig. 3.

not in use, fits tightly over the wick and on a shoulder, as shown in the sectional view. This shoulder, which is made to receive the cap, is set out from the tube slightly, forming a chamber for the oil that escapes from the vent, returning the same back into the lamp. When not in use and the cap on it, it is perfectly air-tight and no oil can escape, which makes them perfectly safe in transporting, while in many lamps no safe provisions are made against the leakage of oil. This lamp is the invention of Messrs. Lyon & Healy, of Chicago, who are the leading importers and manufacturers of band-instruments in the United States, and to whom we are indebted for the many original illustrations of musical instruments throughout the work. See *Drum-major*.

BANDAGES.—Contrivances used by Surgeons, in the field and elsewhere, to apply pressure on a part, or to retain dressings upon wounds. The most common bandage is a strip of linen, calico, or elastic web, from three to five or more inches in breadth, rolled longitudinally; hence the name *roller*. There are also bandages to suit special purposes, as the four-tailed for the head or knee, which consists of a piece of cloth split up on each side towards and nearly to the center. When applied, the tails are crossed and tied so as to make an extemporaneous night-cap. In applying the roller-bandage to a leg, the Surgeon first turns it round the foot, then round the ankle; and so by repeated turns, each one of which should overlap about a third of the previous one, till he reaches the calf of the leg, when he must fold at each turn the bandage sharply back on itself, by which maneuver the bandage will lie flat and smooth on the limb. The operator must remember that the bandage must be applied more tightly at the foot than on the leg, so that it may not impede the course of the blood through the veins. This requires to be practiced, as the effect of a bandage is always for good or evil as it is well or ill applied.

BANDALEER—BANDALIER.—An ancient appendage for facilitating the charging of muskets. It consisted of a broad belt thrown over the left shoulder, serving as a support to the fire-arms, and having suspended from it a dozen boxes (each containing a charge of powder) and a bag for balls. It was both cumbrous and dangerous, and the rattling of the boxes often betrayed the soldier to the enemy.

BANDED-MAIL.—A kind of armor, which consisted of alternate rows of leather or cotton and single chain-mail.

BANDERET.—In military history, *banderet* implies the Commander-in-Chief of the troops of the Canton of Berne, in Switzerland.

BANDEROL.—A small flag used to convey signals from any particular spot to a saluting battery or other post; also, to mark the position to be taken up by the flanks of a regiment at a review in deploying, etc.; also used in marking out a camp. Frequently written *Bandrol* or *Bannerole*.

BANDES.—A common name for bodies of infantry. *Bandes Françaises* was the ancient name of the French infantry; the term, however, became less general, and was confined to the *Prevôt des Bandes*, or the Judge or Provost-marshal that tried the men belonging to the French guards.

BANDIT.—A word originally signifying a "banished" or outlawed person; then one who, because outlawed, wages war against civilized society; and finally a highway-robber. The banditi, or banditti, formed in Italy, in earlier times, as it were a separate community or guild, who submitted to their own stringent laws, carried on both open and secret war with civilized society, and kept up a certain romantic idea of honor. By means of the severe measures which were adopted in 1820 by the Papal Government against the banditti and their abettors, their haunts were broken up. Those who still occasionally disquiet the frontiers of Naples are in general people settled on the spot, who regard robbery and murder as equally a branch of their trade with agriculture. Peter the Calabrian, one of the most famous bandit-chiefs, in 1812 assumed the titles of "Emperor of the Mountains, King of the Woods, and Lord of the Highroads from Florence to Naples." The Government of Ferdinand I. found themselves obliged to conclude treaties with them. The banditti must be distinguished from common robbers, who were called *malviventi*. In later times the banditti were joined by adventurers of all kinds, to such an extent that the Austrian troops who occupied Naples were obliged to make frequent expeditions against them. In Sicily, the banditti are most numerous in the Val Demone. They formerly acquired so much power there that the Prince of Villafranca, as a piece of policy, declared himself their patron, and treated them with much confidence. In the years 1841–43 political fugitives united with robbers and adventurers of all kinds in the Abruzzi, Calabria, and Romagna, and since then they have never been entirely extirpated. The Revolution of 1848–49 added greatly to their numbers, and in several districts of Italy, especially in the States of the Church, between Ferrara and Ancona, they reached an unheard-of degree of boldness, notwithstanding the Austrian army of occupation. Under the command of one Bellino (known by the name of "Il Passatore"), a daring and talented man, who died in 1851, they kept the country in terror, and even burned several villages to the ground. They also carried on a real guerrilla warfare against the military forces of the country. Recent events in Italy have, it is said, recalled numbers of these banditti to a more honorable life. See *Camorra*.

BANDOLEER.—Two centuries ago soldiers' muskets were provided with *matchlocks*, a very slow and ineffective contrivance for firing. The musketeers were furnished with gunpowder in small cylindrical boxes made of wood, tin, or leather, each containing sufficient for one charge. Twelve of these little boxes were fixed to a belt called a *bandoleer*, worn over the left shoulder. See *Bandaleer*.

BAND-SAW MACHINE.—An endless steel belt running over wheels and revolved continuously. It is pliable, so as to conform to the faces of the wheels, and is serrated on one edge. The ends are joined by solder and by neat clamps. Arrangements are made for straining the saw by regulating the relative distances of the wheels; this adjustment also permits the machine to take in saws of different lengths. One advantage of the band-saw over the reciprocating-saw is that there is no lost time in its operation, and no effort required to keep the work to the table, as the action of the saw tends to this result. There is no need of a pump or blower to clear away the sawdust, as it is carried continually downward.

In the English practice the minimum diameter of the band-saw pulley is set at 30 inches; but for wider saws the diameter must be increased. Thus, saws of 2 to 3 inches wide ought not to be worked over pulleys of less than 42 inches in diameter, and for a blade 6 inches wide the pulleys should be 70 to 80 inches.

It will not be uninteresting to give some facts and figures concerning the sawing of lumber by band-saw machinery. A few moments' calculation will serve to convince any one of the great saving in lumber which results from the use of the band instead of the circular saw in working it up. This is quite a consideration, and should be duly appreciated. The scarcity of timber in some parts of our country, and the great value of foreign woods, requires that there should be the least possible loss in its sawing. The saving which results from the use of the band-saw can easily be demonstrated.

If we take a log 30 inches square and 20 feet long, and by calculation cut it up first with a circular saw, then with a band-saw, the result will be found about as follows: The log contains 1500 feet of lumber. Cut with circular saw, $\frac{5}{16}$-inch kerf, into 1-inch boards, we have twenty-three 1-inch boards, 1150 feet; balance kerf, 350 feet—total, 1500 feet. Now cut with band-saw, $\frac{1}{12}$-inch kerf, into 1-inch boards, we have twenty-seven 1-inch boards, 1350 feet; one $\frac{3}{4}$-inch board, 37½ feet; balance kerf, 112½ feet—total, 1500 feet.

It will be noticed that with the circular saw 23 per cent of the log is kerf, and that with the band-saw only 7 per cent. That is, by using the band-saw we have saved 237½ feet of lumber. See *Bevel Band-saw Machine*, *Circular Saw*, *Re-sawing Band-saw Machine*, and *Swing-saw*.

BANISHMENT.—Excepting in the penal sense of transportation, with which it is popularly synonymous, can only now be said to have a legal meaning historically. Formerly, in England, parties who were required to *abjure the realm*—that is, renounce and depart from the country—were, so to speak, *banished;* but the word appears to have a more technical and precise significance in the Scotch law than in the English, and in Scotch law-books is defined as the punishment of exile from Scotland inflicted on persons convicted of certain offenses for which that punishment is provided. But, as a punishment it has either been abolished in that country by express enactment or become obsolete by disuse.

BANNER.—A piece of cloth attached to a pole and usually bearing some warlike or heraldic device or national emblem. In this sense banner is a generic term, including many species, such as standard, ensign, pennon, flag, etc. Banners have been used from the earliest times and in all countries for the purpose of directing the movements of troops. We read of them constantly in the Old Testament, as in Numbers ii. 2: "Every man of the children of Israel shall camp by his standard, and under the ensign of his father's house." The earliest Roman standard was a bundle of straw fixed to the top of a spear. This was succeeded by figures of animals—the horse, the boar, etc.—all of which soon gave place to the eagle, which continued all along to be the chief Roman ensign, and was afterwards assumed by the German and latterly by the French emperors of the Napoleonic dynasty. In addition to the eagle each Roman cohort had a banner, generally a serpent or dragon woven on a square piece of cloth. The standard of the cavalry was a square piece of cloth expanded on a cross, and it was to this that the term *vexillum* properly applied. Examples of these standards are sculptured on the Arch of Constantine at Rome. The top of the staff was also frequently adorned with a figure of Mars or of Victory, and in later times with the head of the reigning Emperor. After Constantine embraced Christianity, the cross was substituted for the head of the Emperor on the purple banner of Byzantium. Standards were less in use amongst the Greeks than has been usual with warlike nations; but a standard, and sometimes a scarlet flag, was employed as a signal for giving battle. On the rise of chivalry in the Middle Ages, the ordering of banners, like every other branch of military organization, attained to something like scientific exactitude. From the banner-royal, which bore the national emblems, to the small streamer attached to the lance, with its cross or stripes, there was a regular subordination, each emblem having its place and its meaning. The pennon of the simple knight differed from the square banner of the banneret, it being pointed at the ends. In addition to their varieties in size, shape, and color, these banners were distinguished by the emblems which they bore. One of the earliest is the Danish raven, depicted on the standard taken by Alfred, of which Asser mentions the tradition that "in every battle, wherever that flag went before them, if they (the Danes) were to gain a victory, a live crow would appear flying on the middle of the flag; but if they were doomed to be defeated, it would hang down motionless." Nor did the privilege of carrying banners belong to princes and knights alone; bishops and abbots displayed similar ensigns, which were carried before them in religious processions and under which their retainers fought in their defense. It was to these that the term "gonfalon," a word as to the origin of which much diversity of opinion exists, was more commonly applied. In place of the heraldic emblems of the knight, the banner of the Church and of towns and communes usually bore the effigies of saints. Some banners, however, displayed no ensigns whatever and were known simply by their color. Of this the *oriflamme*, or plain ruddy flag of St. Denis, was a famous example. The celebrated Bayeux tapestry throws considerable light on banners, as well as on other matters connected with the warlike arrangements of the Middle Ages. By every warlike people the banner has been regarded as the emblem of national honor, as a palladium for the defense of which the individual warrior was at all times ready to sacrifice his life. From the converse of this feeling, banners and flags taken from the enemy have always been regarded as special trophies of victory, and places of honor in churches and public buildings have consequently been assigned them. See *Colors*, *Flags*, and *Standard*.

BANNERET.—A higher grade of knighthood conferred by the Sovereign for some heroic act performed in the field, and so called because the pennon of the knight was then exchanged for the banner—a proceeding which was effected by the very simple means of rending the points from the pennon. The first Banneret in England is said by Froissart to have been made by King Edward I., and the last time the honor was conferred was by Charles I. after the battle of Edgehill, the recipient being an individual who rejoiced in the familiar name of John Smith. The ceremony of the creation of a Knight-banneret must have been very impressive to persons filled with the ideas which were prevalent in the Ages of Chivalry. The King or his General, at the head of his army, drawn up in order of battle after a victory under the royal banner displayed, attended by all the Officers and Nobility of the Court, received the Banneret-elect, who was not necessarily a knight previously, led between two knights of note or other men famous in arms, carrying his pennon in his hand, the heralds walking before him and proclaiming his valiant achievements, for which he deserved to be made a Knight-banneret, and to display his banner in the field. The King, or General, then said to him, "Advance, Banneret!" (*advances toy bannerel*), and caused the point of his pennon to be torn off. The new knight, with the trumpeters sounding before him and the Nobility and Officers bearing him company, was sent back to his tent, where a noble entertainment was provided by the King. Some attempts have been made to revive the title in recent times, as when George III., at a review of the navy at Portsmouth in 1773, conferred it on Admiral Pye and several other officers.

BANQUETTE.—In fortification, a device by which the men are able to deliver their fire over the parapet. It is made just high enough above the terre-plein to allow men of medium stature to fire over the interior crest. The distance of the tread below the crest is taken, for this purpose, at four feet and six inches; sometimes it is taken three inches less, or four feet and a quarter. The width of the tread depends upon the number of ranks expected to occupy it. In the days of smooth-bores and muzzle-loading muskets it was made wide enough for two ranks. It is rarely occupied, at the present time, by more than one rank. A width of two feet is sufficient for one rank, although it is usually made *three* feet wide in ordinary field-fortifications. The tread is made with a slope to the rear, to allow the water falling on it to drain off. It is connected with the terre-plein either by a slope or by steps. The inclination of the former is usually $\frac{1}{2}$; it may be greater if the banquette is low. When steps are used, the tread of each step should not be less than twelve nor more than eighteen inches; the rise should not be less than nine nor more than twelve inches. Steps are generally used whenever it is a matter of importance to gain space. All other things being equal, the ramp or inclined slope is preferred to steps. See *Field-fortification*.

BANQUETTE SLOPE.—In fortification, a slope of earth or timber placed in rear of the banquette when the top cannot be reached by an ordinary step.

BAPTISM OF BLOOD.—The act of being baptized with blood, and used specially with reference to soldiers who fought on their first battle-field. In the old French service, the *baptism of blood* equalized all grades; and military services, not rank, were the recognized claims for promotion.

BAPTISM OF FIRE.—A figurative term applied to soldiers who have passed through their first fire in battle.

BAR.—1. In Heraldry, one of those more important figures or charges which are known as *ordinaries*. By heralds, the ordinaries, or as, by way of eminence,

they are called, the "honorable ordinaries," are commonly reckoned as ten in number, the subordinaries, or minor charges, being greatly more numerous. The bar, like the fess, is formed by two horizontal lines passing over the shield, but it differs from it in size, the fess occupying a third, the bar only a fifth part, of the shield. There is this further difference between these two ordinaries, that the fess is confined to the center, while the bar may be borne in several parts of the shield. There is a diminutive of the bar, called the closet, which is half a bar; and again of the closet, called the barrulet, which is half a closet, or the fourth part of a bar.—BAR-GEMEL is a double bar, from the French terms *jumeau*, *jumelle*, a twin. Also written *barr*.

2. An elongated piece of wood, metal, or other solid substance. In the iron-manufacture, bar is a rod, either round or square shafted. The round ones are made by drawing the iron red-hot through a bore or hole in a plate, and the square ones by passing it likewise red-hot through a roller-mill between two rollers counter-grooved, with their triangular-grooved faces forming the square opening for the passage of the iron. Railway and knee iron is made in the same manner. Bars have various denominations in the construction of artillery-carriages, etc., as sweep-bars and cross-bars for tumbrils; fore, hind, and under cross-bars for powder-carts; shaft-bars for wagons; and dowel-bars, used in mortar-beds.

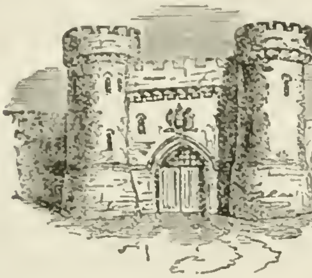
3. In hydrography, a bar is a bank opposite the mouth of a river, which obstructs or *bars* the entrance of vessels. The bar is formed where the rush of the stream is arrested by the water of the sea, as the mud and sand suspended in the river-water are thus allowed to be deposited. It is thus that deltas are formed at the mouths of rivers. The navigation of many streams (as the Danube) is kept open only by constant dredging or other artificial means.

4. In law, the word has several meanings; thus, it is the term used to signify an inclosure or fixed place in a Court of Justice where lawyers may plead, or, perhaps more correctly, where they can address their advocacy on behalf of their clients. A veiled-off space within the Houses of Parliament is similarly called the bar. The dock, or inclosed space where persons accused of felonies and other offenses stand or sit during their trial, is also called the bar; hence the expression "prisoner at the bar." This word has also a general meaning in legal procedure, signifying something by way of stoppage or prevention. There is also a *trial at bar;* that is, a trial before the judges of a particular court, who sit together for that purpose *in banc*.

BARB.—1. The reflected points of the head of an arrow; also, the armor for horses.

2. The designation of a noble breed of horses cultivated by the Moors of Barbary, and introduced by them into Spain. Barbs are less remarkable for their beauty and symmetry than for their speed, endurance, abstinence, and gentle temper.

BARBACAN—BARBICAN.—A projecting watch-tower, or other advanced-work, before the gate of a castle or fortified town. The term barbacan was more specially applied to the outwork intended to defend the drawbridge, which in modern fortifications is called the *tête du pont.* "To begin from without, the first member of an ancient castle was



Barbacan.

the barbacan, a watch-tower for the purpose of descrying an enemy at a greater distance" (Grose's *Antiquities of England and Wales*); and, to the same effect, Camden, speaking of Bedford Castle, says it was taken by four assaults: in the first was taken the barbacan; in the second, the *outer* balia. (See also Parker's *Glossary of Architecture.*) There are a few perfect barbacans remaining in England, as at Alnwick and Warwick; but the best examples of it, as of the other parts of the fortification of the Middle Ages, are probably to be seen in the town of Carcassone. A very curious and minute account of the siege of Carcassone in 1240, in the form of a report to Queen Blanche by the Seneschal who defended it, preserved in the archives of France, has been published in Hewitt's *Ancient Armor*, in which the uses of the barbacan are fully illustrated. The street called Barbican in London, near Aldersgate Street, marks the site of such a work, in front of one of the gates of the old city.

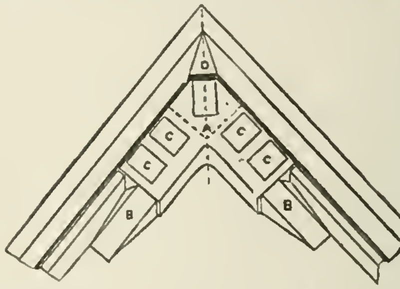
BARBED AND CRESTED.—An heraldic term by which the comb and gills of a cock are designated, when it is necessary to particularize them as being of a different tincture from the body. The common English term is *wattled and combed*, gules, or whatever else the tincture may be.

BARBETS.—Peasants of Piedmont who abandoned their dwellings when an enemy had taken possession of them. They formed into bodies and defended the Alps.

BARBETTE.—The barbette is a construction by means of which a piece can fire over a parapet. It consists of a mound of earth thrown up against the interior slope; the upper surface of which is level, and two feet nine inches below the interior crest for guns of small caliber, and four feet for heavy guns. If the barbette is raised behind a face, its length should be sufficient to allow sixteen and a half to eighteen feet along the interior crest for each gun; and its *depth*, or the perpendicular distance from the foot of the interior slope to the rear, should be twenty-four feet, for the service of the guns. The earth of the barbette at the rear and sides receives the natural slope. To ascend the barbette, a construction termed a *ramp* is made; this is an inclined plane of earth, which connects the top of the barbette with the terre-plein. The ramp is ten feet wide at top, and its slope is six base to one perpendicular. The earth at the sides receives the natural slope. The ramp should be at some convenient point in the rear, and take up as little room as possible.

As barbettes are usually placed in the salients, an arrangement is made for the guns to fire in the direction of the capital. A pan-coupée of eleven feet is first made; from the foot of the interior slope at the pan-coupée, a distance of twenty-four feet is set off along the capital; at the extremity of this line a perpendicular is drawn to the capital; and five feet are set off on this perpendicular on each side of the capital; from each of these points, on the perpendicular, a line is drawn perpendicular to each face respectively; the hexagonal figure thus laid out is the surface of the barbette for one gun. The ramp in this case is made along the capital.

If three or more guns are placed in the salient, a pan-coupée is formed as in the last case; and twenty-four feet are in like manner set off on the capital; but instead of proceeding as in the last case,



Barbette, with Pan-coupée.

a perpendicular is drawn from this point to each face, as shown in the drawing, and the pentagonal space thus inclosed will be taken for the gun in the salient; from the perpendiculars last set off as many times sixteen and a half feet will be set off, on the interior crest of each face, as there are guns required: this will give the length of the barbette along each face; the depth will be made twenty-four feet, and the two will be united in the salient. One or more ramps may be made as most convenient.

To give temporary cover to guns on a field of battle and enable them to command a wide field of fire, a parapet of just sufficient height to allow the guns to fire over it may be thrown up for the purpose, the earth being taken from a ditch in front. The ground may be roughly leveled off far enough to the rear for the maneuver of the guns. Between each gun a shallow trench may be dug parallel to the wheels, where the gunners can find shelter when not serving their pieces.

The advantages of the barbette consist in the commanding position given to the guns, and in a very wide field of fire; on these accounts the salients are the best positions for them. Their defects are that they expose the guns and men to the enemy's artillery and sharp-shooters. Light guns, particularly howitzers, are the best for arming barbettes, because the hollow projectile of the latter is very formidable both to the enemy's columns and to his cavalry, and when his batteries are opened against the salients the light pieces can be readily withdrawn.

BARBETTE CARRIAGE.—A carriage of the stationary class, on which a gun is mounted to fire over a parapet. A barbette gun is any gun mounted on a barbette carriage.

BARBETTE FIRE.—Barbette fire can only be obtained by some arrangement which raises the gun into a position from which it can be fired over the parapet. There are two methods by which this can be done: *one*, by mounting the gun on a high carriage, or on a carriage which admits of the gun being raised to the necessary position; *the other*, by building a mound of earth sufficiently high behind the parapet, and placing the gun on this mound. The latter is the method generally employed in field-works. The artillery used in the defense of field-works may be either siege or field guns; but most generally the latter are employed. The upper surface of the platform on which the wheels rest, or the upper surface of the barbette when no platform is used, should be at a distance below the interior crest just sufficient to allow the gun to fire over the interior crest and parallel to the superior slope. A distance greater than this would interfere with the efficiency of the gun; a distance less would unnecessarily expose the gun and carriage to the enemy's fire. The axis of the trunnions of a field-gun, in the United States service, is about forty-three inches above the ground on which the wheels rest. The diameter of the piece at the muzzle and the inclination of the superior slope being given, it is easy to determine what should be the distance of the upper surface of the barbette below the interior crest. The general rule used is to take this distance at two feet and nine inches for field-guns, and four feet for siege-guns, when mounted upon the ordinary carriages.

BARBOLE.—A heavy battle-axe used in ancient times; now obsolete.

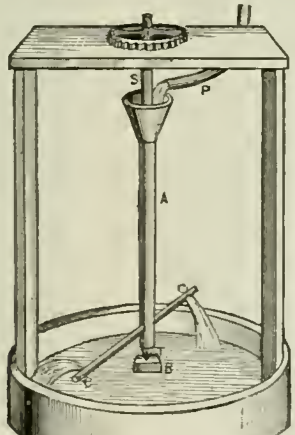
BARCE.—A small gun, shorter and thicker than a falconet, which was formerly used on board ship. Also written *Berche*.

BARDINGS.—Such parts of horse-armor as protect the animal's head, neck, and rump: the *champ-front*, the *manifaire*, the *poitrel*, and the *croupier*. Also written *Bard*.

BARIL ARDENT.—A barrel filled with layers of tarred chips intermixed with powder, and primed at each end with a shell-fuse. It was formerly used for illuminating purposes, and had holes bored in it for the purpose of admitting air to the burning contents.

BARIL FOUDROYANT.—A contrivance of the same nature as the *baril ardent*, with the addition of grenades placed between the layers of chips. These were used at the defense of a breech, by rolling them upon the assailants. Also written *Baril d'artifice*.

BARKER'S MILL.—A water-wheel invented by Dr. Barker towards the end of the seventeenth century. It is represented in its simplest or typical form in the drawing. A is a wide metal pipe, resting at



its lower end, by the steel spindle T, on a metal block B, and kept in a vertical position by the spindle S at its upper end, which passes through the frame of the machine, so that it can easily revolve round its axis. Near its lower end two smaller pipes or arms, C, C, are inserted, which project horizontally from it, and these have each, at the outer extremity, a hole cut vertically in them, opening towards opposite sides. The water is supplied by the pipe P, which opens over a funnel-like widening on the upper part of A, and the quantity is so regulated that while the pipe A is kept nearly full, no more is admitted than issues from the lower orifices. The reaction caused by the water gushing from the arms forces them backwards, and gives to the whole machine a rotary motion. This reaction is much the same as is seen in the recoil of a gun when fired, or in the pushing back of a small boat by the foot on stepping ashore. It may be also thus explained: Suppose that the arms were closed all round, the water would press against the sides with a force proportional to the height of the water in the pipe A, and the pressure against any particular surface of the side would produce no motion of the arm, because an equal pressure is exerted in a contrary direction by a corresponding surface opposite to it. Now, if one of these surfaces be cut out, the pressure against the other, being uncounteracted, forces the arm in the opposite direction to that of the side in which the hole is made. This being done to both arms on opposite sides, two equal pressures are produced, which conspire in generating the same motion of rotation. As soon as motion ensues, centrifugal force comes into play, which, throwing the water out towards the ends of the arms, increases the rapidity of its discharge, and also its reacting power. When the wheel is in action, the water thus acts under the influence of two forces—one being the pressure of the column in A, and the other the centrifugal force generated by the rotation of the wheel itself. The motion of the wheel is transmitted, by the spur-wheel fixed to the spindle S, to the machinery which is to be driven by it.

The power is manifestly increased by heightening the water-column, or by lengthening the arms—the former increasing the pressure of the water, and the latter increasing the leverage at which this pressure acts. In the mill shown in the figure, the column in A cannot be advantageously heightened, for the higher it rises the greater must be the weight which the conical spindle, T, has to sustain, and the greater, consequently, becomes the friction. It is from this circumstance that such mills are found, in practice, to yield but a small mechanical effect—the friction consuming too large a proportion of the work of the wheel. Hence, in the reaction-wheels now in use, the original Barker's mill has been so modified as to allow of the water being conducted from the reservoir below the arms instead of above. This is effected by making the vertical pipe revolve below in a stuffing-box at its junction with the conduit, and above by a pivot moving in the fixed frame. By this arrangement the friction attending the rotation is reduced to a minimum, for not only is the weight of the water placed out of account, but also a large proportion of the weight of the wheel itself, which is borne by the upward pressure of the water. The mechanical performance of such wheels is said to be highly satisfactory, producing, with a limited supply of water falling from a considerable height, a useful effect hardly to be obtained by any other contrivance. The power of these machines may be also increased by using curved instead of straight arms. With straight arms a considerable loss of force is incurred by the sudden change of the direction of the current when it leaves the arm, which does not take place to the same extent with curved arms, where this change is effected gradually. In Whitelaw's mill (hence called the Scottish turbine), the form of Barker's mill generally met with in Scotland, there are three instead of two curved arms of this description. Considerable difference of opinion still exists as to the merits of Barker's mill, some considering it as the most perfect way of applying water-power, and others putting it in the same rank as an undershot-wheel, with the same water-supply. Of late years it has been more extensively employed than formerly.

BARNACLES.—1. In Heraldry, barnacles resembled what are now called twitchers, instruments used by farriers to curb and command unruly horses. Barnacles are frequently introduced into coats of arms as a charge.—2. A noose attached to a stock or handle, and nipped around the upper lip of a horse. It is twisted so as to be somewhat painful, in order to give the command of the head to the person holding the same. It enables a trooper to hold the horse's head aloft to keep him from biting, occupy his attention, and measurably prevent his kicking.

BARNEKOV-GREENE GUN.—A breech-loading rifle having a fixed chamber closed by a movable breech-block, which slides in the line of the barrel by indirect action, being moved by levers from above. Its distinguishing characteristic is a short sliding block, back of which is a pair of links, secured at their forward end to the block, and in rear to the frame. The rearmost one of them contains the hammer, in cocking which the combination is bent upward and so withdraws the block. The cartridge-shells, when extracted, drop through a hole left for the purpose in the frame.

BAROMETER.—If a straight tube 32 or 33 inches long and closed at one end is filled with mercury and, the open end being stopped with the finger, immersed in a vessel filled with the same substance and the finger removed, the fluid will stand at about 30 inches above the level of the mercury in the vessel. The column of mercury in the tube is supported by the pressure of the atmosphere upon the surface of the mercury in the cup, and it is therefore assumed that the weight of a column of mercury of uniform diameter, 30 inches high, is equal to the weight of a column of air of the same base, extending to the top of the atmosphere. This is the barometer invented by Torricelli in 1643 and still used in essentially its original form. As every fluctuation of atmospheric pressure is faithfully shown by the varying height of the fluid in the Torricellian tube, the instrument is, as its name implies, a measure of the weight of the atmosphere. The barometer as usually made consists of a glass tube about 34 inches long, closed at one end, filled with mercury, and placed in a vertical position with the open end immersed in the mercury, contained in a cup called a cistern. A scale of inches and tenths, placed at the top of the column, enables the height of the mercury to be read, and in the higher grade barometers a vernier facilitates the reading of the scale to hundredths. A thermometer is usually attached, so placed that its temperature shall be the same as that of the barometer column, by which the correction for temperature may be accurately made. The tube should not be too small; to allow freedom of motion to the column it should have an internal diameter of from one-third to one-half inch. The mercury must be absolutely pure, freed from moisture, and of the specific gravity of 13.594. Extreme care is necessary in excluding from the tube both air and moisture, the pressure of which filling the tube above the mercury and exerting a pressure upon the upper surface of the column, would depress it below the proper height. The tube should be absolutely clean, and the mercury should be filtered, and both should be heated in order to expel moisture. A small portion of mercury being carefully introduced into the tube, it is held over a charcoal-fire until the mercury boils, the tube being held in an inclined position so that any air-bells may readily escape. More mercury is added and the process of boiling repeated until the tube is filled. When a barometer-tube has been carefully filled and properly freed from air and moisture, the mercury will, when the tube is reversed, strike the top of the tube with a sharp metallic sound. The barometer tubes are usually attached to wood frames, of which there is an infinite variety in design and cost, but in standard barometers for strictly scientific purposes a cylindrical brass frame is used, the index of expansion of that metal being more nearly the same as that of glass. As now arranged, with adjusting screw below the cistern, the mercury can be forced up into the tube and the barometer rendered perfectly portable. It has been stated that the height of the column above the level of the mercury in the cistern indicates the weight of the atmosphere. It is obvious, however, that the level of the mercury in the cistern must vary with the amount of mercury which the varying atmospheric pressure causes to enter or leave the tube. To compensate for this difference of level of the mercury in the cistern, various forms of barometer have been devised, the principal of which are that on Fortin's principle, the Kew barometer, and the siphon, or Gay-Lussac, barometer. In Fortin's barometer, Fig. 1, a straight tube enters a cistern, the upper part of which is glass, while the lower part is of flexible leather under which is a lifting-screw. The lower extremity of a small ivory point, pointing downwards, denotes the zero-point of the scale, which is in true inches. At every observation the surface of the mercury in the cistern is exactly adjusted by the lifting-

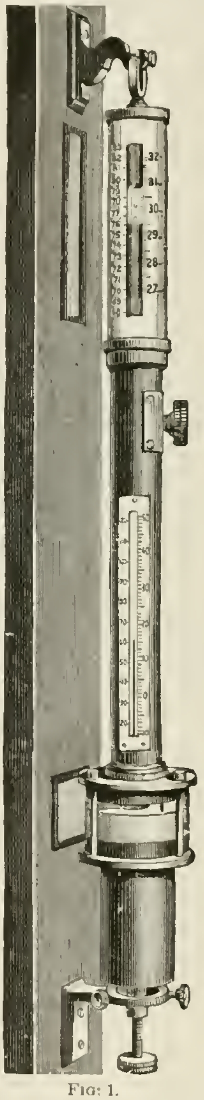


Fig. 1.

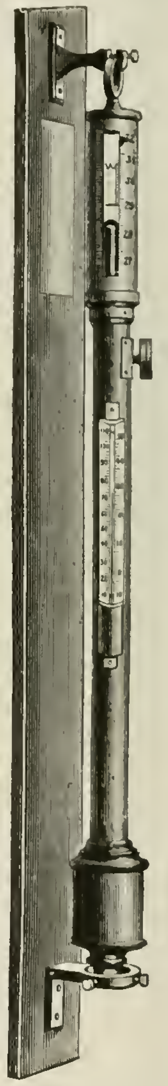

Fig. 2.

screw to the level of the ivory point. This lifting-screw and flexible cistern bottom serve the purpose, also, of making the barometer portable by confining the mercury in the tube and preventing that pumping of the fluid which in transit is apt to endanger the instrument. The Fortin barometer can only get out of order by the admission of air or moisture, and it is not affected by changes in the material of the cistern or of the fluid itself. It is therefore well adapted for scientific purposes, and the higher grade of standard barometers are usually made on this principle. The Kew barometer, Fig. 2, was originally recommended to the Government by the Kew Committee of the British Association, as a form of barometer well adapted for marine observations, and was adopted by the British Government for that purpose. It has been found equally well suited to land and marine service, and is in extensive use in meteorological stations. In this form of barometer the cistern is closed and is composed of iron or wood. Cisterns of wood are sufficiently pervious to permit of the mercury being affected by the variations of atmospheric pressure. Those made of iron have a small aperture at the top, which is closed by a piece of leather. Sufficient mercury is contained in the cistern to cover the end of the tube in whatever position the instrument may be placed. To compensate for variations in the level of the mercury in the cistern the scale is shortened from above downward in proportion to the relative size of the diameter of the tube and of the cistern. For use at sea the tube of this barometer is contracted to prevent oscillation during the heaviest storms. In the siphon barometer the open end of the tube is bent upward in the shape of a siphon, the short limb being from six to eight inches long. The pressure of the atmosphere upon the surface of the mercury in the short limb sustains the column of mercury in the long limb, the fluid in the short limb falling with its rise in the tube and rising with its fall. The upper part of the tube is made of equal diameter with that of the lower limb, so that the distance between the upper and lower levels of the mercury is always the height of the barometric column. A scale of inches, starting from a zero-point, taken near the bend of the tube, with verniers fitted to each limb, gives the means of measuring the long and short columns. The difference of the two readings is the height of the barometer. By another method the zero-point is taken at some intermediate position, and the distances of the mercury-levels upward and downward from this measured, their sum being the height of the barometer. With this barometer no correction for capillarity is required, the capillary action of the glass being considered the same at each of the mercury surfaces. The barometer-scale being divided into inches and tenths, the vernier enables us to subdivide the tenths to hundredths and thousandths of an inch. Fig. 3 shows the scale of a standard barometer divided into half-tenths, or .05, of an inch, as A B. The vernier D is made equal in length to twenty-four of these divisions, and is divided into twenty-five equal parts; one space on the scale is larger, therefore, than one on the vernier by the one twenty-fifth part of .05, which is .002 inch, so that the vernier shows differences of .002. The vernier reading upwards, the lower edge, D, indicates the top of the mercurial column and is the zero of the vernier-scale. In the drawing, the zero being exactly in line with $29\frac{5}{10}$ inches of the fixed scale, the barometer reading would be 29.500 inches. The figures 1, 2, 3, 4, and 5 on the vernier measure hundredths, and the intermediate lines thousandths, of an inch. In Fig. 3 the zero of the vernier is between 29.65 and 29.70 on the scale. Looking up the vernier and scale, the second line above 3 is perceived to lie evenly with a line of the scale. This gives .03 and .004 to add to 29.65, so that the actual reading is 29.684 inches. For the ordinary purposes of the barometer such minute measurement is not required. In household and marine barometers the scale is only divided to tenths and the vernier constructed to measure hundredths of an inch. This is accomplished by making the vernier either nine or eleven tenths of an inch long and dividing it into ten equal parts. To take a reading, place a piece of white paper behind the tube to reflect the light and aid in setting the vernier accurately. Adjust the surface of the mercury in the cistern carefully to the ivory point or zero of the scale. To determine the contact it will be found best to slightly immerse the point in the mercury first and then slowly lower the screw until the depression caused by this immersion disappears. Tap the barometer with the hand to free the mercury from the sides of the tube. Sufficient force should be used to agitate the top of the column. Bring the lower edge of the vernier exactly on a level with the top of the mercurial column. When set properly, the front edge of the vernier, the top of the mercury, and the back edge of the vernier should be in the line of sight, which line will thus just touch the middle and uppermost point of the column. Care must be taken to read with the eye exactly on a level with the top of the mercury. The inches and tenths may then be read from the scale, and the hundredths and thousandths from the vernier. A reading of the attached thermometer should also be taken. All readings of the barometer are subject to corrections, in order to eliminate various sources of error and to harmonize the indications of different instruments, so that the observations can be used for scientific purposes. These corrections are for index error, capacity, capillarity, temperature, altitude above sea-level. It is necessary to find the index error of each instrument by comparison with a standard instrument whose constant of error is known. This being determined, is a fixed quantity to be added or subtracted from each observation. In all barometers on the Fortin principle, the correction for capacity is made by the lifting-screw. The Kew barometer requires no capacity correction. The siphon barometer requires no correction for capillarity. All barometers require to be corrected for temperature and altitude. The capillary action of glass and mercury cause a depression of the mercury by a quantity very nearly in inverse proportion to the diameter of the tube. The following table gives the corrections to be applied to tubes from 0.6 to 0.10 diameter, with boiled mercury:

FIG. 3.

Diameter of Tube.	Correction.	Diameter of Tube.	Correction.
0.60 inch....	0.002 inch	0.30 inch....	0.014 inch
0.50 do.	0.003 do.	0.25 do.	0.020 do.
0.45 do.	0.005 do.	0.20 do.	0.029 do.
0.40 do.	0.007 do.	0.15 do.	0.044 do.
0.35 do.	0.010 do.	0.10 do.	0.070 do.

As mercury expands $\frac{1}{55}$ of its volume between the freezing and boiling points of the Fahrenheit thermometer, it is necessary that all observations should be reduced to a uniform temperature, and for this purpose the barometer is always accompanied by a thermometer, which should be observed at each time that an observation is taken of the barometer itself. It is universally agreed that the temperature to which all barometrical observations shall be reduced is 32° Fahr. For every degree of the thermometer, above 32° Fahr., we must subtract the ten-thousandth part of the observed height. If the temperature be below 32 this correction must be added. At sea-level, in latitude 45°, and at a temperature of 32° Fahr., the normal height of the mercurial column is about 29.922. As the pressure of the atmosphere diminishes as we ascend, it is evident that the length of the mercurial column will be less in proportion to the altitude of its station. In order that observations may be intercomparable, they are reduced to the level of the sea. The correction to be applied is for the height of the column of air extending from the sea-level to that of the station. But as the weight of the column of air varies with its temperature, it is necessary to take this into consideration. Tables have been computed, giving corrections for every degree from 20° to 100°, and from sea-level to 1500 or more feet. The formulary still often found engraved upon barometer-scales—

At 31 inches	....	Very dry,
30.5 do.	....	Settled fair,
30 do.	....	Fair,
29.5 do.	....	Changeable,
29 do.	....	Rain,
28.5 do.	....	Much rain,
28 do.	....	Stormy

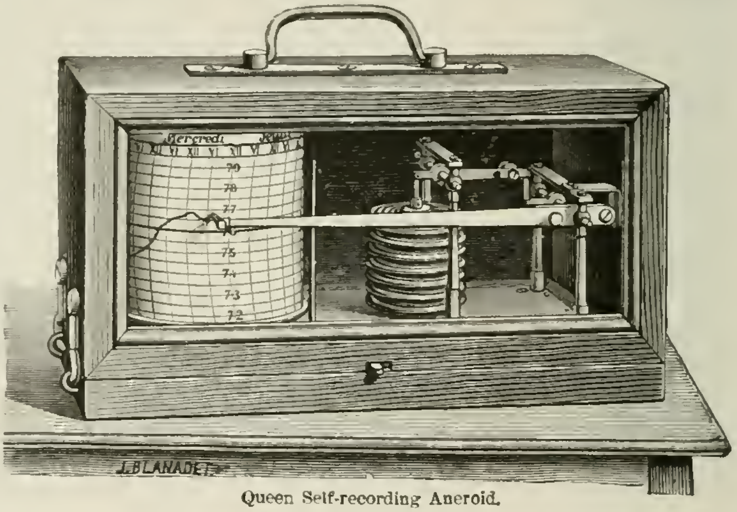
—has tended to discredit the barometer as an instrument for foretelling changes of weather. These words are useless and incorrect. The mere height of the barometer is no indication of the weather to be expected. The point to be observed is whether the barometer has risen or fallen or remained steady since the previous observation. The late Admiral Fitzroy proposed the following words for barometer-scales, which have been very generally adopted:

RISE.	FALL.
FOR	FOR
NORTH	SOUTH
N. W.-N.-E.	S. E.-S.-W.
DRY	WET
OR	OR
LESS WIND.	MORE WIND.
EXCEPT	EXCEPT
WET FROM NORTH.	WET FROM NORTH.

Generally, it may be said that when the barometer rises, owing to a change of wind, the weather gets colder, and if it remains high (above 30) the weather will probably be fair. If the barometer falls, owing to a change of wind, and remains steady at about 29.5, the weather will be warmer and wet and cloudy. A gradual rise is an indication of continued fair weather, whilst a gradual fall indicates that prolonged bad weather is to be expected. Either a very sudden rise or a sudden fall are dangerous, as they indicate a disturbance of atmospheric conditions and consequent unsettled weather. In forecasting the weather it is important that the state of the thermometer and hygrometer be observed as well as the height of the barometer, and that the direction of the wind and the time of the year be considered. Reasoning from all these factors, it is undoubtedly possible to foretell local changes with great accuracy. The best barometers in the United States are made by Messrs. James W. Queen & Co., Philadelphia.

The uses of the barometer are physical, hypsometrical, and meteorological. It is of essential use in all physical researches where the mechanical, optical, acoustical, and chemical properties of air or other gases are dependent on the pressure of the atmosphere. Its use in hypsometry, or the art of measuring the heights of mountains, is very valuable. When a barometer is at the foot of a mountain, the pressure it sustains is greater than that which it experiences at the top by the weight of the column of air intervening between the top and bottom. A formula of considerable complexity is given by mathematicians for finding very nearly the true height of a mountain from barometrical and thermometrical observations made at its base and summit, the interpretation of which does not come within the compass of this work. The following rules give very nearly the same result: 1. Reduce the mercurial heights at both stations to 32 Fahr. 2. Take the logarithms of the corrected heights, subtract them, and multiply the result by 10,000, to give the approximate height in fathoms of the upper above the lower station. 3. Take the mean of the temperature at both stations, take the difference between this mean and 32, multiply the difference by the approximate height, and divide the product by 435. This last result is to be added to the approximate height if the mean temperature is above 32, and subtracted if below, to find the true height in fathoms. See *Aneroid Barometer*.

BAROMETROGRAPH.—An instrument by which the variations of atmospheric pressure are automatically recorded on a sheet of paper. The drawing represents the Queen Self-recording Aneroid, which is remarkable for the simplicity of its construction and the accuracy of its work. It consists of an aneroid barometer, composed of a series of vacuum boxes, the movements of which are transmitted through a simple mechanism to a long lever, terminating in a metallic pen which touches a drum within which is an eight-day clock. This drum, around which is wound the record-blank, makes one revolution in seven days, so that each diagram forms a complete barometric record for the week. After winding the clock and setting the barometer, the instrument requires no attention whatever until the weekly record is finished. The pen retains enough ink to last for several weeks. The following are important advantages of this instrument: the unvarying accuracy and precision of the indications



Queen Self-recording Aneroid.

resulting from the parts specially employed; the absence of anything fragile in the apparatus, in consequence of which it is not liable to become deranged; the facility with which the instrument is set in operation, and the ease with which the record-papers can be changed; the regularity of the curves on the diagrams obtained, resulting from the special metal pen employed, which retains sufficient indelible ink to last for a month if necessary; the small size and weight of the instrument, rendering it most convenient for transportation. See *Aneroid Barometer* and *Barometer*.

BARON.—This term, as to the origin of which much difference of opinion exists, is probably derived from the Latin word *baro* (allied to *vir*, a man, a hero), which originally signified a stupid, brutal man, afterwards came to signify a man simply, and latterly, by one of those strange transmutations which are not uncommon in language, a man pre-eminently, or a person of distinction. Teutonic, Celtic, and even Hebrew derivations have also been assigned to the word; but the fact of its having been introduced into England by the Normans seems in favor of a Romanic origin. It is now the title which is applied to the lowest degree of hereditary nobility. The degree of baron forms a species of landing-place, corresponding amongst noblemen, in a certain sense, to that of gentleman, at a lower stage of the social pyramid. It was in this sense that the word was used in former times to include the whole nobility of England, because all noblemen were barons, whatever might be the higher ranks in the peerage which they occupied. The word Peer has recently come to be used with the same signification, perhaps because it is no longer necessarily the case that every nobleman should be a baron, there being instances in which earldoms and other honors have been given without a barony being attached to them, and in which the barony has been separated from the higher degree by following a different order of descent. The general theory of the Constitution, however, still is, that it is as barons that all the peers sit in the Upper House; and it is on this ground that the archbishops and bishops are said to sit in virtue of their baronies. The distinction into *greater* and *lesser* barons seems from an early period to have obtained in most of the countries of Europe. The greater barons, who were the king's chief tenants, held their lands directly, or *in capite* as it was called, of the Crown; whilst the lesser held of the greater by the tenure of military service.

BARON AND FEMME.—In Heraldry, the expression used to designate the bearing by which the arms of husband and wife are carried per pale or marshaled side by side on the same shield. The husband's arms are always carried on the dexter side. Where the wife is an heiress—i.e., the representative of her father's house—her husband carries her arms, not *per pale*, but in a shield of pretense; and they are quartered with the paternal coat by the issue of the marriage.

BAROTS.—In the construction of wire guns, barots are small hardened steel pieces placed at the termini of the wire layers, in recesses in the flanges of the steel core or body (between which the layers are placed). These barots are slotted across, the slot being of a less width (at the middle) than the diameter of the wire (which is driven into it with a hammer), so as to leave about two thirds of the strength of the wire as a bind. As the tension is about one third of the ultimate strength, sufficient tensile strength is left to securely withstand the pull of the tensed wire. See *Wire Guns*.

BARRACK-ALLOWANCE.—In the British Army, a specific allowance of bread, beef, wood, coal, etc., to regiments stationed in barracks.

BARRACK-GUARD.—When a regiment is in barracks, the principal guard is called the Barrack-guard, the Officer being responsible for the regularity of the men in barracks, and for all prisoners duly committed to his charge while on duty.

BARRACK-MASTER.—The Officer who superintends the barracks of soldiers. The condition of British soldiers has, ever since the disasters in the Crimea in the winter of 1854, been an object of much public solicitude. This solicitude was so strongly expressed as to break through the cold formalities of the official departments. Returns were ordered, and commissions and committees appointed, partly to inquire into existing facts, partly to suggest improvements. The Barrack-master-general was replaced at the beginning of this century by Commissioners for Barracks, whose functions were absorbed by the now extinct Board of Ordnance in 1822. Barracks are now under the supervision of the Surveyor-general of the Ordnance, who provides for their construction and maintenance through the Royal Engineers; and for their victualing and daily service through Commissaries of the Control Department. Under these Commissaries are Barrack-clerks and Barrack-sergeants, to assist them in their duties.

BARRACKS.—Permanent structures for the accommodation of soldiers, as distinguished from huts and tents. Originally, the word, derived from the Spanish *barracas*, applied to small cabins or huts; but in England the term is now always considered to relate to structures of brick or stone. Great opposition was made in England to the introduction of permanent barracks during the early part of the last century, on the ground that the liberty of the subject might possibly be endangered by thus separating the soldiery so completely from the citizens, and placing them in the hands of the ruling power. On the other hand, it was contended that the older system of billeting the soldiers on the people is vexatious and burdensome; and that the morals of towns-people and villagers are liable to be vitiated by the constant presence of soldiers. The permanent barracks were few in number down to the year 1792, when George III. obtained the consent of Parliament for the construction of several new ones, and for the founding of the office of Barrack-master-general. Various changes in the arrangements were made from time to time.

The furniture of the barracks is bought by the War Office. The French have a singular plan of *hiring* such furniture at 15 francs per man per annum; the English cost is about 25 shillings per man, and some Officers are of opinion that it might with advantage be superseded by the French plan. The barrack-rooms have arm and accouterment racks, shelves, and pegs; with a regular order for depositing everything thereon. During the day all the bedding is placed in exact array; as well as dishes, tins, and canteens. A Subaltern Officer visits every room every day. The iron bedsteads are turned down every evening, and up every morning. One Non-commissioned Officer (Sergeant or Corporal) has control over each room, and is responsible for quiet, cleanliness, etc. Married women, in the ratio of 6 to a company of 100 soldiers, may live in the barracks with their husbands, in separate rooms known as "Married Soldiers' Quarters," but not unless the marriage has been with consent of the Commanding Officer. The married soldier may, however, sleep out of barracks, and is allowed an extra twopence per day if he does so. Each soldier in a barrack has an iron bedstead, a rug, a paillasse, a bolster, two blankets, and two sheets; he pays nothing for these. Each soldier has his name and number written near his bed and knapsack.

Notwithstanding the order and regularity established in barracks, Committees of Inquiry appointed in 1855 and 1857 ascertained the existence of grievous defects. It was found that, out of 252 barracks, only 20 had separate sleeping-rooms for married soldiers; the wives of such soldiers, in the other 232, being obliged to put up with arrangements repugnant to all decency and propriety, or else sleep away from the barracks altogether.

In regard to sanitary arrangements, great efforts have been made at vast cost in recent years to improve all the hygienic conditions, such as drains, ventilation, means of ablution, recreation, circulation of air, etc. The result has been very apparent in the reduced rate of mortality. Army Physicians recommend 600 cubic feet of room-space per soldier; and this is the standard now demanded in all practicable cases by the War Office. It has been estimated that a new barrack for 1000 Foot-guards in London would cost £150,000 *besides land*, the cost of which would depend wholly on the particular site selected. The necessity for grounds for exercises, stores, library, offices, etc., renders a barrack a very costly congeries of buildings. Twenty acres may be taken as the minimum space needed for 1000 men. In relation to all the various subjects of barrack-life, a Committee of Military Officers has drawn up a most comprehensive scheme of reform; but unfortunately the cost of making these improvements would be so enormous that nothing better than a very gradual adoption can be expected.

The finest barracks existing are perhaps those at Aldershott, attached to the camp noticed in another article. The buildings extend in two long lines, branching out of the Farnborough and Farnham road, with a large parade-ground between them. The infantry and artillery barracks are on the north side of this space, and the cavalry barracks on the south. The infantry barracks are divided into blocks, forming each a spacious quadrangle, with a court-yard in the center. Each block is a complete barrack for a full regiment, with all the men's rooms, store-rooms, school-rooms, offices, etc. The Officers' rooms are, however, separate, and occupy open spaces between the blocks of buildings. All the four sides of each quadrangle are occupied by various rooms and buildings; the men's living and sleeping rooms being mostly on the side next to the parade-ground. The sleeping-rooms, each for 24 men, are very large and airy; the washing-rooms are ample and well-fitted; and the cooking-rooms will each cook for 350 men. Dry play-grounds and drill-yards under glass roofs are provided. A broad balcony outside every range of sleeping-rooms enables the soldiers to look out upon these grounds. The married soldiers and their wives are comfortably provided for, in rooms wholly apart from the rest. The artillery and cavalry barracks resemble in their general features those for the infantry.

In the United States Army 225 square feet of space is allowed for every six soldiers, with a height of 12 feet, giving each one about 450 cubic feet. There are few masonry-built barracks in the United States; most of them are of logs or lighter timber. Of the more permanent are Madison Barracks, at Sackett's Harbor, N. Y.; the Citadel, at Charleston, S. C.; Pensacola, at Pensacola, Fla.; Jackson, at New Orleans, La.; Jefferson, at St. Louis, Mo.; Baton Rouge Arsenal, at Baton Rouge, La.; Mt. Vernon Arsenal, Miss.; Oglethorpe, at Savannah, Ga.; Benicia, in California; Carlisle, in Pennsylvania; Fort Leavenworth, Kansas; Newport, in Kentucky; Ringgold and Fort Brown, in Texas; and the Cadet Barracks at West Point, N. Y.

An annual inspection of the public buildings at the several stations is made at the end of June by the Commanding Officer and Quartermaster, and then the Quartermaster makes the following reports: 1. Of the condition and capacity of the buildings, and of the additions, alterations, and repairs that have been made during the past year. 2. Of the additions, alterations, and repairs that are needed, with plans and estimates in detail. These reports the Commanding Officer examines and forwards, with his views, to the Quartermaster-general.

BARRACK-SERGEANTS.—Faithful old Sergeants, in the British service, who are selected from the Line and placed in charge of barracks, under the superintendence of the Barrack-masters or Commissaries of the Control Department. A similar duty is performed by roster in the United States service, the time of the detail usually being one week.

BARREL.—1. The hilt of a sword, adapted to be grasped by the hand.—2. A large vessel for holding liquids—probably from *bar* in the sense of to guard, confine, contain—and then a certain *measure*, but varying in every locality, and almost for every liquid. In the old English measures, the barrel contained 31½ gallons of wine, 32 of ale, and 36 of beer—the wine-gallon itself differing from that of ale and beer. In imperial gallons, their contents would be: old wine-barrel = 26¼ gallons; ale do., 31½; beer, 36¼. The Italian barile varies from 7 to 31 English gallons; the French barrique of Bordeaux = 228 French litres = 50 English gallons. Four barriques make a tonneau. In many cases, barrel signifies a certain *weight* or other quantity of goods usually sold in casks called barrels. In America, flour and beef are sold on the large scale in barrels: a barrel of flour must contain 196 lbs.; of beef, 200 lbs. A barrel of butter = 224 lbs.; of soft-soap, 256 lbs.; of tar, 26¼ gallons. Barrels or casks of various kinds are largely used for military purposes.—3. The barrel is the most important part of a fire-arm, its office being to concentrate the force of a charge of powder on a projectile, and give it proper initial velocity and direction; for these purposes, and for the safety of the firer, it should be made of the best materials and with the greatest care. In determining the exterior form of a barrel, it is not only necessary to give such thickness to the different parts as will best resist the explosive effort of the charge, but such as will prevent it from being bent when used as a pike or subjected to the rough usage of the service. A sufficient *weight* is required to give steadiness to the barrel in aiming, and to prevent it from springing in firing. The latter defect generally arises from bad workmanship, whereby there is a greater thickness of metal, and, consequently, less expansion, on one side of the bore than the other. In the military service, where the rifle is carried by the soldier, the barrel should seldom weigh more than five pounds.

The principal parts of a barrel are the *breech*, the *breech-screw*; the *flats*, the *bevels*, and the *oval*; the *cone*, and *cone-seat*; the *bayonet-stud*, and *front-sight*; the *bore*, the *grooves*, and the *lands*. The *breech-screw* is composed of a *body*, *tenon*, and *tang*, and its object is to close the bottom of the bore. The tenon fits into a mortise cut in the stock, and prevents the barrel from turning in its bed; the tang is the part by which the breech of the barrel is secured to the stock, and for this purpose it is pierced with a hole for the *tang-screw*, which passes through the stock and screws into the guard-plate. The *flats* are two vertical plane surfaces, situated at equal distances from the axis of the bore. They serve to prevent the barrel from turning in the jaws of the vise when the breech-screw is taken out; the flat, on the right side of the barrel, also presents a surface of contact for the lock-plate, which prevents the hammer and cone from changing their relative position. The corners of the flats are beveled to prevent the barrel from being marred, and to improve its finish. The functions of the cone are to support the percussion-cap when exploded by the hammer, and to conduct the flame to the vent of the piece. The parts are the *nipple*, upon which the cap is placed; the *square*, the part to which the wrench is applied; the *shoulder*; the *screw-thread*; and the *vent*. To increase the effect of the hammer on the cap, the upper surface of the cone is diminished by chamfering the corners. The *cone-seat* is a projecting piece of iron welded to the barrel, near the breech, for the purpose of sustaining the cone. The principal parts are the *female screw*, the *vent*, and the *rim*; the latter prevents the flame from penetrating between the lock and barrel. The position of the cone-seat should be such that the vent will have a direct communication with the bore. To prevent the blow of the hammer from straining the cone and breaking it off in the cone-seat, the plane of the face of the hammer should pass through the axis of motion.

The length of a gun-barrel is determined by the nature of the service to which it is applied, rather than by the effect which it exerts on the force of the charge. It has been shown by experiment that the velocity of a projectile, in a smooth-bored musket, increases with the length of the bore up to 108 calibers; but a musket with this length of barrel would be too heavy as a fire-arm and too unwieldy as a pike. The points to be observed in constructing the grooves for military arms are range, accuracy of fire, endurance, and facility of loading and cleaning the bore. For expanding projectiles, experiment shows that these points are best attained by making the grooves broad and shallow and with a moderate twist. The effect of decreasing the depth of rifle-grooves is to increase the accuracy, but it diminishes the range. The twist is dependent on the length, diameter, and initial velocity of the projectile; in other words, it should be increased in a certain proportion to the length of the projectile; and for the same weight of projectile it should be increased in a certain proportion as the length of the bore is diminished. See *Gun-barrel* and *Powder-barrel*.

BARREL-HEADED SIGHT.—This sight consists of a steel bar, an elevating-nut, a cross-head, two thumb-screws, and a leaf. One side of the bar is graduated to degrees, the other to yards. The degrees are divided into six parts of ten minutes each; and any number of minutes up to ten can be obtained by turning round a graduated elevating-nut on the top of the bar, which works an internal screw and so raises the head of the scale. The bar is inclined to the left to allow for *deviation*, but it is fitted with a horizontal scale or cross-head, graduated to give one half-degree of deflection either to the right or left. At each end of this slide is a graduated nut divided into minutes up to ten, and these nuts are connected by a screw which crosses the bar at right angles. A leaf with the sight-notch slides along the scale, and can be moved right or left by either nut.

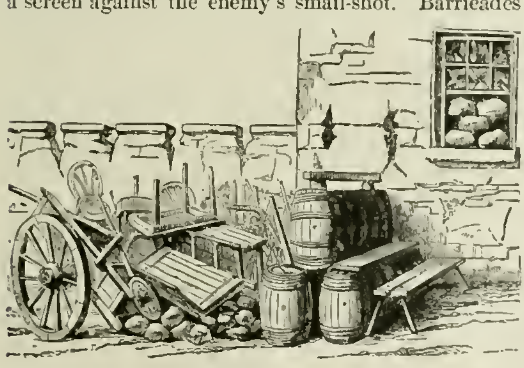
BARREL-PIERS.—Casks or barrels formed into piers, when no pontoons or boats can be obtained for the passage of troops across a river.

BARREL-PLATE.—A plate employed to hold the barrels of certain machine guns in place. In the Gatling gun, the breech-ends of all the barrels are firmly screwed into a disk, or *rear barrel-plate*, which is fastened to the shaft; while the muzzles pass through another similar disk, called the *front barrel-plate*, on the same shaft. The shaft is considerably longer than the barrels, and projects beyond the muzzles, while it extends backward for some distance behind the breeches of the barrels. See *Gatling Gun*.

BARREL-SETTER.—A cylindrical mandrel used by armorers for straightening the barrel of a fire-arm and in truing the bore or exterior surface.

BARREL-VISE.—A bench-vise having a longitudinal groove in its jaws to fit it for the reception of a gun-barrel, which may be protected from direct contact of the jaws of the vise by sheet-lead or other soft-metal cheeks.

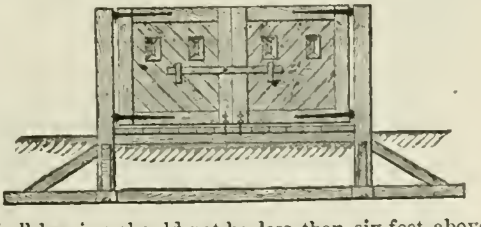
BARRICADES.—Military engineers, and sappers and miners, are instructed in the art of barricading streets and roads with beams, chains, *chevaux-de-frise*, and other obstacles, either in defending a town against besiegers, or in suppressing popular tumults. In a ship, a strong wooden rail, supported on stanchions, and extending across the foremost part of the quarter-deck, is called a barricade; during a naval action, the upper part of this barricade is sometimes stuffed with hammocks in a double rope-netting, to serve as a screen against the enemy's small-shot. Barricades



have been made use of in street-fights since the Middle Ages, but they are best known in connection with the insurrections in the city of Paris. As early as 1358 the streets of Paris were barricaded against the Dauphin, afterwards Charles V. A more noteworthy barricade-fight was that in 1588, when 4000 Swiss soldiers, marched into Paris by Henry III. to overawe the Council of Sixteen, would have been utterly destroyed by the populace, firing from behind barricades, had the Court not consented to negotiation; and the result was that the king fled next day. The next barricade-fight of importance in Paris was that of 1830, which resulted in the expulsion of the Bourbons from the throne of France, and the election of the Citizen-king, Louis Philippe. During the three days which this revolution lasted, the number of barricades erected across the streets amounted to several thousands. They were formed of the most heterogeneous materials—overturned vehicles, trees, scaffolding-poles, planks, building-materials, and street paving-stones; men, women, and children taking part in their erection. In February, 1848, the insurrection against Louis Philippe commenced with the erection of barricades; but the most celebrated and bloody barricade-fight was that between the populace and the Provisional Government, which, commencing on the night of the 23d June, 1848, lasted throughout the three following days, when the people had to surrender. The national losses by this fight were estimated at 30,000,000 francs; 16,000 persons were killed and wounded, and 8000 taken prisoners. The Emperor Napoleon III. has so widened and macadamized the principal streets of Paris since he ascended the throne as to render the successful erection of barricades next to impossible. There was a remarkable barricade-erection in London in 1821. The Ministry desired that the body of Queen Caroline should be conveyed out of the country to Germany, for interment, without the populace having the opportunity of making any demonstration. On the matter becoming known, a vast barricade was erected at the point where the Hampstead road joins the new road; and as nothing but the use of artillery could have forced the way, the officer in charge of the funeral cortege deemed it prudent to change his course and pass through a more central part of the metropolis. During the revolutions of 1848, barricades were successfully carried in Paris, Berlin, Vienna, and other places, by abandoning the attack in front and breaking through the houses of contiguous streets, taking their defenders in the rear.

BARRIERS.—Carpentry obstructions in fortifications. The purpose regulates the construction. If the barrier is to be permanently defensible, it should be musket-proof, and then becomes a *stockade*. If occasionally defensible, palisading will suffice, with a sand-bag or other temporary parapet when required, behind and near enough to fire between the palisades. The gates in both the above should, if possible, be of palisading, as the heavy stockade-gate is unwieldy. Barrier-gates should never be left unprotected.

The barrier-gate is most frequently made with two leaves, hanging on posts by hinges, and made to open inward. The frame of each upright is composed of two uprights, called *stiles;* two cross-pieces, one at the top and the other at the bottom, called *rails;* and a diagonal brace called a *swinging-bar*. Since the gate must be strong, the leaves of it are necessarily very heavy. The leaves must be hung upon stout posts firmly braced into the ground, to sustain the great weight of the gate. The top rails

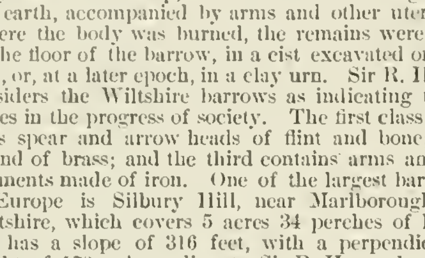


of all barriers should not be less than six feet above the ground. In the barriers with open leaves, the vertical pieces are usually extended from eighteen inches to two feet above the top rails, and their upper ends sharpened. In those which are solid, it is usual to arrange some obstruction upon the top rail, such as sharp-pointed spikes, broken glass, etc., to interfere with persons climbing over the top. It is usual to provide apertures in the leaves, through which the men can fire upon the ground on the outside.

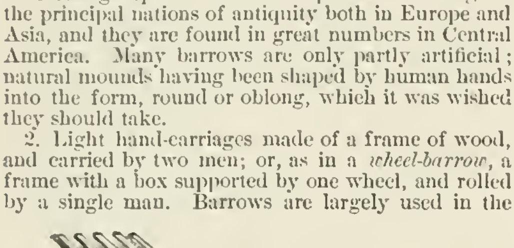
BARRITUS.—A word which not only signified the battle-cry of the ancient Germans, but all battle-cries were formerly so called. Also written *Bardites*.

BARROWS.—1. Artifical mounds of earth generally believed to have been erected for sepulchral or monumental purposes. They are very numerous in Great Britain, and many of them are supposed to belong to a period long prior to the Roman Invasion. The counties of Wilts and Dorset are especially rich in these remains, and the barrows of the former have been thoroughly explored, described, and classified by Sir R. C. Hoare in his *Ancient Wiltshire*. In the sepulchral barrows the human remains are buried either in a rude stone "cist" or chest, in which the body was doubled up, or are laid at full length in the earth, accompanied by arms and other utensils. Where the body was burned, the remains were laid on the floor of the barrow, in a cist excavated on the spot, or, at a later epoch, in a clay urn. Sir R. Hoare considers the Wiltshire barrows as indicating three stages in the progress of society. The first class contains spear and arrow heads of flint and bone; the second of brass; and the third contains arms and instruments made of iron. One of the largest barrows in Europe is Silbury Hill, near Marlborough, in Wiltshire, which covers 5 acres 34 perches of land, and has a slope of 316 feet, with a perpendicular height of 170. According to Sir R. Hoare, barrow-burial was practiced down to the eighth century, from a period of unknown antiquity. The practice of erecting sepulchral mounds prevailed among all the principal nations of antiquity both in Europe and Asia, and they are found in great numbers in Central America. Many barrows are only partly artificial; natural mounds having been shaped by human hands into the form, round or oblong, which it was wished they should take.

2. Light hand-carriages made of a frame of wood, and carried by two men; or, as in a *wheel-barrow*, a frame with a box supported by one wheel, and rolled by a single man. Barrows are largely used in the



army, there being no less than fourteen different kinds put to various purposes. The drawings show two varieties, the *rack-barrows* and *wagon-barrows*,



employed for many purposes in the arsenal and store-house.

BARRY.—In Heraldry, the term applied to a shield which is divided transversely into four, six, or more equal parts, and consisting of two or more tinctures interchangeably disposed.

Barry-bendy is where the shield is divided into four, six, or more equal parts, by diagonal lines, the tincture of which it consists being varied interchangeably.

Barry-pily is where the shield is divided by diagonal lines, the colors being interchanged as in the example.

Barry.

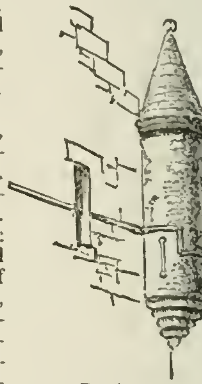
Barry-bendy.

Barry-pily.

BAR-SHOE.—A horseshoe which is not open at the heel, but continued round at the rear. It is used with horses that are liable to contraction of the heel, to spread that part of the foot.

BAR-SHOT.—A projectile formerly used, consisting of two cannon-balls, or half-balls, united by a bar of iron, and employed for severing the rigging of vessels, as well as for field and fort artillery. Shot used in proving ordnance may be considered as belonging to this class, consisting as they do of a bar with hemispherical ends, weighing twice or three times that of the solid shot used in service. See *Chain-shot*, *Projectiles*, and *Shot*.

BARTIZAN.—A small stone closet, thrown out upon corbels over doorways, and on other parts of mediæval castles, generally for defense, but sometimes only for convenience to the inmates and defenders.



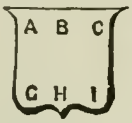
Bartizan.

BASCHI.—A Turkish title, signifying a superior commander, officer, chief, etc. This title is only used in connection with the office title. The most prominent are: Toptschijy-Baschi, General of Artillery and Inspector of Forts, etc; Solacki-Baschi, Sub-commander of the Archers; Sandschjack-Darlárs-Baschi, Chief of the 50 Color-bearers; Konadschijy-Baschi, Quartermaster-general; Boluck-Baschi, Colonel of a regiment of 1000 militia; Oda-Baschis, Company Officers who superintend drill.

BASCINET—BASNET.—A head-piece of mail, over which, in the time of Edward I. and Edward II., the helmet was worn; but in the latter reign the *bascinet* appears without the nasal of the helmet, and occasionally with a movable visor, which rendered the helmet unnecessary. Another form of the bascinet during the latter part of the thirteenth century was its being opened behind and having to be fastened or laced behind. See *Helmet*.

BASCULE BRIDGE.—A counterpoise drawbridge which oscillates in a vertical plane; the inner portion descends into a pit, while the outer ascends and closes the gateway. A bridge which has its truck simply hinged to the edge of the scarp or curbing, and which is lifted by weight or windlass, is classed as a *lifting-bridge*. The *bascule* has an inner portion of roadway, which acts as a counterpoise to the portion which projects over the water-way. The inner portion descends into a dry well when the bridge is lifted into a vertical position, the outer portion closing the opening in the wall outside of the portcullis, if there be one. This form of bridge was not uncommon in the castles of the feudal times, when the rich owned the poor, and learning had no refuge but in the Church.

BASE.—1. In fortification, the base is the exterior side of the polygon, or that imaginary line which connects the salient angles of two adjacent bastions. 2. In ordnance, the base is the protuberant rear portion of a gun, between the knob of the cascabel and the base-ring. The base is the middle member of the *cascabel* when the piece has a base-ring and knob. In the simplicity of modern pieces, many mere ornaments and extraneous matters are omitted. The base is always present, forming the rounded contour at the rear of the breech.—3. In Heraldry, the base is the lower portion of the shield. There is a dexter base,



middle base, and sinister base. The *chief* or principal part of the escutcheon is the top. The shield is always supposed to be on the arm of the wearer, and that it is his right and left hands, not those of the spectator, which are kept in view. The *ground* or surface of the shield, on which all the *charges* or figures are depicted, is called the *field.*—4. In chemistry, a term applied to a compound body, generally consisting of a metal united with oxygen. Thus, the metal potassium (K), when it combines with oxygen (O), forms the base potash (KO); sodium (Na) and oxygen, the base soda (NaO); lead (Pb) and oxygen, the base oxide of lead or litharge (PbO). A distinguishing feature of a base is that it unites with an oxygen acid, such as sulphuric acid (SO_3), to form a *salt.* Thus, the base potash (KO) combines with sulphuric acid (SO_3) to make the salt sulphate of potash ($KOSO_3$); potash with nitric acid (NO_5) to form the salt nitrate of potash, or niter ($KONO_5$). Occasionally sulphur replaces the oxygen in a base. Thus, the metal potassium (K) unites with sulphur (S) to form the *sulphur* base, sulphuret of potassium (KS), which can unite with a sulphur acid like sulpharsenious acid or orpiment (AsS_3) to make the salt sulpharsenite of potash (KS,AsS_3). The metal half of a base need not be a simple element, but may be a compound body which, for the time, plays the part of a simple substance. Thus, the compound ethyl (C_4H_5) can combine with oxygen to form ordinary ether ($[C_4H_5]O$); and the base thus produced can, in its turn, combine with acids to form salts. A base may be soluble or insoluble in water. Thus, the bases potash (KO), soda (NaO), ammonia (NH_4O), baryta (BaO), strontia (StO), lime (CaO), and magnesia (MgO), are more or less soluble in water; whilst the oxide of iron or rust (Fe_2O_3), the red oxide of lead ($PbbO_4$), the red oxide of mercury (HgO), are insoluble in water, but soluble in acids.

BASE-LINE.—In gunnery, a line traced around the gun in rear of the vent; also the measured line used to obtain ranges by triangulation. In military tactics the *base-line* is the line on which all the magazines and means of supply of an army are established. It also means the line on which troops in column move.

BASE OF OPERATIONS.—In all military operations of a general character, and which come under the head of strategy, three principal things are noticeable and demand consideration; these are the line from which the army starts in commencing its onward movements; the point which it aims to attain; and the line which it is obliged to pass over to reach this point. The first of these is termed the *base of operations;* the second, the *objective* or *objective point;* the third, the *line of operations.* When maintaining a strictly defensive attitude, the base of operations becomes what is termed the *line of defense,* and in a backward movement the line of operations becomes the *line of retreat.* The base of operations should be a series of points having the properties of military strength, as the supplies of the army for its onward movements are collected upon it; and it should have commodious lines of communication leading from it to the objective. If these strong points lie upon any natural obstacle, as a river without fords, a rugged mountainous chain, swamps, or thick primeval forests, and have an easy communication between them, the base is all the better, from the difficulties which a line of this character offers to the enterprises of the enemy in case of being thrown on the defensive. A base of some extent is better than a short one, because more latitude is given to operate against the enemy, and, if obliged to retire upon it, there is less chance of being separated from it by the enemy gaining our rear. Should it consist of a single city, for example, with but one line of operations from it, by seizing on this line the enemy might cut off the army from all supplies and reinforcements. The outline which the base assumes is far from being a matter of indifference. If it is concave towards the enemy, or has its two ends resting upon any natural impassable obstacle lying in advance of the general line, the army moving from it will find greater security for its wings than in a case where the base is either generally convex towards the enemy, or presents a salient point to him. When an army moves to a considerable distance beyond its base, it will become necessary to take up a new base in advance of the primitive one, in order to have its depots, from which it has to draw its supplies of every description, nearer at hand. This new line is termed a *secondary base of operations.* It should possess the same military properties as the primitive base, and art should supply whatever nature may be found deficient in for this purpose, in order that everything collected for the army on it may be secure. If prudence points out the necessity of taking up new bases as the army advances further into an enemy's country, it does not follow that the army should be detained to organize them on a suitable footing. This task is devolved on a body of troops left behind for this purpose, who, with the reinforcements sent forward, occupy the fortified places on the new line, erect new field-works, establish magazines, etc., while the army pursues its march to profit by its first successes. When the secondary base is not parallel to the primitive one, that end of it which is most advanced should be strengthened by every accessory means, as it is the one most exposed to the enemy's attacks. The other end, though less exposed, from its retired position, also affords less support to the army in advance. An oblique base affords the advantage of threatening the communications and base of the enemy without exposing our own. The base of operations can seldom be a subject of doubt in a foreign war, as it necessarily lies on that portion of the frontier next to the enemy. The only question that can arise is at what point of the frontier it will be best to advance against the enemy. It is here that a consideration of the general outline of the base comes up. Is it concave, or makes to some extent a re-entering angle, the army then in advancing will find both its rear and wings securely supported. Is it strongly convex, or offers a salient angle, it has the advantage, by assembling our army towards the apex of the angle, of keeping the enemy in doubt as to which side we will adopt for our base, and thus forcing him to distribute his forces on an arc of which we occupy the center. But even should he concentrate on one point, we have still the resource of threatening him on one side, so as to draw his attention there, while by the shortest line we throw ourselves on the opposite one. This convex form is then decidedly advantageous on the opening of a campaign; but, in case of reverse, it may lead to our separation from our base. The inverse holds for the concave base. There can seldom, if ever, be an equality of choice between two frontiers as a base of operations; one will necessarily offer preponderating advantages over the other, which will cause its adoption, and it is upon this one that all our means of attack must be brought together. It is a grave fault to pursue a double offensive, in starting at the same time from two bases. It is much better to stand strictly on the defensive on one of the frontiers, so that by accumulating more troops on the other we may increase our chances of success. It is a rare thing that we arrive at a satisfactory result by dividing our forces; and the same reasons which render double lines of operation dangerous are equally against attempting a double offensive. We should, on the contrary, concentrate our efforts as much as we can, in order that the advantages we obtain may be decisive; and they must always be more so on the preponderating frontier than on the other; it is upon the former, therefore, that we should act with the most vigor, holding back from the other all that is not indispensable to the defensive; as upon the field of battle we refuse one wing, drawing from it troops to strengthen the one engaged, and upon which we count for victory. See *Line of Operations* and *Objective Point.*

BASE OF THE BREECH.—In gunnery, the rear surface of the breech of a gun. See *Piece.*

BASE-RING.—A projecting band of metal adjoining the base of the breech, and connected with the body of the gun by a concave molding. It serves as a point of support for the breech-sight, and rests upon the head of the elevating-screw. The ring is omitted in guns of recent model. See *Cannon.*

BASHAW.—A Turkish title of honor given to Viceroys, Provincial Governors, Generals, and other distinguished public men. The term Bashaw is also used to characterize a man of an arrogant and domineering disposition.

BASHI-BAZOUKS.—Irregular troopers in the pay of the Sultan. Very few of them are Europeans; they are mostly Asiatics, from some or other of the Pashalics in Asiatic Turkey. They are wild, turbulent men, ready to enter the Sultan's service under some leader whom they can understand, and still more ready to plunder whenever an opportunity offers. During the Russo-Turkish war of 1854, etc., they had many encounters with the enemy in that kind of irregular warfare which the Russians intrust to Cossack horsemen; but the peaceful villagers had almost as much distrust of the Bashi-bazouks as of the Russians. When the British Government resolved, in 1855, to take into pay a Turkish contingent, to aid in the operations of the war, a Corps of Bashi-bazouks was put in charge of an Indian officer, but the task of reducing them to discipline was not completed when the war ended. Their ferocity was exhibited in the Servian war, but most relentlessly in the massacre of Batak, where, in May 1876, under Achmet Agha, they slew over 1000 defenseless Bulgarians in a church in which they sought refuge.

BASHFORTH CHRONOGRAPH.—Professor Bashforth of the Artillery School, Woolwich, England, has made extensive experiments to determine the resistance of the air to the motion of rifle-projectiles, with a chronograph of his own invention. A general view of his instrument is given in Fig. 1.

The fly-wheel, A, is capable of revolving about a vertical axis, and carrying with it the cylinder, K, which is covered with prepared paper for the reception of the clock and screen records. The length of the cylinder is 12 or 14 inches, and the diameter 4 inches. B is a toothed wheel which gears with the wheel-work, M, so as to allow the spring, CD, to be slowly unwrapped from its drum. The other end of CD, being attached to the platform, S, allows it to descend slowly along the slide, L, about $\frac{1}{4}$ inch for each revolution of the cylinder. E, E′ are electro-magnets; *d, d′* are frames supporting the keepers; and *f, f′* are the ends of the springs, which act against the attraction of the electro-magnets. When the current is interrupted in one circuit, as E, the magnetism of the electro-magnet is destroyed, the spring, *f*, carries back the keeper, which by means of the arm, *a*, gives a blow to the lever, *b*. Thus the marker, *m*, is made to depart from the uniform spiral it was describing. When the current is restored, the keeper is attracted, and thus the marker, *m*, is brought back, which continues to trace its spiral as if nothing had happened. E′ is connected with the clock, and its marker, *m′*, records the seconds. E is connected with the screen, and records the passage of the projectile through the screens. By comparing the marks made by *m, m′*, the exact velocity of the projectile can be calculated at all points of its course. The slide, L, is fixed parallel to F, and the cylinder, K, by the brackets, G, H. Y is a screw for drawing back the wheel-work, M; and J, a stop to regulate the distance between M and B. The depression of the lever, *h*, raises the two springs, *s*, which act as

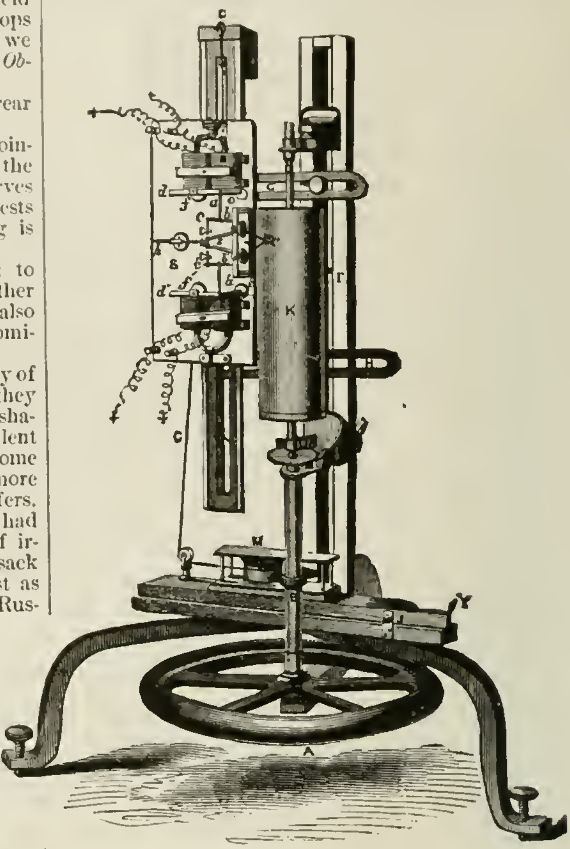


Fig. 1.

levers, and bring the diamond points, *m, m′*, down upon the paper. When an experiment is to be made, care is taken to see that the two currents are complete. The fly-wheel, A, is set in motion by hand, so as to make about three revolutions in two seconds. The markers, *m, m′*, are brought down upon the paper, and after four or five beats of the clock the signal to fire is given, so that in about ten seconds the experiment is completed, and the instrument is ready for another. The pendulum of a half-seconds clock strikes once, each double-beat, a very light spring, and so interrupts the galvanic current in E′ once a second.

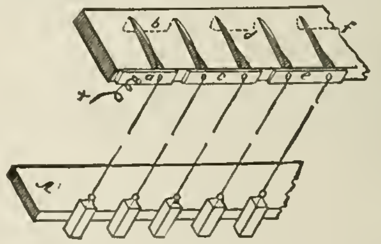

Fig. 2.

Fig. 2 gives the details of the screen. It represents a piece of board 1 inch thick and 6 or 7 inches wide, and rather larger than the width of the screen to be formed. Transverse grooves are cut at equal distances, something less than the diameter of the projectile. Staples of hard brass spring-wire are fixed with their prongs in the continuation of the grooves. Pieces of sheet-copper, *a*, *c*, *e*, are provided, having two elliptical holes, the distance of whose centers equals the distance of the grooves. The pieces of copper are used to connect each wire staple, *b*, *d*, *f*, with its neighbor on each side. These copper connections hold down the wire springs, which, when free, are in contact with the tops of the holes; but, when properly weighted, they rest on the lower edges of the holes. Thus the copper, *c*, forms a connection between the staples, *b* and *d*; the copper, *e*, joins *d* and *f*, and so on. A galvanic stream will therefore take the following course, whether the springs be weighted or unweighted: copper *a*, brass *b*; copper *c*, brass *d*; copper *e*, brass *f*, etc. The current will only be interrupted when one or more threads have been cut, and the corresponding spring is flying from the bottom to the top of its hole. About one fiftieth of a second is required for the complete registration

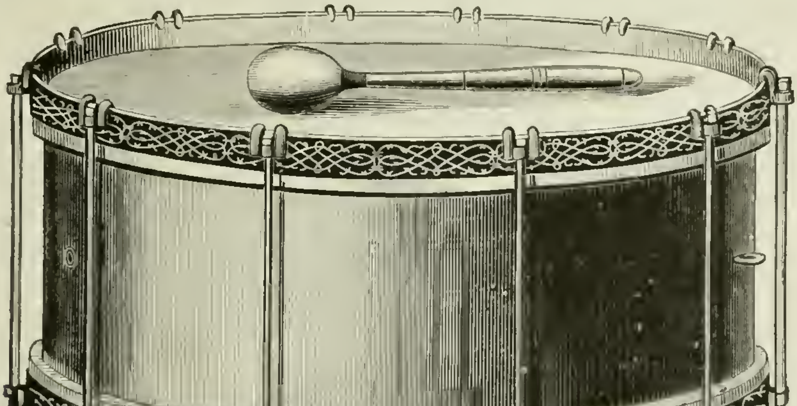
Fig. 3.

of such an interruption, the spring traversing about half an inch. The shelf, A, is placed for the weights to rest against, partly to prevent them from being carried forward by the projectile, but chiefly to prevent the untwisting of the threads which support the weights. The weights used are about 2 lbs. each, and the strength of sewing-cotton for supporting them is equal to a stress of about 3 lbs., which is sufficient to withstand a tolerably strong wind. As the weights are equal, the threads are kept equally stretched. The arrangement of *screens* for an experiment is shown in Fig. 3. The wires for conveying the galvanic current are like the common telegraph-wires carried on posts. *a b c d e f g h* is a continuous piece of wire, and the current is made to circulate through the screens. The ends, *a*, *h*, are connected with the instrument and battery. The projectile, being fired through the screens, in passing cuts one or more threads at each screen, so that, corresponding to the instant at which the projectile passes each screen, there is an interruption of the galvanic current, and a simultaneous record on the paper. See *Chronoscope*.

BASHKIRS—BASHKURTS.—A people in Orenburg and Perm, Russia, on the slope and plains of the Ural. They are a mixture of Finns, Tartars, and Ostyaks. Until the arrival of the Hungarians, about the middle of the thirteenth century, the Bashkirs were strong and independent and troublesome to their neighbors. In 1556 they voluntarily accepted the supremacy of Russia, and the city of Upha was founded to defend them from the Kirghiz. Three times they rebelled, in 1676, 1707, and 1735, but were reduced to subjection. They are now divided into thirteen cantons, under the jurisdiction of the Governor-general of Orenburg. They maintain a military cordon, escort caravans through the Kirghiz steppes, and are employed in various other services. They are divided into settled and nomadic, the former chiefly agriculturists, and the latter cattle-raisers. They are hospitable, but suspicious, poor, apt to steal, and exceedingly lazy. They have large heads, small foreheads, eyes narrow and flat, ears standing straight out, and black hair; but are muscular and strong, and capable of enduring much labor and privation. They are of limited intellect, and their Mohammedanism is rather a profession than a practice.

BASIL.—Tanned sheep-skin, used for various purposes in the arsenal and armory.

BASILICON.—A name given to an ointment composed of yellow wax, black pitch, resin, and olive-oil; hence it was called *unguentum tetra-pharmacum* (*tetra pharmaka*, four drugs). The resin, wax, and pitch are melted together over a slow fire; the oil is then added, and the mixture, while hot, strained through linen. The straining is directed in consequence of the impurities which resin often contains. Basilicon ointment, or resin cerate as it is sometimes called, is much used as a gently stimulant application to blistered surfaces, indolent ulcers, burns, scalds, and chilblains, and other accidents of the march and camp.



Bass-drum.

BASILLARD.—An old term for a poniard or dagger.

BASILISK—BASILISKE.—An ancient piece of ordnance, which was ten feet long and weighed 7200 pounds; so called from its supposed resemblance to the serpent of that name, or from its size.

BASKET-HILT.—The hilt of a sword, so made as to contain and guard the whole hand. The term "basket" is given to the leather guard round the handle of fencing or single sticks, and the leather of condemned pouches is often applied to this purpose.

BASKET-WORK.—In fortification, work involving the interweaving of withes and stakes: such as wicker-work, randing, wattling, waling-gabions, fascines, hurdles, etc.

BASLARD.—A short sword or dagger, worn in the fifteenth century.

BASSART.—An arm-guard worn by knights and soldiers in the Middle Ages.

BASS-DRUM.—A very large drum, beaten at either end, and used chiefly in military bands. The invention of the drum in this form is ascribed to Bacchus, who, according to Polygoenus, gave his signal of battle by cymbal and drum. It was, however, known in very early ages, and in some rude form among almost all nations.

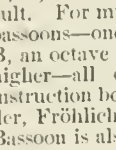
BASSINET.—The pan of the arquebus. The priming is placed in the *bassinet* and covered by another plate called the *couvre-bassinet*.

BASSOON.—A well-known wind-instrument of the reed species, made of maple-wood or plane-tree. The bassoon is an Italian invention; its name, fagotto, meaning *a bundle*, probably from its being made in different pieces laid one against the other. The French call it *basson de hautbois;* the Germans retain its Italian name. Its invention is attributed to Canonicus Afranio, in Ferrara, in 1539. In the middle of the sixteenth century it had already reached great perfection. Sigmund Schnitzer, in Nuremberg, who died in 1578, was a celebrated maker. The bassoon consists of a bored-out tube of wood in several pieces, fixed together alongside each other, so as to bring the holes and keys within the reach of the fingers of each hand. The bassoon has, in general, not less than eight holes and ten keys. In the narrow end of the wooden tube is fixed a small tapering brass tube in the form of an S, on the end of which is placed the reed for producing the tone. The notes for the bassoon are written on the bass clef for the lower part, and on the tenor clef for the higher. The best keys for the bassoon are E flat, B flat, F, C, G, D, and A; all the other keys are more or less difficult. For military bands there are different sizes of bassoons—one a fourth lower; another, the contra B, an octave lower; and a third, the tenor B, a fifth higher—all of the same construction. The best instruction books for the bassoon are by Almenräder, Fröhlich, Ozi, and by the Paris Conservatorium. Bassoon is also the name of an organ-stop, the pipes of which are made to imitate the tones of the instrument.

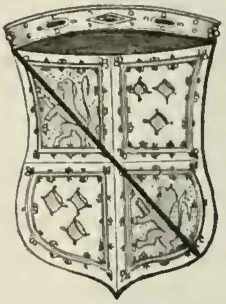
Bassoon.

BASTARD.—An ancient piece of ordnance of about 8 pounds caliber, 9½ feet long, and weighing 1950 pounds. It was invented by Jean Manrique de Lard, Master-general of Ordnance under Charles V. of France, in 1535. He also had several bastards cast of a larger caliber. This term was also applied to guns of an unusual make or proportion, whether longer or shorter.

BASTARD BAR.—In popular speech we frequently hear of a *bar-sinister*, as a mark of bastardy. But a bar-sinister, strictly speaking, is an impossibility, inasmuch as the bar is not formed of diagonal but of horizontal lines. A *bend-sinister*, which by the French is called a bar, has with more reason been confused with the true mark of illegitimacy, and has on that account been avoided even by heralds. But the real bastard bar differs very essentially from the bend-sinister, being half of the scarp, which again is half of the bend-sinister. "The half of the scarp," says Nisbet, "with the English is called a Batton-sinister; by the French, Baston-sinister; it is never carried in arms but as a mark of illegitimation, commonly called the Bastard-barr." In modern practice the baton does not touch the extremities of the shield, or of the quarter in which the paternal arms are placed, but is *couped*—that is, cut short at the ends. In this form the baton, when used as a mark of illegitimacy, is placed over the paternal coat of the bastard, whether used singly or in a quartered shield. Nisbet informs us that the baton-sinister, both in England and Scotland, is comparatively of modern invention, natural children in earlier times not having been permitted to assume the arms or even the names of their fathers. "The unlawful children of John of Gaunt, Duke of Lancaster, begot on Katharine, daughter of Sir Payen Roat Guyn, King of Arms, did not carry the arms of their father the king, though nobilitate, with a baton-sinister, as now used; . . . but after the legitimation of these three natural sons by Act of Parliament, they then assumed the sovereign ensigns of England, within a bordure gobbonated argent and azure." According to the practice of France, which probably was followed in England also, the bastard could not cancel or alter the baton without the consent of the chief of the family or the authority of the sovereign. Even where the baton was not removed, it was common for the sovereign to grant his permission to carry it *dexter*, in place of sinister. Charles VII. of France allowed John, the Bastard of Orleans, for his valor against the English, to turn his sinister traverse to the dexter, with which he and his issue afterwards *bruised* the arms of Orleans, as dukes of Longueville. The same privilege was granted to James, Earl of Murray, natural son of King James V. of Scotland, by his sister Queen Mary, and he thenceforth carried the Lion and tressure of Scotland thus bruised, quartered with the feudal arms of the earldom of Murray. The general practice of the milder heraldry of our own day is to substitute the gobbonated bordure for the bastard bar, not only in the case of the legitimate children of bastards, but of bastards themselves.



Bastard Bar.



Earl of Murray's Arms.

BASTARD-CULVERIN.—A cannon of the French artillery, under Henry II., carrying a projectile weighing 7 pounds 2¼ ounces.

BASTARDEAU.—The small knife often seen on the sheath of the *anelace*.

BASTARD FILE.—A file much used in the armory, of a grade between the *rough* and the *smooth*, in respect of the relative prominence and coarseness of the teeth. The order is as follows: rough, middle-cut, bastard, second-cut, smooth, and dead-smooth. The angle of the chisel in cutting the bastard file is about 10° from the perpendicular. The number of cuts to the inch varies with the length of the file in inches.

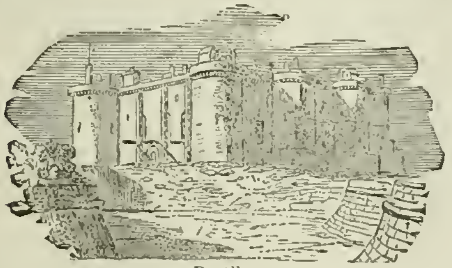
Inches.........	4	6	8	12	16	20
Cuts...........	76	64	56	48	44	34

See *File*.

BASTERNA.—The *basterna* of the Romans was a litter or species of sedan, carried by two mules, differing from the lectica in that the latter was borne by slaves. The name is derived from a people of the Carpathian Mountains, and was afterwards applied to a species of ox-cart or wagon used by the early kings of France. The name survives in a modern European carriage.

BASTIDE.—In ancient times, a bastion, a block-house, a fortress, or other fortification.

BASTILE—BASTILLE.—In France, a general term for a strong fortress defended by towers or bastions, and in this sense it was used in England also after the Norman Conquest. The famous prison to which the name latterly was appropriated was originally the Castle of Paris, and was built by order of Charles



Bastile.

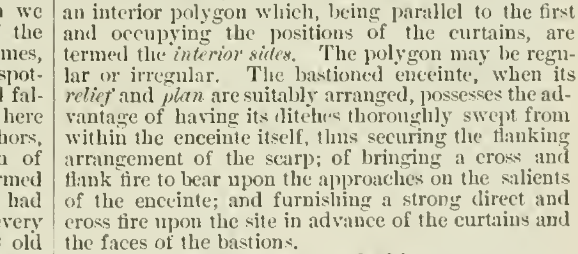
V., between 1370 and 1383, by Hugo Aubriot, Prévôt or Provost of Paris, at the Porte St. Antoine, as a defense against the English. Afterwards, when it came to be used as a State Prison, it was provided, during the sixteenth and seventeenth centuries, with vast bulwarks and ditches. On each of its longer sides the Bastile had four towers, of five stories each, over which there ran a gallery, which was armed with cannon. It was partly in these towers and partly in cellars under the level of the ground that the prisons were situated. The unfortunate inmates of these abodes were so effectually removed from the world without as often to be entirely forgotten, and in some cases it was found impossible to discover either their origin or the cause of their incarceration. The Bastile was capable of containing 70 to 80 prisoners, a number frequently reached during the reigns of Louis XIV. and Louis XV. Though small compared to the number which an ordinary prison contains, these numbers were considerable when we reflect that they rarely consisted of persons of the lower ranks, or such as were guilty of actual crimes, but of those who were sacrificed to political despotism, court intrigue, ecclesiastical tyranny, or had fallen victims to family quarrels, and were lodged here in virtue of *lettres-de-cachet*—noblemen, authors, savans, priests, and publishers. On the 14th of July, 1789, the fortress was surrounded by an armed mob, which the reactionary policy of the Court had driven into fury, and to the number of which every moment added. The garrison consisted of 82 old soldiers and 32 Swiss. The negotiations which were entered into with the Governor led to no other result than the removal of the cannon pointed on the Faubourg St. Antoine, which by no means contented the exasperated multitude. Some cut the chains of the first drawbridge, and a contest took place, in which one of the besieged and 150 of the people were killed, or severely wounded; but the arrival of a portion of the troops which had already joined the people with four field-pieces turned the fortune of the conflict in favor of the besiegers. Delaunay, the Governor—who had been prevented by one of his officers, when on the point of blowing the fortress into the air—permitted the second drawbridge to be lowered, and the people rushed in, killing Delaunay himself and several of his officers. The destruction of the Bastile commenced on the following day, amid the thunder of cannon and the pealing of the Te Deum. This event, in itself apparently of no great moment, leading only to the release of three unknown prisoners—one of whom had been its tenant for thirty years—and four forgers, and in which it is said only the 654 persons whose names now appear on the column in the Place de la Bastille took part, nevertheless finally broke the spirit of the Court Party, and changed the current of events in France.

BASTINADO.—The name given by Europeans to the punishment in use over the whole East, which consists in blows with a stick, generally upon the soles of the feet, but sometimes upon the back.

BASTION.—The precise period that the bastioned system of fortification appeared is not known, but it is generally conceded to have appeared about the time that gunpowder was first used for military purposes. The bastions constructed in 1525 in Verona are among the oldest known. The improvements made in siege-artillery towards the end of the sixteenth century caused Sully, the Prime Minister of France, Grand-master of Artillery and Superintendent of Fortifications, to take measures to modify and strengthen the fortifications then existing in France. His first step was to take them out of the hands of those who had them in keeping, and to put them in the charge of a select body of men, who had military experience, education, and knowledge of construction. From this body of men we date the origin of the French Corps of Engineers, and this period may be regarded as the beginning of the bastioned system in France. The noted military engineers, Errard, of Bar le Duc, De Ville, and Count de Pagan, were successively charged with these modifications and left their impress upon the works intrusted them. They were followed by Vauban, and he by Cormontaigne. Although modifications have been made in the bastioned system since the time of Cormontaigne, we can safely say that its essential basis is that of his method. A knowledge of the bastioned system would not be complete without an acquaintance with his method and those of Vauban.

A bastioned enceinte consists of a series of bastions, A, B, etc., which occupy the salient angles of the polygon within which the enceinte is inclosed; the flanks of the bastions being usually connected by straight curtains. The sides of the polygon which connect the salient angles of the bastions are termed the *exterior sides*, in contradistinction to the sides of an interior polygon which, being parallel to the first and occupying the positions of the curtains, are termed the *interior sides*. The polygon may be regular or irregular. The bastioned enceinte, when its *relief* and *plan* are suitably arranged, possesses the advantage of having its ditches thoroughly swept from within the enceinte itself, thus securing the flanking arrangement of the scarp; of bringing a cross and flank fire to bear upon the approaches on the salients of the enceinte; and furnishing a strong direct and cross fire upon the site in advance of the curtains and the faces of the bastions.

It is not safe to base the flanking arrangements solely upon artillery. The fire of musketry is more



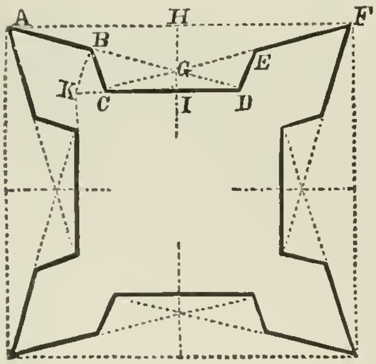
A, B.—Bastions.	KL.—Curtain.
EF.—Exterior side.	EL.—Line of defense.
NO.—Interior side.	SEI.—Salient-angle.
PQ.—Perpendicular.	EIK.—Shoulder-angle.
EI.—Face.	IKL.—Curtain-angle.
IK.—Flank.	IEP.—Diminished angle.

deadly and more effective, and upon it these arrangements are based. Its effective range, the ordinary limits of distinct vision, and the skill in using this arm are all to be considered. Supposing the enemy able to gain a position within 50 yards of the salient, he should there be within range of the musketry-fire of the flanks. With the improved arms of the present time, we may assume this distance to be 300 yards. The musketry may be supplemented by Gatling guns, or other inventions of the same nature, but the basis of the flanking arrangements must be the arm used by the infantry soldier.

The position of the flank will vary between the limits, a perpendicular to the curtain, and a perpendicular to the opposite face let fall from the point where the curtain intersects the line of defense. A position intermediate to these has been generally adopted; in most cases, placing *the flank so as to make an angle of about* 100° *with the curtain*. The length should be sufficient to allow it to be armed with at least two pieces of artillery; this will determine the least length of flank. It may be increased beyond this, to any extent demanded by the circumstances of the defense. From the effect had in so doing to increase the length of curtain and to diminish the interior space in the bastion, the *maximum length* has been restricted to 50 *yards*.

The face of the bastion is usually directed on the curtain-angle. In this case the entire fire of the flank can be brought to bear on the enceinte-ditch along the foot of the scarp-wall of the face. Circumstances may require a different position: directing it on some point on the curtain, or on some point on the flank. With the advantages gained there will be corresponding disadvantages. Their relative values will decide it. The relative positions of the curtain, flanks, and lines of defense, and their respective lengths affect the length of the faces. If the line of defense is equal only to the distance between the curtain-angle and opposite shoulder-angle, the corresponding length of face will be zero; if the curtain and the flanks have their least and the line of defense its greatest length, the resulting face will be the longest that we can have.

BASTIONED FORTS. — The bastioned fort has been devised to remedy defective flanked dispositions. It may consist of a polygon of any number of sides, but for field-forts the square and pentagon are generally preferred. To plan a work of this



kind, a square or pentagon is first laid out, and the sides bisected by perpendiculars, HI; a distance, GH, of one eighth of a side in a square (one seventh in a pentagon) is set off on the perpendiculars; from the angular points of the polygon, lines DA, CF are drawn through the points thus set off: these lines give the direction of the lines of defense; from the salients of the polygon, distances equal to two sevenths of a side are set off on the directions of the lines of defense, which give the faces; from the extremities of the faces the flanks are drawn perpendicular to, or making an angle of 110 with, the lines of defense; the extremities of the flanks are connected by curtains, CD.

In deciding on the general plan to be carried out, the following considerations require attention: the object the work is expected to fulfill, and its situation with respect to the enemy; whether it is likely to be attacked by overwhelming forces; whether artillery is likely to be brought against it, or infantry, and whether it can be surrounded; the number of men there will be for its defense, observing that it is better to have a force concentrated, and that it is therefore injudicious to make works of a greater extent than can be well manned and vigorously defended. Another consideration that must not be omitted is the number of men that can be collected for working, whether they are one's own men or inhabitants, and whether there are tools enough and time enough to do it.

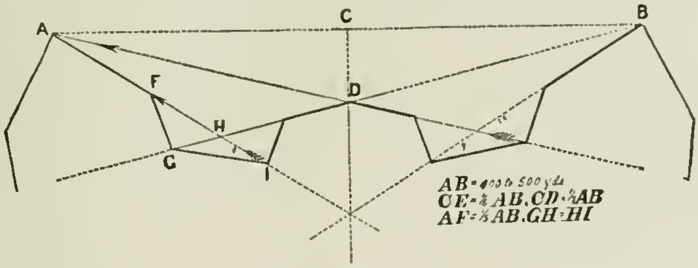
An examination of the arrangement of a bastioned front will show that there are neither dead-angles nor sectors without fire; that the salients, and all the ground within the range of fire, are protected by formidable columns of direct, flank, and cross fire. There is one point in this system that demands particular attention, which is, that the counterscarp of the ditch, if laid out parallel to the interior crest, would form a dead-angle along each face near the shoulder; because the fire of the flank would be intercepted by the crest of the counterscarp. To prevent this, either the counterscarps of the faces must be prolonged to intersect, and all earth between them and the scarp of the flanks and curtain be excavated, or the ditch of each face must be inclined up in a slope from the bottom, opposite the shoulder, so that it can be swept by the fire of the flank. The first method is the best, but requires most labor; the second is chiefly objectionable as it gives an easy access to the ditch, which might be taken advantage of in an assault. It is proposed, to obviate this, to dig a second ditch at the foot of the slope across the main ditch, twelve feet wide and about six feet deep; to make it pointed at the bottom, and to plant a row of palisades in it.

Forts have been proposed with half-bastions, but, being very little superior to the redoubt and much more difficult of construction, they ought never to be used. The exterior sides of the bastioned fort should not exceed 250 yards, nor be less than 125 yards, otherwise the flanking arrangements, with the smoothbore musket in the former case, and the flanks too short in the latter, will be imperfect. With a relief of twenty-four feet, which is the greatest that, in most cases, can be given to field-works, and an exterior side of 250 yards, the ditch of the curtain will be perfectly swept by the fire of the flanks, the lines of defense will be nearly 180 yards, a length which admits of a good defense, and the flanks will be nearly thirty yards. With a relief of fourteen feet, the least that will present a tolerable obstacle to an assault, and an exterior side of 125 yards, the ditch of the curtain will be well flanked, the flanks will be nearly twenty yards in length, and the faces between thirty and forty yards. Between these limits, the dimensions of the exterior side must vary with the relief. See *Fortification*.

BASTIONED LINE.—Owing to the imperfect flanking arrangements of other lines, it has been proposed to use bastioned lines. They are laid out by placing the salients 250 yards apart, and making the perpendicular of the front equal to one sixth.

Another arrangement of the bastioned line, shown in the drawing, has *double flanks*. The salients, in this case, should be between 400 and 500 yards apart. The drawing explains itself. By this arrangement there are fewer assailable points on the same front; one of the bastions is placed in a strong re-entering; and the salients of the advanced bastions are protected by the flank fire of the collateral advanced bastion, and also of the retired bastion. The principal objection to the bastioned line is its great development, and the consequent increase of labor and time for its construction. This objection, however, does not apply to a front of limited extent where the flanks of the line rest upon natural features like unfordable water-courses, or upon an impassable marsh which will prevent the line from being turned.

Continued lines are not suited to an active defense; and this is a grave objection to their use. Moreover, from the great dissemination of the troops over a long defensive line, the resistance at all points will be weak, and if one point is carried the rest of the line is taken in flank. Besides, the main reserve being at the center, the flanks may fail to receive timely succor if attacked. The enemy, if repulsed by their fire, can retreat in good order, and renew the assault at a more opportune moment; because the assailed, if they attempt a sortie, must defile through narrow outlets, and present a feeble front to the enemy during the operation of defiling. They are, however, the best defensive means for irregular troops, owing to the confidence which they inspire. They also serve to guard against a surprise, and to prevent the predatory excursions of small detachments of the enemy. See *Lines.*



Bastioned Line.

BASTIONET.—A small bastion in masonry, either casemated or open and placed at the salient of a work. When casemated, the masonry should be covered by the glacis.

BASTION-FACE CUT.—The object of this cut is similar to the one in the demi-lune face; it confines the enemy to the salient part of the bastion, preventing him from extending his works along the bastion terre-plein, to turn the cavalier by its gorge; so that to obtain possession of this work he must make a breach in its face. The arrangement of the ditch of the cavalier frequently subjects only a part of it to the fire of the parapet behind the cut. This dead space might offer some advantages were the enemy to attempt to carry the parapet of the cut by escalade. To remedy this defect, it has been proposed to place a crenated gallery behind the scarp-wall of the cut, to flank the entire ditch. By placing the door of the postern that leads into the cavalier-ditch at the point where the vertical wall separates the two levels, it will be partially covered from the enemy's lodgment on the bastion terre-plein. The disposition of the cavalier and cuts within the bastion does not leave sufficient space upon the terre-plein of the latter to organize a covered-way. But in the retrenchments of open bastions, resting on the flanks or curtains, to which the form of a tenaille or small bastioned front is given, a covered-way, with a re-entering place-of-arms closed by traverses, can be organized, which will give considerable additional confidence and security in the defense of the breach in the bastion with the bayonet. The organization of these covered-ways presents no peculiarity. They should, as far as practicable, be defiled from the besieger's lodgments within the bastion assailed. See *Demi-lune Cut.*

BASTON.—1. A formidable club which was used as a war-club in the early Norman battles. It was not an unusual weapon at that period, and seems to have been the precursor of the iron mace of the Middle Ages.

2. In Heraldry, a staff or cudgel generally borne as a mark of bastardy, and properly containing one eighth in breadth of the bend-sinister.

BAT.—The name of a kind of pack-saddle; and hence a bat-horse was a baggage-horse bearing a bat or pack, and a bat-man was a servant in charge of the horse and bat. By a modification of meaning, a bat-man is now any soldier allowed to act as servant to an officer. When British troops are sent on foreign service, bat-horses or mules are provided (if carriages are not forthcoming) for carrying the regimental books, the kettles, the tents, the medicine-chest, the veterinary medicine-chest, intrenching-tools, armorers' stores, saddlers' stores, etc.—about twenty such horses or mules to each battalion. Bat-horses and bat-men are also provided for carrying officers' camp-equipage. An allowance for procuring these accommodations is usually called bat-money.

BATAGE.—The time employed in reducing gunpowder to its proper consistency. The French usually consume 24 hours in pounding the materials to make good gunpowder. Supposing the mortar to contain 16 pounds of composition, it would require the application of the pestle 3500 times each hour. The labor required in this process is less in summer than in winter, because the water is softer.

BATAILLON DE LA SALADE.—A name formerly given in France to old corps which wore a peculiar kind of helmet called *salade.*

BATARDEAU.—A strong wall of masonry, built across the outer ditch of a fortress, to sustain the pressure of water when one part of the ditch is dry and the rest wet. It is built up to an angle at the top, and is armed with spikes, to prevent the enemy from crossing; and sometimes a stone tower is provided to strengthen the defense. There is a sluice-gate to regulate the admission of water.

BAT DE MULET.—A pack-saddle used in service when mules are employed to carry stores. Aparejos in the United States service are used for a similar purpose. See *Aparejo.*

BATEAU-BRIDGE.—A floating bridge supported by bateaux or light boats. See *Ponton.*

BATEAU D'AVANT-GARDE.—A small light boat attached to the advance-guard of an army. It is 33 feet in length by 5 feet 6 inches in breadth.

BATH.—The name of the Order of the Knights of the Bath is derived from the ceremony of bathing, which used to be practiced at the inauguration of a knight, as an emblem of the purity henceforth required of him by the laws of chivalry. The ceremony is of rather unknown antiquity, and is spoken of by writers of the thirteenth century as a very ancient custom. The earliest authentic instance of its observance which we have is in the time of Henry IV., who, in preparing for his coronation, made forty-six knights at the Tower of London, who had watched all the night before, and bathed themselves. The last Knights of the Bath created in the ancient form were at the coronation of Charles II. in 1661. From that period till the accession of the House of Hanover, the order fell into oblivion.

Star of the Bath.

It was revived by George I. in 1725, and is now the second order in rank in England, the first being the Garter. By the statutes then framed for the government of the order, it was declared that, besides the Sovereign, a prince of the blood, and a great master, there should be thirty-five knights. At the conclusion of the great war, it was thought expedient, with a view to rewarding the merits of many distinguished officers, both military and naval, to extend the limits of the order, which was effected on the 2d January, 1815. But the order was still purely military, and it was not till 1847 that it was placed on its present footing by the admission of Civil Knights, Commanders, and Companions. The following is its present organization:

First Class.—Knights Grand Cross (K.G.C.); the number not to exceed, for the military service, 50, exclusive of the royal family and foreigners; and for the civil service, 25.

Second Class — Knights Commanders (K.C.B.); military, 102, and civil, 50, exclusive of foreigners. These, like the first, have the title *Sir*, and take precedence of Knights Bachelors.

Third Class.—Companions (C.B.); military, 525, and civil, 200. They take precedence of Esquires, but are not entitled to the distinctive appellation of knighthood. No Officer can be nominated to the military division of this class unless his name has been mentioned in the *London Gazette* for distinguished services in action; and the order has never been conferred on an Officer below the rank of a Major, or Commander in the Navy.

BAT-HORSES.—Baggage horses or mules for carrying officers' baggage on service. The ammunition and regimental stores are also so carried when carts are not procurable.

BAT-MEN. — Originally servants hired in wartime to take care of the horses belonging to a train of artillery, battery, baggage, etc. Men who are excused regimental duty for the specific purpose of attending to the horses belonging to Officers are also called bat-men or bor-men.

BATON.—1. The figure in Heraldry commonly known as the bastard bar. It is variously written Battoon, Batune, and, in old French, Baston.—2. The name of a short staff presented by the Sovereign to each Field-marshal, as a symbol of his newly bestowed authority. It is also the name of the long staff carried by the Drum-major of a band. See *Bastard Bar* and *Drum-major*.

BATTA.—An Indian term implying field-allowances, which were granted formerly to troops in India in addition to their regimental pay; this was called full batta. Half-batta was half this allowance, and was paid to officers serving at the presidency towns, and within 200 miles of them—full batta being given to officers beyond that distance. There is no such distinction in name now as half and full batta in the pay of the officers, though in reality officers of the several Staff Corps in India only receive half-batta, the difference being made up in their allowances. Officers of British regiments receive full batta wherever they may be.

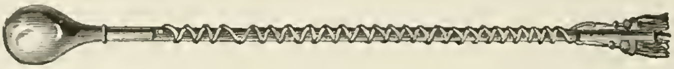
BATTALIA.—The order of battle; disposition or arrangement of troops, brigades, regiments, battalions, etc., as for action. Formerly the term applied to the main body of an army in array, as distinguished from the wings.

BATTALION.—A body of troops, so called from being originally a body of men arranged for battle. In the United States army, a regiment of infantry is composed of ten companies. A regiment, or any part of a regiment composed of two or more companies, is designated a *battalion.* For maneuvers the battalion is generally divided into an even number of companies, and the companies are equalized by transferring men from the larger to the smaller. Two companies constitute a *division.*

In each battalion there is a Color-guard, composed of a Color-sergeant and seven Corporals, which is posted as the left four of the right-center company. The front rank is composed of the Color-sergeant and three senior Corporals, one posted on his right and two on his left; the rear rank is composed of the four remaining Corporals. The Corporals are placed in the order of rank from right to left. The Color-sergeant and Color-corporals are selected from those most distinguished for bravery, and for precision under arms and in marching. The Color-sergeant carries the national color. The regimental color (when present) is carried by a Sergeant, who takes the place of the Corporal on the left of the Color-sergeant.

Posts of Field-officers and Regimental Staff.—The Field and Staff Officers are supposed to be mounted during all maneuvers; the Adjutant is on foot. The Senior Officer present commands the battalion. The *Colonel* is posted thirty yards in rear of the file-closers, opposite the center of the battalion. This distance is reduced as the front of the battalion is diminished. The *Lieutenant-colonel* and *Major* are on a line twelve yards in rear of the file-closers; the Lieutenant-colonel opposite the center of the right wing, the Major opposite the center of the left wing. The *Adjutant* and *Sergeant-major* are opposite the right and left of the battalion, six yards in rear of the file-closers. They aid the Lieutenant-colonel and Major respectively in their duties. At reviews, parades, and inspections, the *Adjutant* takes post three yards to the right of the front rank of the battalion; the *Sergeant-major* three yards to the left of the front rank. The *Surgeon, Quartermaster*, and other Staff-officers, in the order of rank from right to left, are on the left of the Colonel, and three yards in his rear. In column the Staff marches abreast of the center, on the flank opposite the guide, and at the same distance from the column as from the file-closers when in line. If the guide be changed, the Staff, unless otherwise directed, passes by the rear of the column to the opposite flank. In line, if the battalion wheels about by fours, the Staff, unless otherwise directed, passes around either flank to the new position in rear. In all battalion maneuvers, the Staff moves to its new position, in line or column, by the shortest practicable line, not passing between subdivisions. The *Quartermaster-sergeant, Commissary-sergeant*, and the *Hospital-steward* are in rear of the left-center company in the order of rank from right to left, three yards on the right, and in line with the front rank of the band. In all battalion maneuvers, the Non-commissioned Staff, except the Sergeant-major, conforms to the movements of the band.

Posts of the Band, and Trumpeters or Field-music.—The *band* is formed in two or more ranks, with sufficient interval between the files, and distances between the ranks, to permit a free use of the instruments. The *Trumpeters*, if not with their companies, form the rear of the band. When the band is not present, the post of the trumpeters and their movements are the same as prescribed for the band. In line, the band is habitually posted twelve yards in rear of the file-closers, the left opposite the left of the left-center company. At reviews, parades, and inspections, the band is posted on the right of the battalion, the left of its front rank twelve yards from the right of the front rank of the battalion. In column, except at review and inspection, the band is twelve yards from



Drum-Major's Baton.

the center of the column on the flank opposite the guide. If the guide be changed, the band, unless otherwise directed, passes by the rear of the column to the opposite flank. In line, if the battalion wheels about by fours, the band, unless otherwise directed, passes around either flank to its position in rear. In all battalion maneuvers, the band moves at quick or double time, by the shortest practicable line, to its position in line or in column; the march being so conducted as not to pass between the subdivisions, nor delay their march. When the signals for the Drum-major are not used, the band is maneuvered as explained for a squad, the command *band* being substituted for *squad*. When the battalion in column wheels about by fours, the band executes the countermarch; when the battalion executes the *right, left*, or *about face*, the band faces in the same manner. In marching, the different ranks of the band always dress to the right.

A battalion of Cavalry is usually composed of four companies, but may be composed of a less number, or a greater number not exceeding seven. The interval between companies in line is eight yards. In whatever direction the battalion faces, the companies are designated numerically from the right to the left in line, and from the head to the rear when in column, *first company, second company*, and so on. In whatever direction the battalion faces, the companies to the right of the center of the battalion in line constitute the *right wing;* those to the left of the center constitute the *left wing*. If there be an odd number of companies in line, the center company always belongs to the right wing.

Posts of Field-officers, Adjutant, and Sergeant-major.—The Senior Officer present commands the battalion, and in line is thirty yards in front of the center. If there be two Field-officers present, *the Junior*, in line, in line of platoon columns, and in line of double columns, is twelve yards in rear of the center of the battalion. If the battalion faces about, the Junior Field-officer passes by the shortest line to his place in rear. In column, the Junior Field-officer is twelve yards from the flank of the column, abreast of the center and on the side of the guide. In marching by the flank of subdivisions, he is twelve yards in rear of the center subdivision. In the maneuvers, the Junior Field-officer assists as the Commanding Officer may direct. *The Adjutant* is on the line of Chiefs of Platoon, and three yards outside of the right flank of the battalion. When the battalion faces about, the Adjutant wheels about and takes his place on the line of Chiefs of Platoon, but does not change to the other flank. *The Sergeant-major* is in line with the rank, three yards from the left flank. When the battalion faces about, the Sergeant-major wheels about, and takes his place at the prescribed interval from the rank, but does not change to the other flank.

A battalion of Artillery consists of any number of batteries from two to five. The interval between batteries in line is twenty-eight yards. In *horse-batteries* the interval is thirty-six yards. In whatever direction the battalion faces, the batteries are designated numerically from the right to the left in line, and from the head to the rear when in column, *first battery, second battery*, and so on. In whatever direction the battalion faces, the batteries to the right of the center of the battalion in line constitute the *right wing;* those to the left of the center constitute the *left wing*. If there be an odd number of batteries, the center battery always belongs to the right wing.

Posts of Major, Adjutant, Sergeant-major, and Trumpeter.—The *Major*, or Senior Officer present, commands the battalion, and in line is twenty-eight yards in front of the center. The *Adjutant* is in line with the Chiefs of Platoon, and three yards outside of the right flank of the battalion. When the battalion faces to the rear, the Adjutant executes an about and takes his place in line with the Chiefs of Platoon, but does not change to the other flank. The *Sergeant-major* is in line with the Chiefs of Platoon, three yards from the left flank. When the battalion faces to the rear the Sergeant-major executes an about, and takes his place in line with the Chiefs of Platoon, but does not change to the other flank. At review, other Staff-officers, in line, are on the right of the Adjutant; in column, they are in rear of the Major. On all other occasions they accompany the Major.

To Form the Battalion.

Infantry.—The companies being formed on their parade-grounds, *adjutant's call* is sounded, at which the Adjutant and Sergeant-major, the latter on the left, each covered by a Marker, march to the regimental parade-ground, where they post the Markers facing each other at a distance apart a little less than the front of a company; the Adjutant posts the Marker nearest the right of the line, the Sergeant-major the one nearest the left, each standing three yards in rear of the Marker nearest him; the Markers being assured, the Adjutant takes a side-step to the left, the Sergeant-major a side-step to the right, draw swords, and face about; the Adjutant then proceeds company distance toward the right of the line, the Sergeant-major company distance toward the left of the line, when they halt, face about, and again cover the Markers; the line is prolonged in the right wing by the Right Guides, who precede their companies on the line by fifteen or twenty yards, and establish themselves facing the Markers, each at company distance from the Marker or guide in front of him; the Adjutant assures the position of the Right Guides, placing himself in their rear as they successively arrive; the line is similarly prolonged in the left wing by the Left Guides, the Sergeant-major assuring them in their positions as they successively arrive. The Guides invert their pieces in front of the center of the body, barrel to the right, the right hand below the left, the small of the stock above the head. The color-company is the first established, and is conducted by its Captain so as to arrive from the rear, parallel to the line of Markers. When it arrives at three yards from the line, the Captain halts it, places himself facing to the front, near the left Marker, and then dresses the company to the left, the breasts of the men opposite the right and left Markers resting respectively against their left and right arms; the companies of the right wing form successively from left to right, each being halted at three yards from the line and dressed to the left as explained for the color-company; the Left Guide, at the command *halt*, returns to the line of file-closers; the companies of the left wing form successively from right to left, and are dressed to the right. In all alignments, the First-sergeants, if not employed to mark the line, step into the rear rank to enable the Captains to dress their companies. To enable the Captain of the company on the left of the color to align his company to the right, the Captain of the color-company steps a pace forward if he be the Senior, or into the rear rank if he be the Junior; if the Senior, he steps back into the front rank as soon as the Junior Captain commands *front;* the latter steps back to the rear rank; the First-sergeant of the left center company steps back to the line of file-closers. Each Captain commands: 1. (such) *Company*, 2. *Support*, 3. Arms, as soon as the Captain next succeeding him in his own wing commands *front;* the flank companies *support arms* as soon as dressed. Before sounding *adjutant's call*, the band takes a position designated by the Adjutant, and marches at the same time as the companies to its position in line. The Colonel takes post facing the line, at a distance in front of the center of the battalion, about equal to half its front. The Adjutant having assured the position of the Right Guide of the right company, faces about, marches three yards to the right of the front rank, faces to the left, moves two yards to the front, faces to the left and halts, and, when the last company arriving on the line is brought to *support arms*, commands: 1. *Guides*, 2. Posts. At the command *guides posts*, the Captains, Guides, and Markers take their posts in line; the First-sergeants, who are not employed to mark the line, step a pace to the rear to permit the Second-sergeants or Markers to pass through their intervals to the line of file-closers, after which they return to the front rank. *This rule is general.* The Adjutant then passes along the front in rear of the Captains, to the center, turns to the right, halts midway between the Captains and the Colonel, faces about, brings the battalion to a *carry*, and a *present arms*, resumes his front, salutes his Colonel, and reports: *Sir! The battalion is formed.* The Colonel returns the salute with the right hand, directs the Adjutant: *Take your post, Sir*, draws his sword and commands: 1. *Carry*, 2. Arms. The Adjutant faces about, and returns to his post, passing in rear of the Captains of the right wing around the right of the battalion.

Cavalry.—The companies being formed and mounted on their own grounds, *adjutant's call* is sounded, at which the Adjutant and Sergeant-major, the latter on the left, proceed to the battalion parade-ground, and post themselves facing each other, a few yards outside the points where the right and left of the right center company is to rest in line. The companies approach the line so as to arrive from the rear, and parallel to the line established by the Adjutant and Sergeant-major. The right-center company (or center company, if the number of companies be uneven) is first established on the line. As the right-center company approaches the line, its Principal Guides detach themselves, and, preceding the company by fifteen or twenty yards, place themselves between the Adjutant and Sergeant-major, facing each other, at a distance a little less than the front of the company. The Adjutant rectifies the position of the Right Principal Guide; the Sergeant-major rectifies the position of the Left Principal Guide. The Captain of the right-center company halts his company three yards from the line, places himself on the line, facing to the front, at the point where the left of his company will rest in line, and then dresses it to the left against the Principal Guides, so that the heads of the horses opposite the Principal Guides shall touch the boots of the Principal Guides. The other companies successively approach the line, in their order on the right and left of the right-center company. The Principal Guides of each company detach themselves as prescribed for the Guides of the right-center company, and hasten to place themselves on the line to be occupied by their respective companies; they face toward the Principal Guides already established, at a distance from each other a little less than the company front; the Principal Guide nearest those already established carefully preserves the interval of eight yards between companies. The Adjutant and Sergeant-major, having rectified the positions of the Principal Guides of the company which arrives first on the line, draw sabers; the Adjutant then wheels to the right about, moves toward the right, and again wheels to the right about, so as to place himself in rear of the Right Principal Guide of the company next on the right. The Sergeant-major wheels to the left about, moves toward the left, and wheels to the left about, so as to place himself in rear of the Left Principal Guide of the company next on the left. In this manner the Adjutant in the right wing, and Sergeant-major in the left wing, rectify in succession the positions of the Guides of each company; they then take their places in line. Each Captain halts and dresses his company as prescribed for the right-center company, each company being dressed toward the company first established. The line being formed, the Adjutant advances three yards from his position on the right, wheels to the left, halts, and commands: 1. *Guides*, 2. Posts, at which the Captains and Principal Guides return to their posts in line. The Major takes post facing the line, at a convenient distance in front of the center of the battalion, generally equal to about half its front. The Adjutant then passes in front of the officers to the center, wheels to the right, and halts midway between the Major and the line, wheels to the left about, commands: 1. Draw, 2. Saber, 3. *Present*, 4. Saber, wheels to the left about, salutes the Major and reports: *Sir! The battalion is formed.* The Major returns the salute with the right hand, directs the Adjutant: *Take your post, Sir*, draws his saber, and commands: 1. *Carry*, 2. Saber. The Adjutant wheels to the left about, moves toward the line, wheels to the left, and, passing in front of the officers, takes his place on the right.

Artillery.—The batteries being formed at their own parks, *adjutant's call* is sounded, at which the Adjutant and Sergeant-major, the latter on the left, proceed to the battalion parade-ground, and post themselves facing each other, a few yards outside the points where the right and left of the right-center battery is to rest in line. The batteries approach the line so as to arrive from the rear, and parallel to the line established by the Adjutant and Sergeant-major; the right-center battery (or center battery, if the number of batteries be uneven) is first established on the line. As the right center battery approaches the line, the First-sergeant and Guidon, who are called *Principal Guides*, detach themselves, precede the battery by fifteen or twenty yards, and place themselves between the Adjutant and Sergeant-major, facing each other, at a distance apart a little less than the front of the battery; the Adjutant rectifies the position of the First-sergeant; the Sergeant-major that of the Guidon. The Captain of the right-center battery halts it at three yards from the line and dresses it to the left as prescribed in the School of the Battery, so that the heads of the lead-horses of the leading carriages of the right and left sections shall be in line with the boots of the Principal Guides. The other batteries successively approach the line on the right and left of the right-center battery. The Principal Guides of the other batteries detach themselves as prescribed for the guides of the right-center battery, and hasten to place themselves on the line to be occupied by their respective batteries; they face toward the Principal Guides already established, at a distance from each other a little less than the battery front; the Principal Guide nearest those already established carefully preserves the interval of twenty-eight yards between the batteries. The Adjutant and Sergeant-major, having rectified the positions of the Principal Guides of the battery which arrives first on the line, draw saber; the Adjutant then executes a right about, moves toward the right, and again executes a right about, so as to place himself in rear of the Right Principal Guide of the battery next on the right; the Sergeant-major executes a left about, moves toward the left, and executes a left about, so as to place himself in rear of the Left Principal Guide of the battery next on the left. In this manner the Adjutant in the right wing, and the Sergeant-major in the left wing, rectify in succession the positions of the guides of each battery; they then take their posts in line. Each Captain halts and dresses his battery as prescribed for the right-center battery; each battery is dressed toward the right-center battery. The line being formed, the Adjutant advances three yards from his post on the right, wheels to the left, halts, and commands: 1. *Guides*, 2. Posts, at which the Captains and Principal Guides return to their posts in line. The Major takes post facing the line, at a convenient distance in front of the center of the battalion, generally equal to about half its front; the Adjutant then passes in rear of the Captains to the center, wheels to the right, and halts half-way between the Major and the line, executes a left about, commands: 1. *Present*, 2. Saber, executes a left about, salutes the Major, and reports: *Sir! The battalion is formed.* The Major returns the salute with the right hand, directs the Adjutant: *Take* *your post, Sir,* draws saber, and commands: 1. *Carry,* 2. SABER. The Adjutant executes a left about, moves toward the line, wheels to the left, and, passing in rear of the Captains, takes his post on the right. See *Inspection of Troops, Muster,* and *Review.*

BATTARD.—An early cannon of small size, now obsolete. See *Cannon.*

BATTEN.—1. The sloping of a wall which brings the perpendicular from the top inside the base.—2. A species of sawn fir timber, of smaller dimensions than the kind called planks. Battens are usually from 12 to 14 feet long, 7 inches broad, and 2½ inches thick. Cut into two boards (1¼ inches thick), they are used for flooring; cut into three boards, they are put on roofs below slates; in narrower pieces, they are put upright on walls for fixing the laths for plastering. The best battens are brought from Norway, and sold wholesale by wood-merchants.

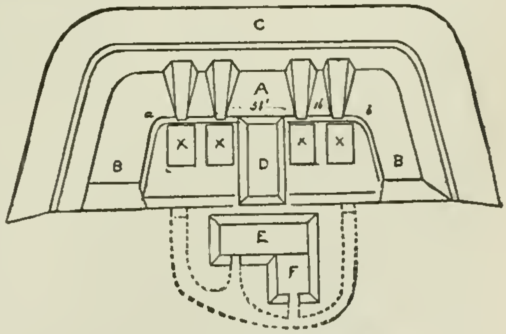
BATTER.—1. A cannonade of heavy ordnance, from the first or second parallel of an intrenchment, against a fortress or other works. To batter *in breach* implies a heavy cannonade of many pieces directed to one part of the revetment from the third parallel.—2. In fortification, the backward slope of a revetment or retaining wall. The drawings show the batter-slopes adopted by Engineers at the present time. These slopes are 1 in 4, 1 in 5, 1 in 6, 1 in 8, 1 in 10, and 1 in 12.

BATTERIE EN ROUAGE.—An enfilading battery, when directed against another battery.

BATTERIES.—A battery consists of two or more pieces of artillery in the field. The term *battery* also implies the emplacement of ordnance destined to act offensively or defensively. It also refers to the company charged with a certain number of pieces of ordnance. The ordnance constitutes the battery. Men serve the battery. Horses drag it, and epaulments may shelter it. A battery may be with or without embrasures. In the latter case it is *en barbette,* and the height of the *genouillère* varies according to the description of the gun-carriage used. The ordnance constituting the battery requires substantial bearings either of solid ground for field-pieces, or of timber, plank, or masonry platforms, for heavy artillery. Batteries are sometimes designated as follows: *Barbette battery,* one without embrasures, in which the guns are raised to fire over the parapet; *Ambulant battery,* heavy guns mounted on traveling carriages, and moved as occasion may require, either to positions on a coast, or in besieged places; *Covered battery,* intended for a vertical fire, and concealed from the enemy; *Breaching battery; Joint batteries,* uniting their fire against any object; *Counter battery,* one battery opposed against another; *Coast battery; Direct battery; Cross batteries,* forming a cross fire on an object; *Oblique battery,* forming an angle of 20° or more with the object against which it is directed, contradistinguished from direct battery; *Raised battery,* one whose terre-plein is elevated considerably above the ground; *Sunken-battery,* where the sole of the embrasures is on a level with the ground, and the platforms are consequently sunk below it; *Enfilading battery,* when the shot or shell sweeps the whole length of a line of troops or part of a work; *Horizontal battery,* when the terre-plein is that of the natural level of the ground, consequently the parapet alone is raised and the ditch sunk; *Open battery,* without epaulment or other covering, wholly exposed; *Indented battery,* or battery *à crémaillère,* battery constructed with salient and re-entering angles for obtaining an oblique as well as a direct fire, and to afford shelter from the enfilade fire of the enemy; *Reverse battery,* that which fires upon the rear of a work or line of troops; *Ricochet battery,* whose projectiles, being fired at low angles, graze and bound without being buried; *Masked battery,* artificially concealed until required to open upon the enemy.

Field-batteries, in sieges, are usually of two kinds, viz., Elevated batteries and Sunken batteries, and they are placed either in front of the parallel, in the parallel itself, or in rear of it. In an elevated battery, the platforms for the guns or mortars to stand upon are laid on the natural level of the ground, and the whole of the covering mass, or parapet, is raised above that level, the earth for forming it being obtained from a ditch in front. In a sunken battery, the whole interior of the battery is excavated about three feet deep, and the platforms laid on the bottom, the earth is thrown to the front, and the parapet is formed out of it. Great care must be taken that no rise in the ground before the battery obscures the view from the soles of the embrasures; for this purpose, the officer laying out the battery should lie down and look along the ground, in order to be sure that his guns can range freely from their embrasures, before he fixes his details for construction. When guns are fired with an elevation, when the soil is sandy or gravelly, when the weather is dry, or the ground elevated, this construction is approved. The depth of the excavation for the interior must depend on the height of the carriages upon which the guns are mounted: it should be deeper in rear than in front, that it may be drained. The interior slopes of these batteries, and the cheeks of the embrasures, must be supported by field-revetments of gabions, fascines, sand-bags, casks, or sods. In batteries exposed to a heavy fire, especially of shells, it is necessary to provide as much cover as possible for the men serving in them; for this purpose, traverses are usually placed between every two guns; and as these masses serve to protect the men from the splinters of the bursting shells, they are generally called splinter-proof traverses. There is nearly twice as much work in the elevated as in the sunken battery.

A battery for four siege-pieces is represented in the drawing. In this construction, the parapet (A) is



Battery for Four Siege-Pieces.

made of earth taken from the front, thus forming a ditch (C). To protect the pieces (× × × ×) from flank fire, the parapet is continued around on one or both ends, forming epaulments (B B). The guns are in pairs, separated by a traverse (D). The interval between the axes of the embrasures of each pair is 16 feet for guns on traveling carriages, and from 18 to 22 feet for sea-coast guns. Between the two middle pieces this distance is increased by the thickness of the traverse, generally about 15 feet. The entire length of the interior crest of the parapet, from *a* to *b,* will therefore be 79 feet. This and other given dimensions are not absolute, but indicate the method of obtaining the data necessary for laying out *any* battery. The length of the flank epaulments will depend upon the direction of the enemy's fire; in all cases it must be sufficiently great to give full protection to the whole interior from an enfilading fire;

generally it would be about 24 feet. The thickness of the parapet and epaulments will depend upon the power of the artillery they are expected to resist.

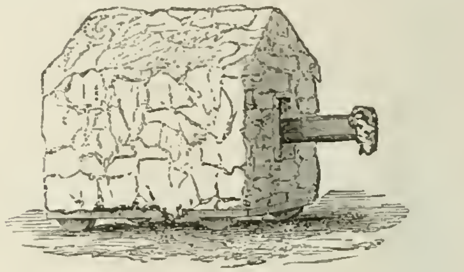
Batteries for even the heaviest pieces may be constructed on marshy ground by laying a grillage of timber over the surface and building up the parapet on it with sand-bags. To prevent the parapet from settling over towards the front, the grillage should extend several feet beyond it in that direction. In order that the platform of the piece may not be moved from its true horizontal position by any settling of the parapet, the space to be occupied by it is inclosed with strong sheeting piles. In this inclosed space several layers of fascines are laid, crossing each other at right angles; on these earth or sand is rammed, and the platform laid in the usual manner. If sand is used on top of the fascines, two or three thicknesses of paulins should be spread over them to hold the sand. Magazines in such localities must, of necessity, be entirely above ground, and supported on grillage in the same manner. See *Embrasure*.

BATTERING CHARGES.—In the service of artillery there are two classes of cartridges, *battering* and *full*. The first is used with Palliser projectiles, and only under certain circumstances with common shell; the second is the ordinary charge used with common, double, shrapnel shell, and case-shot. The powder used would be pebble for all battering charges, and for full charges of 40 pounds and upwards.

The reason why pebble-powder is now used with all large guns instead of ordinary powder is explained as follows: that the pressure on the gun is much less, and the velocity greater, with the former than the latter. This increased velocity is due to the lower pressure of the powder, which is kept up longer in the bore than with quicker-burning powder, the velocity depending upon the pressure and the space over which it is exerted.

BATTERING PROJECTILES.—Projectiles for battering purposes are made of cast-iron, chilled iron, and steel. Against parapets of earth common shell containing large bursting-charges are the most effective. Compound shot, having chilled cast-iron heads and cast-steel bodies, give good results, but they lack the power to carry their bursting-charge behind the armor which they can penetrate. The hardness and tenacity of steel shot and shell make them very effective against all kinds of armor. Their great cost prevents their use when good results can be accomplished by chilled shot. Gunpowder is not a sufficiently powerful explosive for these strong shells, and, moreover, it explodes on impact. Satisfactory experiments have been made with bursting-charges of gun-cotton, which only explodes when the penetration is complete. Both forged and cast steel shells, well tempered, have perforated great thicknesses of wrought iron, in direct hitting, without being injured. Cast-steel projectiles, compressed by an hydraulic press while in a fluid state to drive out bubbles, give excellent results. In direct fire against steel-faced armor, cast-steel shells, owing to their great hardness, behave better than those of forged steel. The reverse is the case in oblique fire, where tenacity and toughness are the main considerations. All steel projectiles thus far tried break up against steel-faced armor in oblique fire. The longer the head of the projectile the greater the effect in direct fire, while for oblique fire the best effects are obtained with heads struck with a radius of two diameters. The flat-headed projectiles are much inferior to those with pointed heads in both direct and oblique fire. The respective advantages of light and heavy shells may be said to be as follows, assuming the powder-charge to be constant: The heavier shells, though starting with a lower initial velocity, keep up their velocity better than lighter ones, and so have a longer range of penetrative effect. The lighter shells have a higher velocity at short ranges, and a flatter trajectory; also, a greater number can be carried for a given weight. The projectile must not be so heavy as to strain the gun unduly, but this is easily avoided by the use of slow-burning powder and air-spacing. The cavity in shells should be as capacious as possible, so as to carry a large bursting-charge, but this will be controlled by the thickness which the head and walls must possess to give the necessary strength. See *Armor-plates*.

BATTERING-RAM.—An engine of war used in ancient times and in the Middle Ages. It consisted of a beam of wood with a mass of bronze or iron on one end, resembling the head of a *ram*. In its simplest form it was borne and impelled by the hands of the soldiers; afterwards it was suspended in a frame, and made to swing. Another form moved on rollers.



Battering-ram.

The alternating motion was communicated by ropes. To protect those working it, a wooden roof (*testudo*) was constructed over it, and the whole was mounted on wheels. The beam of the ram varied from 60 to 120 feet in length, the head sometimes weighed above a ton, and as many as 100 men were employed in impelling the machine. When the blows were long enough continued, hardly any wall could resist. When or where it was invented is unknown. It is mentioned by Ezekiel. The Romans derived it from the Greeks.

BATTERING-TRAIN.—A train of artillery used solely for besieging a strong place, inclusive of mortars and howitzers. See *Siege-train*.

BATTERY-BOXES.—Square chests or boxes, filled with earth and used in making batteries where gabions are not to be had.

BATTERY-GUN.—A gun having a capacity for firing a number of shots consecutively or simultaneously without stopping to reload. There are many varieties.

1. A piece of ordnance having a number of load-chambers attached to a vertical axis, and consecutively presented at the rear of the cannon-bore. As each takes its place at the breach, it is advanced into the bore and locked before firing.

2. A chambered breech-piece, revolving in a vertical plane, and presenting its chambers consecutively at the open rear of the barrel, which is common to all the chambers. The principle of construction is that of the revolving chambered pistol.

3. A number of parallel barrels arranged in rank, and having connected vents for intercommunication of fire. The infernal-machine of Fieschi, which he fired on Louis Philippe, was a row of barrels clinched to a frame, and had a train of powder which was laid over all the vents in succession, like the row of barrels in a proving-house.

The Requa battery consists of 25 rifles, each 24 inches long, mounted in a horizontal plane upon a field-carriage. It is breech-loading, the cartridges being forced into the chambers by a sliding-bar worked by two levers. By a lever beneath the frame the barrels may be diverged, so as to scatter the balls 120 yards in a distance of 1000 yards. The weight of the battery-gun used at Charleston, S. C., was 1382 pounds. Served by three men, it fired seven volleys, or 175 shots, per minute. Its effective range was 1300 yards.

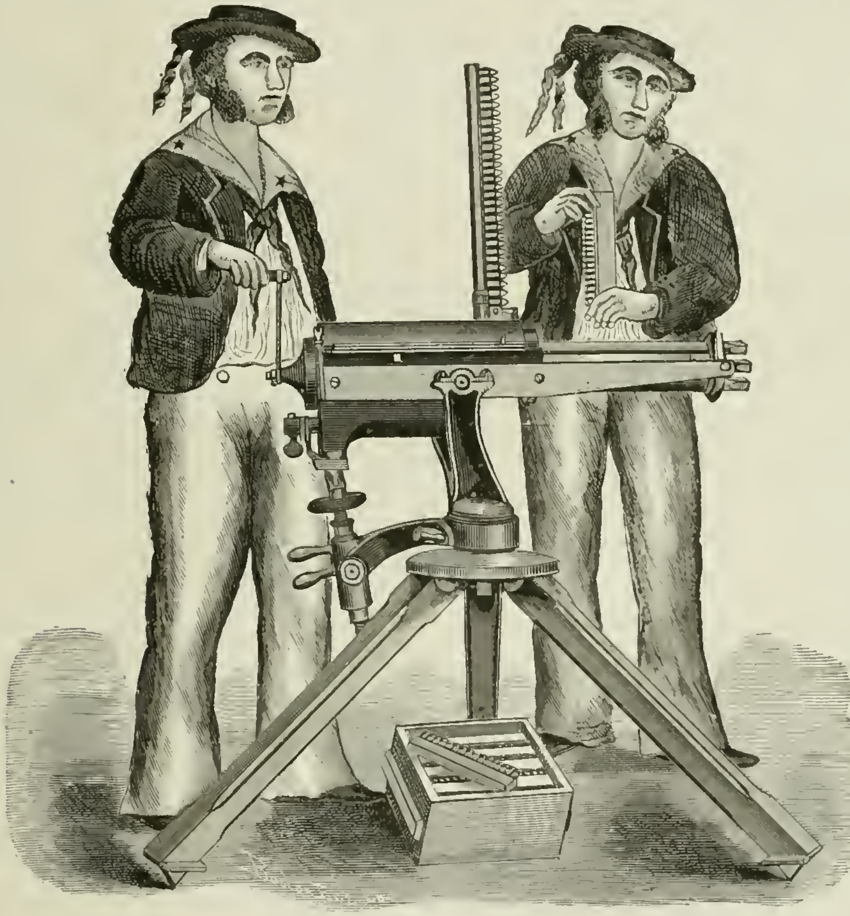
4. Forms of many-barreled cannon revolving on a vertical axis, the pieces being muzzle-loaded.

5. A cluster of rotating barrels, consecutively loaded and fired by automatic action.

6. A cluster of barrels, in whose rear is placed a chambered plate, each of whose chambers corresponds to one of the clusters of barrels, against whose rear it is locked before firing.

7. A number of chambered blocks brought consecutively to the positions for loading, and then for firing, through a group of barrels equal in number to the number of chambers.

The drawing shows the Lowell battery-gun, mounted on a tripod, and ready for firing. A brief notice of its action will suggest the requisite features of all battery-guns. The feed comprises the feeding-tube and carrier-rolls; the former keeping each cartridge horizontal till it is received by the latter. A double extractor, grasping as it does the butt of the cartridge on both sides, works with very great certainty. This certainty is not only due to the fact of its being double, but also to the fact of the extractors not depending on their spring or elasticity, but to a positive movement being given to their hooks by a shoulder on the lock-plunger, working on the curved portion of their rear ends. Thus the extracting hooks are obliged to retain hold of the flange of the cartridge until entirely extracted, when the empty shell is readily removed from the hooks by the carrier-rolls. The working parts being exposed by simply turning back their cover, allows the mechanism to be at once seen and readily removed; and whenever a stoppage may occur, its cause is *immediately seen* and easily remedied. The shape of the cam which operates the lock is such that after the plunger has shoved the cartridge into the barrel, and it has been fired, it continues to be supported in rear by the cam during a portion of its revolution. This arrangement is of great value in a machine-gun, where the cartridges are entered and extracted from the barrel with such rapidity that hang-fires are liable to occur. The gun, firing as it does all its shots from one barrel at a time, compares in this respect very favorably indeed with any machine-gun. Twice during a recent trial three hundred shots were fired considerably within a minute, the actual time being fifty-three and fifty-four seconds respectively. It is proposed by the inventor to construct a gun with double the number of barrels, making eight, with two locks, so that a fire of four or five hundred shots a minute can be steadily maintained without being obliged to give a too rapid motion to the crank. The question of rapidity of fire being well established for all well-known machine-guns, it seems that the points to which attention should now be given in the trial of a machine-gun are simplicity of mechanism, liability to get out of order, and accessibility of parts. In these are included the feed and extracting, also durability. These points have been highly developed in the gun before us, and its mechanism brought to a fair state of perfection. See *Gardner Machine-gun*, *Gatling Gun*, *Hotchkiss Revolving Cannon*, *Lowell Battery-gun*, *Nordenfelt Gun*, and *Taylor Gun*.



Lowell Battery-gun, mounted on Tripod.

BATTERY-WAGON.—A wagon designed to accompany a field-battery, for the purpose of transporting carriage-maker's and saddler's tools, spare parts of carriages, harness, and equipments, and rough materials for replacing different parts. It is made of equal mobility with other field-carriages, in order to accompany them wherever they may be required to go. The following are the supplies usually carried in the battery-wagon and forge for a battery of six guns:

Contents of Limber-Chest. (Smith's tools and stores.)	No.	Weight Lbs.	Place.
Horseshoes, Nos. 2, 3....lbs.	100	100.00	Box A 1.
Horseshoes, Nos. 2, 3....lbs.	100	100.00	Box A 3.
Horseshoe-nails, Nos. 2 and 3.........lbs.	50	50.00	Box A 2, large division.
Washers and nuts, No. 2....	30	5.25	In box A 2, 91.11 lbs.
Washers and nuts, No. 3....	10	3.20	
Washers and nuts, No. 4....	4	2.15	
Nails, No. 1, C............lbs.	1	1.00	
Nails, No. 2, C............lbs.	1	1.00	
Tire-bolts..............	10	5.00	
Keys for ammunition-chests	5	1.80	
Linch-washers (caisson).....	8	7.30	
Linch-pins (caisson).........	12	8.37	
Linch-pins (for piece)........	6		
Chains, Nos. 1 and 2.....feet	2	1.54	
Cold-shut S links, No. 3......	50	2.50	
Cold-shut S links, No. 5......	12	2.00	
Hand cold-chisels...........	2	2.00	In box A 4, 28.52 lbs.
Hardie	1	0.75	
Files, assorted, with handles	12	10.00	
Buttress	1	1.50	
Hand-punches, round and square	2	2.00

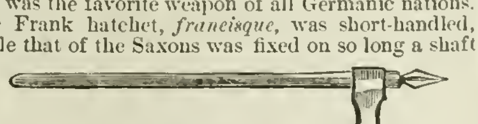
The battery-wagon here mentioned is that furnished from the arsenals; but, being cumbersome and quite unsuitable for field-service, it is better to utilize its body and limber-chest by placing them on the running-gear of the army transportation-wagon. The limber-chest can be attached to the front part of the wagon-body by strong iron brackets, and serves as a seat for the driver. A similar chest can be placed, in like manner, on the rear end in place of the forage-rack. In the front chest is carried the carriage-maker's outfit, and in the rear one that of the saddler. See *Traveling Forge.*

BATTLE-ARRAY.—Array or order of battle; the disposition of forces preparatory to a battle.

BATTLE-AXE.—A cuneiform weapon, like the common hatchet, from which it is modified. It was best known in the so-called ages of stone and bronze, and was the favorite weapon of all Germanic nations. The Frank hatchet, *franeisque*, was short-handled, while that of the Saxons was fixed on so long a shaft



Battle-axes.

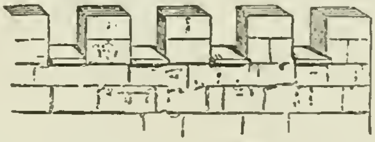
that among the Anglo-Saxons it was named pole-axe. The foot-soldier's battle-axe of the fourteenth century differs considerably from the weapon of an earlier date. Though on one side an axe, it becomes on the other a war-hammer, either with a saw-edge or a sharp point, but generally large and curved, called *falcon-beaked;* whilst the term *parrot-beaked* was applied when the weapon was short in the handle and belonged to a horseman. In this last form it is frequently found to have a gun-barrel encased in the handle, either the primitive hand-cannon or the wheel lock pistol. A long dart or sword is sometimes fixed at the top of the battle-axe.

BATTLE-GROUND CEMETERIES.—In order to secure, as far as possible, the decent interment of those who may fall in battle, it is made the duty of Commanding Generals to lay off lots of ground in some suitable spot near every battle-field, so soon as it may be in their power, and to cause the remains of those killed to be interred, with head-boards to the graves bearing numbers, and, where practicable, the names of the persons buried in them. A register of each burial-ground is preserved, in which are noted the marks corresponding with the head-boards. See *National Cemeteries, Post Cemeteries,* and *Superintendent of National Cemeteries.*

BATTLEMENTS.—Notched or indented parapets used in fortifications. The rising parts are called cops or merlons; the spaces by which they are sepa-

Early English Traceried Battlement.

rated, *crenels*, embrasures, and sometimes loops. The object of the device is to enable the soldier to shelter himself behind the merlon, whilst he shoots through



Simple Form of Battlement.

the embrasure. The bass-reliefs of Nineveh, and the Egyptian paintings, testify to its antiquity, and there is perhaps no nation by which it has not been adopted.

BATTLE-PIECES.—Paintings representing battles. The modern mode of warfare is less favorable for this branch of art than the ancient, where personal valor had more room to display itself. Among the greatest paintings of this kind are the Battle of Constantine, sketched by Raphael and executed by Giulio Romano; Lebrun's Battles of Alexander; and the Battle of the Amazons by Rubens. In smaller scenes, such as skirmishes and surprises, Antonio Tempesta, Hans Snelink, Pet. Snyders, Fulcone, Phil. Wouverman, etc., are distinguished. The most eminent of recent battle-painters is Horace Vernet.

BATTLE-RANGE.—The range corresponding to the maximum "dangerous space" for the trajectory of any fire-arm. This range is somewhat greater for such fire-arm employed against mounted troops than against foot-troops. See *Dangerous Space.*

BATTLES.—General actions in which all of the divisions of an army are or may be engaged. Considered in their political relations, the importance of battles is not always in proportion to their magnitude. There are some battles which claim our attention, independently of the moral worth of the combatants, on account of their enduring importance, and by reason of their practical influence on our own social and political condition, which we can trace up to the results of those engagements. They have for us an actual and abiding interest, both while we investigate the chain of causes and effects, by which they have helped to make us what we are; and also while we speculate on what we probably should have been if any one of those battles had come to a different termination. The fifteen battles which, in Professor Creasy's opinion, have had the most decisive influence are the following:

B.C.
490. Battle of Marathon.
413. Defeat of the Athenians at Syracuse.
331. Battle of Arbela.
207. " " the Metaurus.

A.D.
9. Defeat of the Romans under Varus.
451. Battle of Chalons.
732. " " Tours.
1066. Battle of Hastings.
1429. Joan of Arc's victory at Orleans.
1588. Defeat of the Spanish Armada.
1704. Battle of Blenheim.
1709. " " Pultowa.
1777. Defeat of Burgoyne at Saratoga.
1792. Battle of Valmy.
1815. " " Waterloo.

Battles, though planned and fought almost solely on tactical principles, have in many cases important strategical bearings which it is the province of an able General to see and to take advantage of. Skillfully combined strategical marches, when ably executed, may alone decide the fate of a campaign, without the necessity of coming into collision with the enemy; but this is a rare case, and a battle is usually the necessary sequence to an important strategical movement, and, if well planned and successfully fought, may prove decisive of the war.

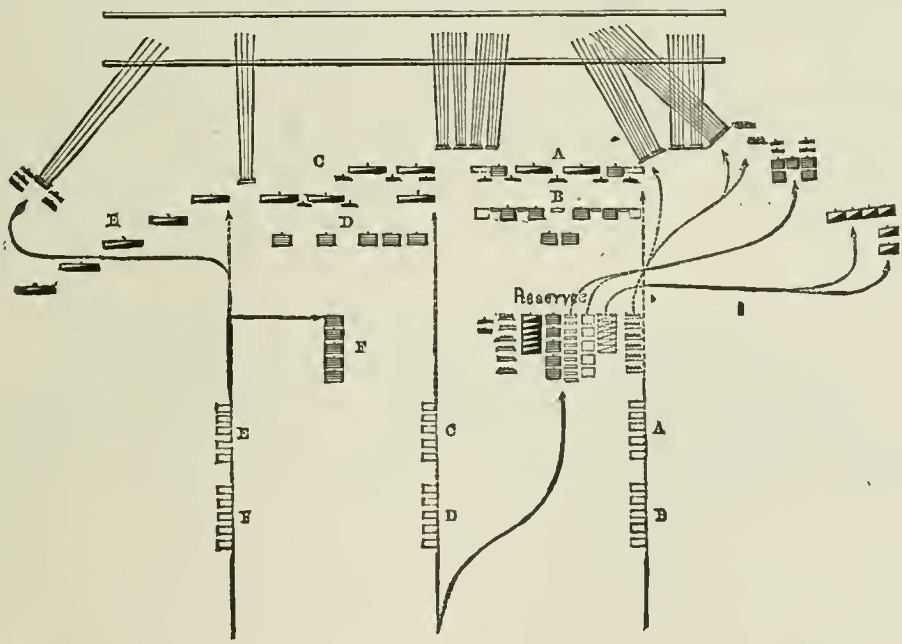
Military writers designate by *orders of battle* the general combinations made to attack one or more points of an enemy's position; whilst they apply the term *line of battle* to the disposition of the troops, in their relations to each other for mutual co-operation, acting either offensively or defensively. Whatever may be the disposition of the troops, the line of battle of any considerable force will present a well-defined center and two wings; thus offering to an assailant one or more of these as his point of attack. This has led to dividing orders of battle into several classes, arising from the necessary disposition of the assailing force, as it moves to attack one or more of these points. If an equal effort is made to assail every point of the enemy's line, the assailing force must necessarily advance on a line parallel to the one assailed, and this therefore has received the name of the *parallel order of battle*. If the line of the assailing force is sensibly perpendicular to that of the assailed, the disposition is said to be the *perpendicular order*. If the main attack is made by one wing, the center and other wing being held back, or *refused* as it is termed, the positions of the lines of the two parties become naturally oblique to each other, and this is termed the *oblique order*. In like manner, the *concave order* results from an attack by both wings, the center being refused, and the *convex order* from refusing the wings and attacking by the center, etc. The order of battle should result from the position in which the enemy's forces are presented for attack; and as these, if skillfully disposed, will be posted so as to take advantage of the points of vantage which the position they occupy offers, the order of battle for assailing may vary in an infinity of ways. Still it is not to be inferred that one order is not superior to another, or that the choice between them is one at pleasure. In the parallel order, for example, the opposing forces being supposed equal in all points, there is no reason why one point of the enemy's line should be forced rather than another, and, therefore, success depends either upon destroying his whole line, or simply pushing it back; as chance alone will determine a break in any part of his line. In the oblique order, on the contrary, one wing being refused, or merely acting as a menace, the other may be strongly reinforced, so as to overwhelm the wing opposed to it, and, if this succeeds, the assailing army, by its simple onward movement, is gradually brought to gain ground on the enemy's rear, and to threaten his line of retreat. Again, in crossing a river on a bridge, or passing through any other defile to assail an enemy opposing this movement, the order of battle becomes necessarily convex; the extremity of the defile itself becoming the center from which the assailing forces radiate, to enlarge their front, whilst they are obliged to secure the defile on each flank. To lay down rules therefore as to what order of battle should, in every case, be employed would be pure pedantry. Talent, skill, and experience can alone enable a General to decide this point in any given case. As to the distribution of troops belonging to the separate fractions of the entire force, as an army corps, a division, etc., the rule is to so distribute them that they shall fight under the immediate eye of their respective Commanders, and support each other. Having, for example, a division, composed of four brigades, to distribute in line of battle, the question may arise as to whether all four of the brigades shall be in one line, the first, for instance, or two be in the first and two in the second line. By the first distribution, the four brigades will be under the immediate eye of the Division Commander, but their supports of the second line may be a stranger division, and be led by a General, a rival or enemy of their own Commander. In the second case, the Commanding General, being separated from the two divisions in the first line, will not be able to give them that direct supervision as in the first case; but a more hearty co-operation of the brigades and more unity of concert may be looked for than in the contrary case.

The following example will serve to show how much depends upon the General's ability to adapt his troops to the position they are to fight on. Assume an army of about 37,000 troops of all arms, about to attack an enemy's position, the main effort being directed on the enemy's left wing, our left being refused. This force we will suppose to be organized as follows:

40 battalions of 750 men each.......	30,000
12 squadrons " 120 " "	1,440
18 batteries, 72 pieces, 130 men each.	2,340
30 companies of Sharp-shooters	3,000
2 companies Engineer troops.......	200
Total	36,980

In this organization it will be noticed that the proportion of cavalry to the infantry is very small, and that but two guns are allowed to every thousand men; proportions which would be only suitable for a theater of war in which cavalry would but rarely find any but a very confined field of action, and in the case also of excellent infantry, which admits of a reduction in the amount of artillery. Having divided the battalions of infantry into four divisions, one of these is taken to form part of the reserve, to which is assigned the whole of the cavalry, and all the disposable artillery, and the Sharp-shooters. The other three divisions are designed to move on the right, the center, and the left of the enemy's position. As the main attack is on the right, ten companies of Sharp-shooters are attached to it, and five, to each of the other two; ten being with the reserve. In the attack on the right and center, each division, when formed in line of battle, is to occupy only a front of four battalions, the remaining six of each to be so placed, in second or third line, as the respective Generals of division may deem best. Five battalions of the left division will deploy, in echelon, on the left of the second division; the remaining five being in column to the rear, so as to move to the support of either the second or third division as circumstances may demand. Having decided upon this preliminary plan of attack, the three first divisions are put in motion on their respective points, the heads of column on the same level; the reserve following the center column. The advance of each leading column will be covered by an advanced-guard, composed of the Sharp-shooters, and the flank companies of the leading brigade of each, and by one battery of artillery. The deployment will be that which naturally results from the positions of the brigades in column of march; each brigade forming one line, its artillery on the right, the Sharp-shooters in the intervals of the battalions, and the flank companies on the wings. So soon as the three advanced-guards, which are from 1000 to 1500 paces in advance of their respective columns, have come within good range, the Sharp-shooters are thrown out as skirmishers, the flank companies supporting them, each of these companies keeping nearly opposite to the battalion to which it belongs; the artillery, in the mean time, having opened at a convenient range for its round shot. The skirmishers stick to their work until they are either repulsed or called in, when they will retire behind the flank companies; one half of these last forming the new chain of skirmishers, the other half the supports; and, in this order, they fall back, but keeping up their fire, to the intervals between the battalions. The Sharp-shooters then take position to the rear of the first line in the battalion intervals; the flank companies doubling on the wings; and the batteries, which have thus been unmasked, proceeding, on a trot, to the front, to pour in a heavy continued fire on the enemy. The two first divisions in this way enter into the engagement; the third merely covering its position by its batteries.

from each other, and has thrown out one of his batteries on his left, giving it the companies of Sharp-shooters as a support, with the view of checking any movement on this wing. In the mean time, the General Commanding, seeing the affair well under way, has massed his reserve, in rear of the center of the first division, seeing the moment come to complete his stroke, has detached a brigade of the reserve, four companies of Sharp-shooters, six batteries, and the half of his cavalry to the front; giving the artillery orders to take position on the right and left of the batteries of the first division, so as to get a slant fire on the enemy's line; the infantry to mass itself on the right of the artillery, to cover it, and also by proper precautions to guard itself from a flank movement; the cavalry to post itself, in echelon, on the right of the infantry, to prevent a flank movement of the enemy's cavalry. At the same time, two batteries are also sent forward to reinforce those of the second division. To give room for these movements of the batteries, the flank battalions of the first line of the first division are thrown into column in mass, whilst those of the second incline towards the center so as to avoid being behind the batteries. As the reserve is weakened by these movements, the Commanding General orders the second brigade of the third division to take post in rear of the center of the second division, to be on hand for any emergency. The order of battle which, in the early phase of the engagement, was parallel, has now become oblique. The first division, having kept its center battalions of the first line deployed until ready to charge, will, for



This stage of the action is shown in the drawing as the intentions of the Commanding General may have been interpreted by his subordinates. The Commander of the first division has taken a battalion from each of his lines to form a small reserve, which he has placed in a third line, to be ready for any emergency. The Commander of the second division has formed his first line into two echelons, and has placed a second battalion to support the right one of the advanced echelon, and has thrown forward all his Sharp-shooters into the first line. In disposing of his second brigade, he has placed three battalions nearer to the center to strengthen the troops engaged. The Commander of the third division has deployed the battalions of the first line in echelons, at 150 paces this last stage, throw these two battalions also into column, whilst the battalions of the second line will spring forward and fill the intervals of the first, so as to present an unbroken wall to the enemy. In this way the division will move forward rapidly, bringing down the bayonet only when within ten or twenty paces of the enemy's line. If the line should be forced to deploy, to again open fire, the battalions of the first line will fall to the rear, forming as the second, leaving this task to those of the second and the Sharp-shooters. This onward movement of the right will be followed by the center and left, care being taken that the whole movement is performed connectedly. This example gives the spirit of the phases of an action for the case supposed. The problem to be resolved, with the arms now in the hands of troops, being to extend our front as much as possible, without, however, weakening too much our line of battle, so as to bring all the fire we can upon the enemy's line. See *Defensive Battle*, *Mixed Battle*, and *Offensive Battle*.

BATTRE DE FRONT.—An expression meaning to throw cannon-balls in a perpendicular or almost perpendicular direction against any body or place which becomes an object of attack. This mode of attack is less effectual than any other unless *battering in breach*.

BAUDRIC.—A short shoulder-belt which crossed the figure like a scarf, and to which the sword was adjusted so as to be worn behind the person. The habit of thus wearing the sword commenced in the reign of Louis XIII. See *Baldrick*.

BAULOIS.—A piece of punk stuff, used by miners for firing the saucisson, or train.

BAUME FLUX.—A foundry composition, consisting of 3 parts of niter, 1 part of sulphur, and 1 part of sawdust. This flux is capable of inducing the fusion of different metals, partly on account of the heat evolved by deflagration, and partly because it converts a portion of the metal into a more fusible sulphide.

BAVIERE.—The beaver of the helmet. It is sometimes called *mentonière* and is pierced with holes for respiration. Also written *Bavier*.

BAVINS.—In the pyrotechny of warfare, small bundles of easily ignited brushwood, from 2 to 3 feet in length. They are made by arranging the bush-ends of the twigs all in one direction, tying the other ends with small cord, dipping the bush-ends into a kettle containing an inflammable composition, and drying them. They are employed among the combustible materials in fire-ships.

BAXTER KNAPSACK-SUPPORTER.—This consists of two pieces of ash, curved to conform to the shape of the back, fastened together at top and bottom by straps, with rings and straps to secure knapsack or blanket; carried by broad cross-straps across the shoulders and fastened to the supporter behind, and also to the waist-belt.

BAY.—An expression for the length of bridge corresponding to the space between two pontons from center to center.

According to Mr. Bruce, the latest authority on the subject, the tapestry contains, besides the figures of 505 quadrupeds, birds, sphinxes, etc., "the figures of 623 men, 202 horses, 55 dogs, 37 buildings, 41 ships and boats, and 49 trees—in all, 1512 figures." The tapestry is divided into 72 distinct compartments, each representing one particular historical occurrence, and bearing an explanatory Latin inscription. A tree is usually chosen to divide the principal events from each other. This pictorial history—for so it may be called, and indeed, in several particulars, it is more minute than any written history we have—opens with Harold prior to his departure for Normandy, taking leave of Edward the Confessor. Harold is next observed, accompanied by his attendants, riding to Bosham with his hawk and hounds; and he is afterwards seen, successively, embarking from the Sussex coast; anchoring in France, and being made prisoner by Guy, Earl of Ponthieu; redeemed by William, Duke of Normandy, and meeting with him at his Court; assisting him against Conan, Earl of Bretagne; swearing on the sacred relics never to interfere with William's succession to the Saxon throne, etc; and finally re-embarking for England. The tapestry then represents Harold narrating the events of his journey to Edward the Confessor, whose death and funeral obsequies we next see. Harold then receives the crown from the Saxon people, and ascends the throne; and next we have the news brought to William, who takes counsel with his half-brother, Odo, Bishop of Bayeux, as to the invasion of England. Then follow representations of the active war-preparations of the Normans; their embarkation; disembarkation; march to Hastings, and formation of a camp there; the battle and death of Harold, with which the tapestry finishes. The Bayeux tapestry gives an exact and minute portraiture of the manners and customs of the times; and it has been remarked that the arms and habits of the Normans are identical with those of the Danes, as they appear in the miniature paintings of a manuscript of the time of King Cnut, preserved in the British Museum. M. Lancelot appears to have been the first to direct attention to the existence of this curious monument, by a description of an illuminated drawing of a portion of it he had discovered, in a paper presented to the Academy of Inscriptions and

Battle of Hastings.

BAYBERRY TALLOW.—A product of the wax myrtle, much used as a lubricant for bullets.

BAYEUX TAPESTRY.—A web of canvas or linen cloth, 214 feet long by 20 inches wide, preserved in the Public Library, Bayeux, upon which is embroidered, in woolen thread of various colors, a representation of the Invasion and Conquest of England by the Normans. Tradition asserts it to be the work of Matilda, wife of William the Conqueror, and it is believed that if she did not actually stitch the whole of it with her own hand, she at least took part in it, and directed the execution of it by her maids; and afterwards presented it to the Cathedral of Bayeux, as a token of her appreciation of the effective assistance which its Bishop, Odo, rendered to her husband at the battle of Hastings. Some antiquaries contend that it was the work not of Queen Matilda (the wife of the Conqueror), who died in 1083, but of the Empress Matilda (the daughter of King Henry I.), who died in 1167.

Belles-lettres, in 1724. This led to the discovery of the tapestry itself, in the Bayeux Cathedral, by Père Montfaucon, who published an engraving of it in 1730, with a commentary on the Latin inscriptions. In 1767 Dr. Ducarel gave an account of it in his *Anglo-Norman Antiquities*. From that time until 1803, when Napoleon had it conveyed to Paris, the Bayeux tapestry excited little attention. Its exhibition, however, in the National Museum there awakened public curiosity concerning it, and gave rise to various speculations as to its age, intention, etc. The discussion satisfactorily established it to be what tradition asserted it—a contemporary pictorial record of the events of the Norman Conquest. The Society of Antiquaries (London) published an engraving of the whole in the sixth volume of the *Vetusta Monumenta*. The Bayeux tapestry would have been destroyed at the Revolution, had not a priest fortunately succeeded in concealing it from the mob, who demanded it to cover the guns. It was formerly preserved in the Cathedral of Bayeux, where it was wont to be exhibited on certain days every year, in the nave of the church, round which it exactly went.

BAYONET.—A short sword or dagger (usually triangular in cross-section) fitted on to the muzzle of a musket or similar weapon, so as to give the soldier increased means of offense and defense. The name is said to be derived from the town of Bayonne in France, where, it is stated, it was first invented in 1640. The first regiment which appears to have had bayonets attached to their muskets is the Grenadier Guards, so far back as the year 1693. It is stated by Macaulay that in consequence of the awkward mode of attaching the bayonet the English lost the battle of Killiecrankie, as the Highlanders were upon the troops before they could convert their fire-locks into pikes. The bayonets then used were called *bayonets-à-manche*, and had handles which fitted into the muzzles of the guns; but at a later date were introduced the *bayonets-à-douille*, or socket-bayonets, having sockets which enabled the bayonets so to be used as not to interrupt the firing. The use of pikes went out when that of bayonets came in. It seems very probable that the first bayonet was a dagger, which the musketeer stuck by means of its handle into the muzzle of his weapon, to shield him from a cavalry charge; and that the usefulness of the contrivance suggested a permanent arrangement.

Bayonets are now made with great rapidity in the United States, at the Government Rifle Factory at Enfield, and elsewhere. The process of manufacture is very simple. Two pieces of metal are first selected—viz., a piece of the very best cast-steel, 7 inches long by ¾ inch square, and a piece of the best wrought-iron rod, 4 inches long by about 1 inch in thickness. The steel is to form the blade, and the iron the socket-handle. The steel being properly shaped at one end, is joined to the iron by welding. A forging-machine is next employed to give a rough outline of the required shape. Then comes the action of a swaging-machine, with dies which come down upon the metal in great force and counter-dies beneath the metal. The metal is then annealed; turned in a cutting-machine to remove a wire-edge thrown up in the act of stamping; cut to a proper length, and the socket-end made square; drilled and bored, to make the socket hollow; shaped and furrowed along the blade; bent at the neck; hardened and tempered; and finished by a numerous train of minor operations. The drawing represents the triangular bayonet, one fourth size, as at present used on the Springfield rifle in the United States. A is the blade; B, the neck; C, the socket; D, the bridge; E, the stud-mortise; F, the clasp. The bayonet-charge is now one of the most terrible maneuvers of trained infantry, in which each nation fancies itself to excel all others. See *Chillingworth Bayonet*, *Sword-bayonet*, and *Trowel-bayonet*.

BAYONET-CLASP.—A movable ring of metal surrounding the socket of a bayonet, in order to strengthen the socket and render the bayonet less easily detachable. See *Bayonet*.

BAYONET-EXERCISE.—If the sword-exercise be of use to officers, there are many hundreds in the rank and file to whom a proper command of the bayonet is indispensable. In close-quarter engagements there is no weapon more formidable: from its length and weight the thrust of the bayonet gives a terrible wound, and its force is such that there is great difficulty in parrying the attack. Like other small-arms, it is most serviceable when handled on scientific principles; and the art of using it to advantage is so simple as to be very easily acquired, while the exercise, from the weight of the rifle, admirably aids in developing the muscles of all parts of the body.

Of course the bayonet is always fixed at the end of the musket, when it becomes virtually a pike. The position of the feet in the bayonet-exercise remains always the same relatively, and absolutely until advance or retreat be effected. The right foot is thrown back 24 inches, and the weight of the body thrown upon it. The heels are kept in a line with each other, both knees bent and well apart; the right knee directly over the foot, the left easy and flexible, pointing to the front. In this position of the body all the defensive motions of the bayonet are made. In "guard," the bayonet is brought nearly to a horizontal direction, level with the waist, and pointing towards the breast of an advancing enemy. Similarly to "guard," the positions "low," "high," and "second point" are assumed. The butt of the rifle is always kept well to the right side, the hand behind the trigger-guard, and the whole body in attitude to offer great resistance. In "low," the barrel is turned downwards; but in all the other defensive motions it is held upwards. The position of the arms is in each case that which would naturally be taken in placing the bayonet and musket in the required direction. See Fig. 1.

The offensive position of the body is acquired by the extension of the right leg, and bending forward of the left without moving the feet. The butt of the rifle is at the same time pressed firmly to the shoulder. This position is called "point," and constitutes an extension of the weapon in a direction parallel with either of those previously taken. As there were four "guards," so there are four points. The barrel is in each case upward, and the motions for each are similar, except in pointing from "2d point," as may be seen in Fig. 2, when the rifle, seized by the

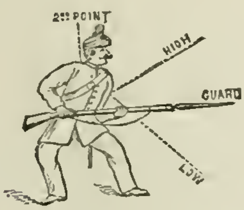


Fig. 1.

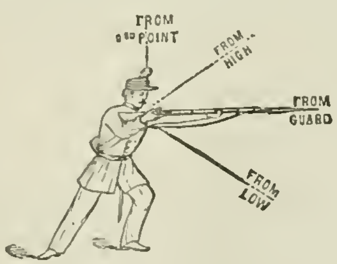

Fig. 2.

Fig. 3.

right hand round the small of the butt, is thrust straight up above the head to the full extent of the arm, the left hand falling along the thigh, and the legs being straightened so as to form an isosceles triangle. "Shorten arms" is a useful motion, both as a defense and as a preparation for a strong attack. It consists in carrying the butt back to the full extent of the right arm, while the barrel (downwards) rests upon the thick part of the left arm. The body is thrown upon the right leg, and the left straightened. This powerful position is seen in Fig. 3. In all the guards and points, and also "shorten arms," the bayonet may be turned directly to the front, to the right, or to the left, as circumstances may suggest. In contending with a swordsman, the action of changing from right to left, when at the "high" or "low," is sufficient defense against the ordinary cuts of the latter. See *Cavalry Parries*, *Disengage*, *Guard*, *Lunge*, *Parry*, and *Thrust*..

BAYONET-SCABBARD.—A leather or metallic case for carrying the bayonet, suspended from the belt.

BAZAR.—The sutler establishment which accompanies a native regiment in the India service wherever it goes.

BEACH COMBINATION SIGHT.—A sight extensively used for both sporting and target practice. It is so constructed that by turning it up or down the rifleman can have a globe or open sight at will, a peep-sight being attached to the small of the stock. The globe of this sight is so constructed as to permit the use of all descriptions of sights, detachable pieces of the various forms in use being slipped into a slot in the globe and held by a screw. There is a great diversity of opinion as to what is the best form of sight; but the four disks represented are favorites with many of the best long-range shots.

Beach Sight, and Disks.

A spirit-level and wind-gauge adjustment is usually attached to this sight, and insures any degree of nicety.

BEACH-MASTER.—Formerly a Superior Officer appointed to superintend the disembarkation of an attacking force, who holds plenary powers, and generally leads the storming party. His acts when in the heat of action are unquestioned.

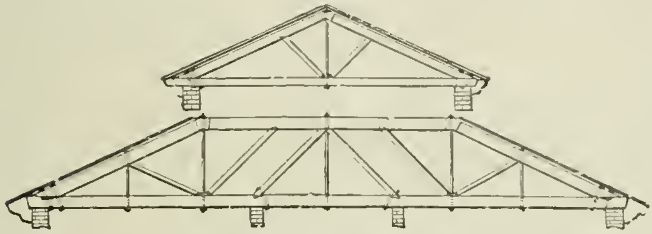
BEACON.—Any signal set upon a height, but especially the alarm-fires at one time used to spread the intelligence of foreign invasion or other great event. These fire-signals were in use in the earliest times, and notices of them are found in the literary remains of ancient Persia, Palestine, and Greece. They were made by kindling a pile or bale of wood on the tops of lofty mountains, and keeping the flame bright by night, or having the fire so covered as to emit a dense smoke by day. There were various preconcerted modes of exhibiting the light or smoke, so as to indicate the nature of the intelligence. Thus, an Act of the Parliament of Scotland, in 1455, directs that one bale on fire shall be warning of the approach of the English in any manner; two bales blazing beside each other, that they are *coming indeed;* and four bales, that they are coming in great force.

An early instance of beacon-signals is found in the Book of the Prophet Jeremiah, in his call, in chapter vi. 1, to the people of Benjamin to kindle a fire-signal on one of their mountains: "Set up a sign of fire in Beth-haccerem; for evil appeareth out of the North, and great destruction." An instance of the use of a line of beacons in very ancient times is given in a passage of the tragedy of *Agamemnon*, by the Greek poet Æschylus. The Commander-in-Chief of the Greek army at the Siege of Troy is represented as communicating the intelligence of the fall of the city to his Queen, Clytemnestra, at Mycenæ, in the Peloponnesus. The line consists of eight mountains, and the news is supposed to be conveyed in one night from Troy.

In England, the beacons were kept up by a rate levied on the Counties, and had watches regularly stationed at them, and horsemen to spread the intelligence during the day, when the beacons could not be seen. They were carefully organized while the Spanish Armada was expected. In the beginning of 1856, an old beacon-work on Malvern Hill, in Worcestershire, which had done its part in the former days in spreading the intelligence of the appearance of the Armada, of the approach of the Young Chevalier, and of that of the Dutch fleet afterwards dealt with by Admiral Blake, was lighted up in anticipation of the close of the Crimean War, and afforded an interesting amusement to scientific persons in estimating the distance at which the blaze could be seen from distant mountains. See *Signal*.

BEALS GUN.—A breech-loading rifle having a fixed chamber closed by a movable breech-block, which slides in the line of the barrel by indirect action, being moved by levers from below. It is opened by depressing the lever; this brings down the rearmost of two folding-wedges which form the breech-block, by means of a toggle or link, and at the same time withdraws the upper section of the block to its full extent and then drops it out of the way of the cartridge. The hammer is simultaneously brought to the half-cock. The piece is closed by reversing the action of the lever, when the sections of the block are brought into place. The last movement of the upper section being in the line of the barrel, thus tends to press the cartridge into the chamber if it be not already completely inserted. The piece is locked by the position of the breech-block, and is fired by a tang-lock of the usual pattern. Extraction and ejection are accomplished by a sliding extractor on the side of the barrel, impelled backward by a spring, when by the descent of the breech-block the way for it is clear. See *Rifle*.

BEAM.—A straight piece of wood or iron in the frame of a structure, usually occupying a relatively elevated, horizontal, and transverse position; as the beams of a magazine, stretching across it, and supported by the side walls or posts. Relative size, character, position, and importance have caused the word to be applied to a long straight piece in a machine or tool, whether poised, journaled, or fixed. Specific denominations have been conferred upon beams in framed structures. 1. *Tie-beam;* one uniting the ends of a pair of principal rafters, or a pair of posts, to prevent spreading or divergence. 2. *Collar-beam;* a horizontal strut connecting and bracing two opposite rafters. 3. *Dragon-beam;* a piece of timber to receive and support the foot of the hip-rafter. 4. *Straining-beam;* one used in a truss or frame to confine principal parts in place. 5. *Camber-beam;* a horizontal beam in a simple span, whose sill has two posts, two struts, and a camber-beam uniting the top of the posts. 6. *Hammer-beam;* a tie-beam proceeding from the feet of a pair of principal rafters, but having its middle portion removed; the ends of the gap are stayed by ribs springing from corbels below, and support other ribs which spring into an arch. 7. *Binding-beam;* a tie-beam which binds together portions of a frame. 8. *Truss-beam;* the principal horizontal timbers of a truss, called the *top* and *bottom chord*, and from which proceed the *stays* and *braces* which hold and push respectively, so to speak, and confer rigidity upon the frame. 9. *Summer-beam;* a central floor or ceiling timber, resting at its ends upon the walls or the girders of the exterior frame, and supporting the ends of the joints which are notched into it. 10. *Arched-beam;* a beam bent, cut, or built into an arched form to support a structure. 11. *Built-beam;* a beam made of several parts, scarfed or strapped together. 12. *Kerfed-beam;* one whose under side has a number of transverse kerfs penetrating to a certain depth, so as to enable the beam to be bent. 13. *Ground-beam;* a sill for a frame. 14. *Box-beam;* a form of girder having a double web, inclosing a box or cell. It is usually of iron. The drawing shows the beams most frequently used in fortification-work, and the functions they perform. In the case of beams supporting weights over ditches, ravines, etc., if the



depth of the beam be doubled, other things equal, its strength will be increased four times; if its breadth be doubled, other things equal, its strength will be doubled. By increasing the distance between the supports, the strength of the beam is decreased in the same ratio. Half the distance between the supports will enable the beam to bear twice the load. Place a prop or skid under the center of the beam, when possible. If instead of concentrating the load at the center of the beam, it be equally distributed over it, the beam will bear twice the load. The effect of the load on a beam will decrease in the ratio of its proximity to the support. A beam fixed at one end and loaded at the other will bear one half the weight of the same when supported at each end. The strength of round timber is about one half of that of square timber whose side equals the diameter of the round timber.

BEAM-CALIPER.—An instrument for measuring diameters. It usually consists of a square of steel or iron, with two branches, one of which is fixed and the other sliding. The inner edges of the two branches, when pushed together, lie, of course, in contact with each other throughout their length. obtaining correct measurements in the arsenal. The side represented is graduated upon the bar to inches and fiftieths of an inch, and by the aid of a vernier is read to thousandths of an inch. The opposite side is graduated to inches and sixty-fourths of an inch. The outside of the jaws is of suitable form for taking inside measurements, and when the jaws are closed measures 250 one-thousandths of an inch in diameter. This caliper will measure one inch and eleven sixteenths, outside diameter, when the jaws are opened full size. The instrument can be furnished with millimeters (in the place of sixty-fourths of an inch), and provided with a vernier to read to one fiftieth of a millimeter. See *Calipers*, *Gauge*, and *Inspection of Ordnance*.

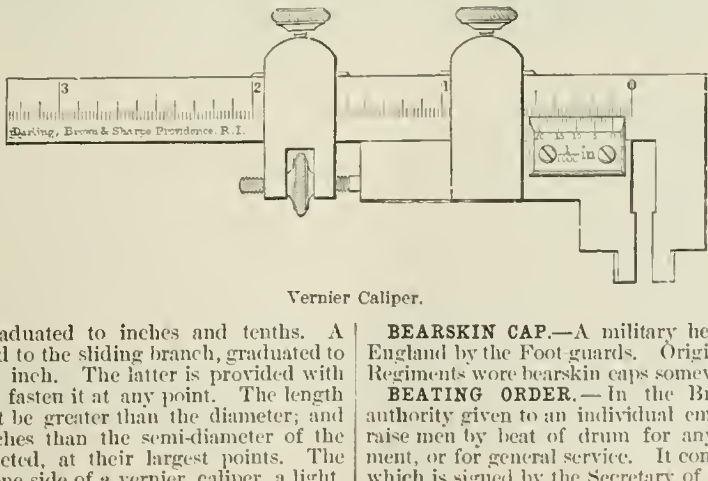
BEAM-CARRIAGE.—In artillery, that part of a gun-carriage included between the breast and trail-point. In the old pattern English field-carriages, the beam is formed of a solid block of wood, if timber of sufficient scantling can be obtained; but if not procurable, it is formed of two pieces tabled one into the other. In this form it is called a *block-trail* carriage. Formerly light field-carriages consisted of two brackets fastened together by transoms; but this form, though it possessed strength, was found to be awkward and unhandy for quick maneuvering; the block-trail, therefore, was substituted for all light field-carriages, and has been also adopted for certain siege-carriages. Since the introduction, however, of wrought-iron guns into the service, the bracket pattern has been re-introduced, and the carriage, which is made of wrought-iron, has the brackets and trail in one. The present pattern of iron carriages is not yet universal in the service, but will be so in the future.

BEAM-COMPASS.—An instrument for describing large circles, and used in connection with the trunnion-square, in the inspection of ordnance. It has a beam or rod, and two sliding sockets which carry the steel point and the pencil or pen points. Set-screws on the sockets hold them to their places on the beam. See *Trunnion-square*.

BEAR.—1. A portable punching-machine for iron plates. A *punching-bear*, much used in armories.

2. The Order of the Bear was instituted by the Emperor Frederick II., in 1213, by way of acknowledgment for the service the Swiss had done him, and in favor of the Abbey of St. Gall. To the collar of the order hung a medal, on which was represented a bear raised on an eminence of earth.

BEARD.—The reflected points of the head of an ancient arrow, particularly of such as were jagged.



Vernier Caliper.

The beam is graduated to inches and tenths. A vernier is attached to the sliding branch, graduated to hundredths of an inch. The latter is provided with a thumb-screw to fasten it at any point. The length of the beam must be greater than the diameter; and that of the branches than the semi-diameter of the guns to be inspected, at their largest points. The drawing shows one side of a vernier caliper, a light, convenient, and valuable instrument for use in

BEARSKIN CAP.—A military head-dress worn in England by the Foot-guards. Originally the Fusilier Regiments wore bearskin caps somewhere about 1805.

BEATING ORDER.—In the British service, an authority given to an individual empowering him to raise men by beat of drum for any particular regiment, or for general service. It consists of a warrant which is signed by the Secretary of War, or issued in his name by the Adjutant-general.

BEATING ORDERS.—Instructions or orders given to recruiting parties before they leave the headquarters of their regiment; they are obtained, on application, by Commanding Officers from the Secretary of State for War. When recruiting parties are quartered in places where a Superintending Officer is stationed, they are to deposit their beating orders with him.

BEATING THE WIND.—A practice in use in the ancient method of trial by combat. If one of the combatants did not appear in the field at the time appointed, the other was to make so many flourishes with his weapon, by which he was entitled to all the advantages of a conqueror.

BEAT OF DRUM.—In military matters, a signal or instruction conveyed by a particular mode of drum-beating. It is an audible semaphore, a telegraph that speaks to the ear instead of the eye. There are many varieties, known by the names of the general, the reveille, the assembly, the foot-march, the grenadiers' march, the retreat, the taptoo or tattoo, the call to arms, the call to church, the pioneers' call, the sergeants' call, the drummers' call, the chamade, the rogue's march, the long roll, etc. Some of the same instructions or commands are also given by the bugle, and some by the trumpet.

BEAUCEANT.—The standard of the Knights Templar; it was white on one side and black on the other. Also written *Beaucent.*

BEAULIEU PROJECTILE.—The plan of this projectile was brought forward as early as 1842. It consisted of twelve zinc studs, or buttons, placed on the shot in pairs, so as to project into the six rounded grooves of the gun. One stud, or projection on the gun, was arranged to push the bearings of the shot tight against those sides of the groove on which it would press in going out, so as to decrease jarring and play.

BEAVER.—That part of a helmet covering the lower part of the face, which shifts on pivots to allow the wearer to drink. The word is derived from the Latin *bevere*, to drink, and is sometimes written *Bever.*

BEBRA.—A sort of javelin used by the ancient Germans; it was an imitation of the *pilum* of the Romans.

BEC DE CORBIN.—A kind of halbert formerly used by the body-guards of the kings of France.

BECHLIS.—Light cavalry of the Turks, composed of picked men and horses.

BED.—1. In artillery, the frame or rest on which mortars are placed and fired from. Mortars have traveling carriages, which are attached to a limber. In battery the carriage is unlimbered, the wheels removed, and the body laid flat upon the ground. Mortar-beds for the larger-sized mortars, viz. the 13-, 10-, and 8-inch land service, are made of iron, and the smaller of wood, viz. the $5\frac{1}{2}$- and $4\frac{2}{5}$-inch. Mortars are elevated by means of quoins.

2. Straw and bedsacks are allowed to soldiers for bedding. The introduction of single iron bedsteads will make it necessary to increase the allowance of bed-furniture. In Prussia and other countries, hammocks are used in place of bedsteads. *Bed* has also other applications: as, camp-bed; bed of a gun-lock; bed of sand; bed of a river; to separate the beds of stone in a quarry, etc.

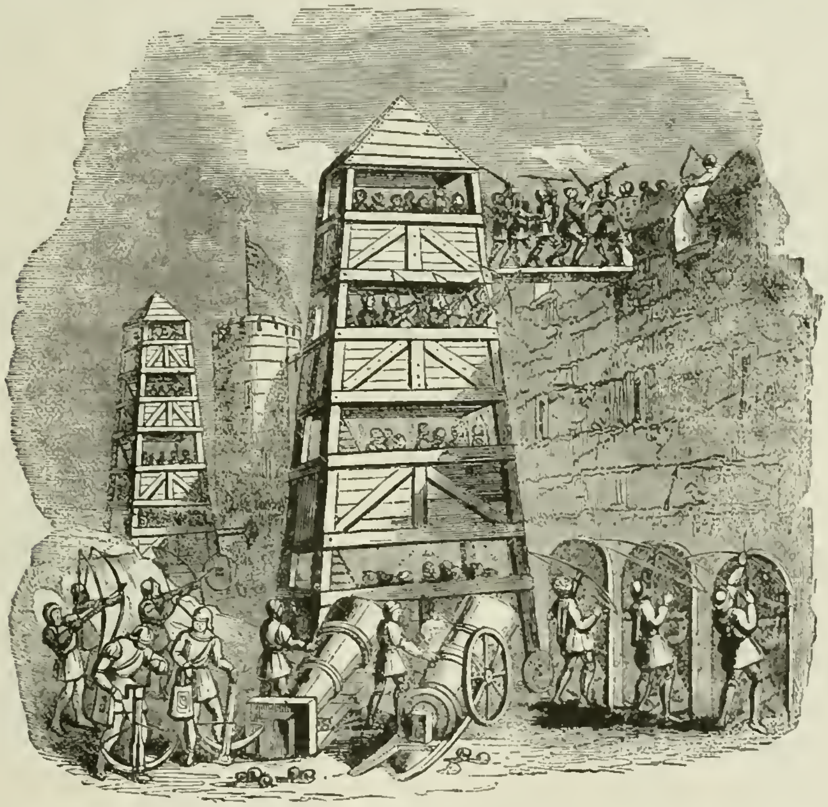
BEDAINES.—Stone bullets which were thrown from catapults during the Middle Ages.

BEDOUINS—BEDUINS.—Arabs who lead a nomadic life, and are generally regarded, according to tradition, as the descendants of Ishmael, and the aborigines of Arabia. The most ancient notices found in Scripture agree, in their descriptions of the manners and customs of the Bedouins, with the facts of the present time. As nomads, the Bedouin Arabs have no united history, but only a collection of genealogies. They have but seldom appeared as a united people, taking a prominent part in the world's politics, and have never been entirely held in subjection by any foreign power. The desert of Arabia, especially the plateau of Nedjid, is their central place of abode; but, even in ancient times, they had spread themselves over the deserts of Egypt and Syria; and in later times, after the decay of ancient civilization, they entered Syria, Mesopotamia, and Chaldæa. The conquest of Northern Africa, in the seventh century, opened up to them still vaster tracts, and they soon extended themselves over the Great Desert to the shores of the Atlantic Ocean. At present, they are to be found scattered over an immense breadth of territory—viz., from the western boundary of Persia to the Atlantic, and from the mountains of Kurdistan to the Negro Countries of Sudan. In the cultivated lands of Mesopotamia, Chaldæa, the Syrian confines, Barbary, Nubia, and the north of Sudan, the Arabs are found intermingled with other nations; but in the deserts they have maintained their distinct character and independence. The characteristics of the Bedouins, as herdsmen and robbers in the desert, are intimately connected with the nature of their habitation. Their abstinent, precarious, and often solitary mode of life makes them disposed to exercise mutual hospitality; but their independence, love of liberty, and other good qualities are associated with violent passions and an infamous love of plunder, which is utterly reckless of the rights of property. They are generally well-made men, lean, sinewy, and active; but, on account of frequent hardships and privations, are commonly below middle stature. Their senses, especially sight, are keen, and their carriage is free and independent. The nose is commonly aquiline, the face rather lengthened, and the eyes are well shaped and expressive of both daring and cunning. In complexion, they have various shades of brown. With the exception of certain tribes in Syria, all the Bedouins are professedly Mohammedans, but by no means strict in the observance of their religious rites and duties. Their *Marabouts*—a class of ascetics—take the place of priests, and exercise considerable influence in all social and public affairs. As the Arabs have no settled government or policy, religious traditions and customs form the only bond of order and union among them. Though their intellectual powers are naturally good, they are miserably destitute of solid knowledge. Their endless tales and poetical effusions show a wonderful activity of imagination and an oriental love of hyperbole. The relation of the sexes to each other is less constrained than among the settled peoples of the East, and a substitute for polygamy is found in a frequent interchange of wives. Their favorite pastimes are the chase, ball-play, dancing, songs, stories, and the *dolce far niente* (pleasant laziness) of drinking coffee and smoking narghiles. Their diet is principally derived from their herds, but includes a few vegetables, and even locusts and lizards. Honey is also a principal luxury with all classes, and, moreover, one which has a religious sanction, for it was indulged in by Mohammed himself, who makes copious mention of it in the Koran. They manufacture their own woolen clothing, which consists of the *haikh*—a long, wide garment fastened on the head, and descending to the feet—and the *burnoose*, a large mantle. Only superior men wear breeches and linen or cotton shirts. The hair of the head is shaven, but the beard is a favorite object of cultivation. The political condition of the Bedouins may be styled patriarchal. One or more families, the males of which bear the title of *Sheik*, form the core of a tribe, and along with the marabouts, or priests, constitute a kind of aristocracy. Out of their number the superior *Sheik*, or Kaid, is elected, who rules in patriarchal style over the whole tribe. This general sketch of the Bedouins applies chiefly to the true nomads, or "dwellers in the desert," and is subject to several modifications with regard to tribes located in Barbary, Syria, and Mesopotamia, who practice agriculture and dwell in houses.

BED-SORES.—A very troublesome complication of disease, to which wounded soldiers are liable when for a long time confined to the ambulance or stretcher, and either unable or not allowed to change position. Thus they are liable to occur in cases of continued fever, or any other prolonged debilitating disorder, in paralysis from injury of the spinal cord, and in cases of fracture of the thigh. The skin at certain projecting bony parts, chiefly about the region of the buttocks, or on the heel, is apt to inflame, ulcerate, and slough, especially if the patient is not kept perfectly clean. The patient sometimes complains of a sense of discomfort at the parts, as if he were lying on dry crumbs of bread; at other times he seems to feel nothing. Hence, in all cases of prolonged supine position, the parts naturally pressed upon by the weight of the body should be carefully examined every day or two, as prevention is far easier than cure. When a long confinement to bed is expected, attempts should be made to thicken the cuticle, and enable it to bear pressure better, by rubbing the skin with a stimulant such as spirits or eau-de-Cologne. If the part, when first seen, looks red and rough, further damage is often prevented by covering it with a piece of calico on which soap-plaster has been spread; the local pressure may be removed by air-cushions specially constructed for cases of this kind, and in many instances Arnott's water-bed affords great comfort. If the case is one in which it is admissible, the patient should be made to alter his position frequently. When there are excoriations, and a threatening of sloughing, a poultice composed of equal parts of bread-crumbs and of finely-grated mutton-suet, mixed over the fire in a saucepan, with a little boiling water, is often a comforting and useful application. After sloughing has fairly begun, stimulating applications, such as resin-ointment, must be applied. It is worthy of notice that bed-sores come on earlier in cases of fractured spine than in any other: they generally appear by the fourth day, and have been seen two days after the accident. They commonly form one of the most powerful agents in destroying life in cases of this accident, diseases of the urinary organs being the other. See *Air-bed and Pillow*.

BEECH-TREE.—Only one species (*Fagus sylvatica*) is common to Europe. In England, the Buckinghamshire and Sussex beech-trees are esteemed the best. The color of the wood is whitish brown, of a uniform texture and closeness. It is considered to be almost chemically free from foreign matters. It is used in the manufacture of fuses, and no wood has yet been found equal to it for that purpose. It is also valuable for wooden types in printing.

BEEF-EATER.—A term now applied jocularly to certain functionaries in England belonging to the Yeomen of the Guard, who, ever since the time of Henry VII., have formed part of the Train of Royalty, attending the Sovereign at royal banquets and other state occasions. They have maintained the same costume, with a slight alteration made in 1858, for nearly four centuries; and this costume has had much to do with their attractiveness to sight-seers. The origin of the term is a case of what Dr. Latham calls "words of foreign simulating a vernacular origin." It was originally *beaufetier* or *buffetier*, one who attends the *buffet* or sideboard. Similar instances of false etymology, arising from resemblance in sound, are seen in *Shot-over* (a hill near Oxford), from *Chateau Vert; sparrow-grass*, from *asparagus; ancient*, for *ensign; dog-cheap*, from the old English *god-kepe*, i.e. *good-cheap*, meaning *a good bargain;* etc.



Beffroi, or Breaching-tower.

BEER-MONEY.—A peculiar payment to Non-commissioned officers and soldiers in the English army. It was established in the year 1800, at the suggestion of the Duke of York, and consisted of one penny per day for troops when on home-service, as a substitute for an issue of beer and spirits. It continued as an addition to the daily pay until 1873, when, the stoppages for rations having been abolished, the opportunity was taken to consolidate beer-money and pay proper.

BEETLES.—In a military sense, very large wooden hammers used for driving down palisades, and for other purposes.

BEFFROI.—The name given to a tower used in the military sieges of ancient and mediæval times. When a town was to be besieged, a movable tower, as high as the walls, was brought near it; and this tower was the *beffroi.* Its use is more than once spoken of by Cæsar in his account of his campaigns in Gaul. Froissart describes, with his usual spirit, a beffroi employed at the siege of the Castle of Breteuil in 1356. At the siege of Jerusalem by the Crusaders, a beffroi was carried in pieces, put together just beyond bow-shot, and then pushed on wheels to a proper position. The object of such towers was to cover the approach of troops. Sometimes they were pushed on by pressure, sometimes by capstans and ropes. The highest were on six or eight wheels, and had as many as twelve or fifteen stories or stages; but it was usual to limit the height to three or four stages. They were often covered with raw hides, to protect them from the flames of boiling grease and oil directed against them by the besieged; and there was a hinged drawbridge at the top, to let down upon the parapet of the wall, to aid in landing. The lower stage frequently had a ram; while the others were crowded with archers, arbalisters, and slingers; or there were bowmen on all the stages except the top, which had a storming or boarding party. During the wars under Charles I., the Royalists made a beffroi to aid in the besieging of a town or castle in Herefordshire; it was higher than the defense-works, and was provided with loop-holes, a bridge, etc.; but the Roundheads captured it before it could be applied to use. Ducange thinks that the name of *belfry* given to a bell-tower was derived from the warlike machine called the beffroi or belfry. See *Battering-ram.*

BEG—BEY.—A Turkish title, rather vague in its import, and commonly given to superior military officers, ship-captains, and distinguished foreigners. More strictly, it applies to the Governor of a small district, who bears a horse-tail as a sign of his rank. The Governor of Tunis has this title.—" Beglerbeg," or, more correctly, Beilerbegi (" Lord of Lords"), the title given to the Governor of a province who bears three horse-tails as his badge of honor, and has authority over several begs, agas, etc. This superior title belongs to the Governors of Rumelia, Anatolia, and Syria.

BEHOURD.—A name given during the Middle Ages to a combat on horseback, lance in hand; also a tilting of cavaliers, which took place at public amusements. Also written *Bihourt* and *Bohurt.*

BELFRY.—A tower of wood, movable on wheels, used in sieges in the Middle Ages. Sometimes a battering-ram was used with it. It was as high as the wall attacked, and a drawbridge was rigged at the top to be dropped on the wall when occasion offered. See *Beffroi.*

BELIDOR SYSTEM OF FORTIFICATION.—This system resembles Rosard's method, but is not so good. A first enceinte consists of small bastions; a second of large bastions with retrenchments; a third of outworks. The reduits of re-entering places of arms are formed of loop-holed walls. The glacis is further defended by lunettes. The profusion of masonry renders this system impracticable, and the great number of outworks necessitates a very strong garrison. Its great merit consists in obliging the besieger to employ a numerous artillery to ricochet a front, and to pass through four periods of breaching-batteries.

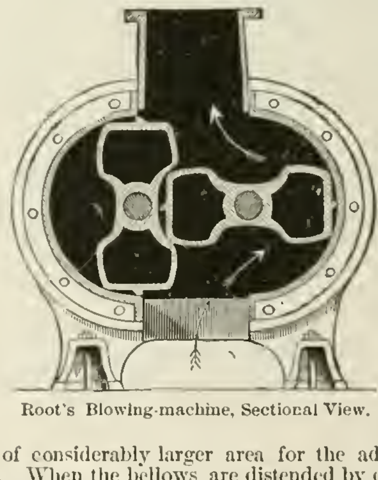
BELIER.—A battering-ram invented by the Carthaginians about 441 B.C.; used in ancient times for siege purposes. Also a wooden machine for driving wedges under a ship's bottom or heavy ordnance.

BELLIGERENT.—Waging war. Hence any two or more countries at war with each other are termed belligerents.

BELL-METAL.—An alloy composed of copper and tin, either alone or with the addition of a greater or less proportion of other metals, usually zinc and lead. It is a species of bronze, and from its hardness and sonorousness is better adapted than any other metal for the purpose from which it derives its name. The usual proportion is 75 parts copper and 25 parts tin, but constituents vary from 50 copper, 33 zinc, and 17 tin, to 80 copper, 10 tin, 6 zinc, and 4 lead. The proportion 78 copper to 22 tin is generally recognized in commerce. This metal is variously employed in the armory.

BELLONA.—The goddess of war among the Romans. She was described by the poets as the companion, sister, wife, or daughter of Mars; she was also represented as armed with a bloody scourge, and as inspiring her votaries with a resistless enthusiasm in battle. In the war with the Samnites, the Consul Appius Claudius vowed a temple to Bellona, which was erected afterwards on the Field of Mars. In this temple the Senate gave audience to embassies from foreign powers, and also to Consuls who had claims to a triumph which would have been nullified by entrance into the city. The priests of the goddess were styled *Bellonarii,* and practiced sanguinary rites, such as cutting their own arms or feet and offering (or even drinking) the blood in sacrifice. This was especially done on the *dies sanguinis* (day of blood), March 24.

BELLOWS.—The earliest blowing-machine was, doubtless, some form of the common bellows, the idea of which is supposed to have been derived from the lungs. A very primitive form of this instrument is still in use in some Eastern countries, consisting simply of the skin of some animal sewed into a rude bag with a valve and nozzle. The older forms of domestic bellows are all constructed on the same principle—viz., a chamber formed of two boards with flexible leather sides, having at one end a nozzle with a narrow mouth, and in the lower board a



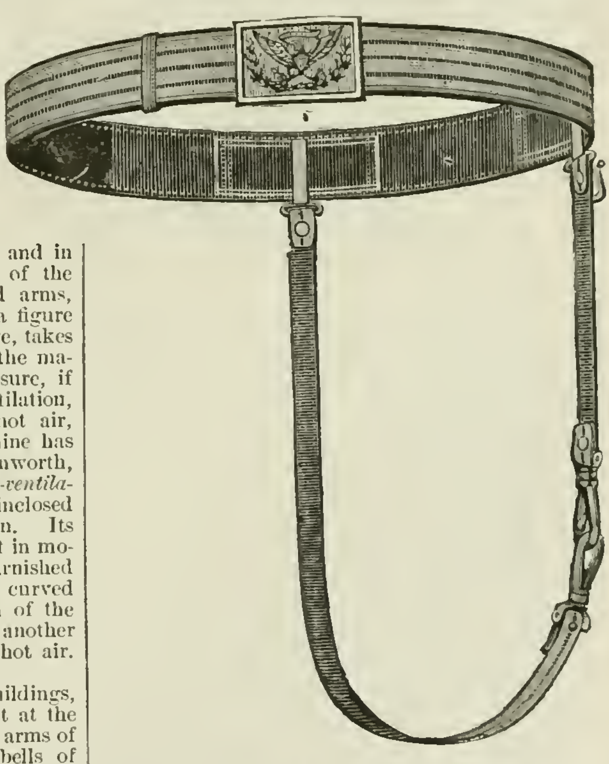
Root's Blowing-machine, Sectional View.

valve of considerably larger area for the admission of air. When the bellows are distended by drawing the boards apart, air is sucked in by the valve, to replace the vacuum which would otherwise be formed; and then, when the boards are being closed, the valve, which only opens inwards, is shut by the compressed air; and the latter, having no other escape, is forced out at the nozzle. The great fault of the common bellows is that it gives a succession of puffs and not a continuous blast. One remedy for this was to use two bellows, so that one was blowing while the other was filling; but it was afterwards found that the double-bellows secured a still more uniform blast. This machine is merely the common bellows with a third board of the same shape as the other two placed between them, so as to form two chambers instead of one. The middle board is fixed, and both it and the lower one have valves placed in them opening inward. A weight on the lower board keeps the under chamber filled with air; and when this board is raised by a lever or otherwise, the air which it contains is forced into the upper chamber. The exit-pipe is attached to the latter, and a weight is placed on the upper board sufficiently heavy to press the air out in a continuous stream, the continuity being maintained by the large quantity of air always present in the upper chamber, and the uniform pressure of the weight. Sometimes a spring is used instead of a weight to press out the air. Even with the double bellows, however, the constant refilling of the upper portion from the lower prevents the blast from being quite regular

Fanners are, at present, much employed for creating blasts to melt pig-iron in foundries, and are used instead of bellows in smithies, on account of their greater convenience and the steadier blast which they yield. A domestic bellows has even been introduced on the fan-principle. The fan is also much used in the ventilation of buildings, ships, and mines. For the last it is now considered preferable to the plan of furnace-ventilation, especially where there are fiery seams of coal. A modified form of the fan, called a *centrifugal disk*, patented by Mr. Rammell, was successfully employed by the Pneumatic Dispatch Company for the transmission of the mail-bags. An ingenious but simple ventilator is in use in the mines of the Harz for supplying fresh air. It consists of two long cylindrical vessels, one of which is so much smaller as, when inverted, to move up and down inside the other. The outer one is partly filled with water, and has a tube leading through the water down to the mine. The inner inverted cask, which has a valve opening inwards, is lifted and then pressed down, so forcing air through the tube. The excellent and well-known blowing-machine of the Messrs. Roots, shown in section in the drawing, may be thus described: A pair of horizontal shafts, geared together at both ends, traverse a case of the form of two semi-cylinders, separated by a rectangle equal in depth to the diameter of the semi-cylinders, and in width to the distance between the centers of the shafts. These shafts carry a pair of solid arms, each having a section somewhat resembling a figure of eight, the action of which, as they revolve, takes the air in by an aperture at the bottom of the machine, and expels it with considerable pressure, if required, at the top. For the purposes of ventilation, and also for expelling accumulations of hot air, dust, waste flyings, etc., in factories, a machine has been constructed by Mr. J. Howorth, Farnworth, Bolton, called a *Revolving Archimedean Screw-ventilator*. It consists of an Archimedean screw inclosed in a tube with proper means of lubrication. Its diameter is 30 inches, and it is made to be set in motion by steam or other power, but it is also furnished with a hood, on the top of which there are curved vanes, which turn the screw by the action of the wind. Immediately beneath these there is another series of lateral vanes for the escape of the hot air. See *Blower* and *Iron*.

BELLS OF ARMS.—Tents or masonry buildings, formerly used in India, and to some extent at the present day, for the deposit and care of the arms of each company of a native regiment. The bells of arms were generally built in front of the lines of the regiment and behind the parade-ground. The tent is frequently painted with the color of the facings of the regimental uniforms.

BELTS.—1. Leathern suspenders of different kinds and for various purposes, viz.: *Sword* belts, to which swords hang (the drawing represents the New Regulation Full-dress Belt in the United States Army); *Shoulder* or *Cross* belts, broad leathern belts, crossing from the right shoulder, and to which the pouch is affixed; and leathern straps fixed round the waist, by which a sword or bayonet is suspended. See *Equipments*.—2. Endless strips of flexible material, usually leather or India rubber, to transmit motion or power from one pulley to another. Ropes and chains serve a similar purpose. When chains are used, the pulleys are provided with projections which engage in the links of the chains and prevent slipping, and the mechanism has the positive relations of a rack and pinion. Ordinary flexible belts transmit power by the friction between them and their pulleys. The pulley which communicates motion is the driving pulley; that which receives, the driven pulley; that part of the belt which runs from the driven pulley to the driver is the driving part of the belt, since it is pulled by the driver, and in turn pulls on the driven pulley; the part of the belt which runs from the driver to the driven pulley is the slack belt. The strain on the driving belt is the sum of the strain of the belt on the pulleys when there is no motion plus the strain of the friction; that on the slack belt is the same strain on the pulleys less the friction. Thus, if a belt is stretched over its pulleys with a strain of 10 lbs. per inch of width, and it requires 5 lbs. to make it slip, then the strain on the driving belt is $10 + 5 = 15$ lbs., and the strain on the slack belt is $10 - 5 = 5$ lbs. per inch of belt. As the two parts of the belt are unequally strained there will be a tendency to move, or *creep*, towards the driving belt over the driven pulley. Hence the velocity ratio of the two pulleys will not exactly follow the inverse ratio of their radii, and the belt cannot be relied upon for giving uniformity of motion. For driving most



machinery, the fact that the belt is elastic, and will slip if unduly strained, makes it a favorite method of communicating power. Rubber belts transmit about 25 per cent more power than leather, because the surface of the rubber conforms more perfectly to the minute inequalities of the pulley surface, and thus acquires a closer grasp. The texture of a rubber belt is more uniform than can be had in leather, and therefore a wide rubber belt will wear more evenly. In damp and exposed places rubber is more durable than leather. If, however, the belt is to be shifted back and forth, as in the stopping and starting of many machines, or in cross-belting—wherever the edge of the belt is liable to wear—leather is preferable. If the pulley be higher at the center than at the side, or higher at one side than at the other, the belt will creep towards the highest part; for this reason the surface of the pulley is usually made not cylindric, but of greater diameter at the center. If this be overdone, the belt does not pull, except along its central part. The pulleys usually lie in the same plane, and with their axes parallel; but this is not necessary, provided that the course of each part of the belt—the driving and the slack part alike—be in the plane of the pulley toward which that part of the belt runs; the belt being always delivered by one pulley into the plane of the other. Transmission of power by belts is more common in the United States than in Europe. Hempen or wire ropes, running over large pulleys with V-shaped edges, are used to transmit power to long distances. The U. S. Arsenal at Rock Island, Ill., carries more than half a mile by one rope the power of four large turbine wheels, sufficient for all the present need of the machine-shops. Such cables have been called teleodynamic cables. They can be run as fast as one mile per minute, and without covering will last three years. Intermediate sheaves are required at every 300 or 400 feet. See *Transmission of Power for Military Purposes.*

BEND.—One of the honorable ordinaries, or more important figures in Heraldry. It is formed by two parallel lines, which may be either straight or indented, engrailed, etc., drawn from the dexter to the sinister base, and consequently passing athwart the shield. The bend occupies a fifth part of the shield in breadth, if plain; and a third part, if charged. The bend is supposed to represent a shoulder-belt, or scarf worn over the shoulder. When heralds speak of the bend simply, the bend-dexter is understood, the bend-sinister being always expressly mentioned. *Bend-sinister* is the bend-dexter reversed, and passing from the left to the right side of the shield, as the dexter does from the right to the left. There are four diminutives of the bend, viz., the *bendlet*, the *garter*, the *cost*, and the *ribbon*. The terms *in bend, per bend, bendy*, etc., are of frequent occurrence in heraldic works, and signify that the charge is placed, or the shield divided, diagonally in the direction of the bend. See *Bar, Bastard Bar*, and *Heraldry.*

Bend. Bendlet. Garter. Cost. Ribbon.

BENGAL LIGHT—BENGOLA.—A brilliant signal-light used at sea during shipwreck, and in ordinary pyrotechny for illuminating a district of country. It is prepared from niter, sulphur, and the tersulphuret of antimony. The materials are reduced to fine powder, thoroughly dried, and intimately mixed in the following proportions by weight: niter, 6; sulphur, 2; tersulphuret of antimony, 1. The mixture constitutes the bengola, and when kindled by a red-hot coal, red-hot iron, or flame, immediately bursts into rapid and vivid combustion, evolving a brilliant, penetrating, but mellow light, which, during the darkness of night, readily overcomes the gloom for a considerable space. As the fumes evolved during the combustion of the bengola contain an oxide of antimony and are poisonous, the light cannot be used with safety in rooms or inclosed spaces.

BENICKE.—A kind of military fête among the Turks, similar to a tournament, but without the presence of ladies.

BENTON CARTRIDGE-BLOCK.—A projecting bolster is left at the forward end of the lock-plate and is under-cut in front and rear. On to this it is designed to slip a detachable magazine-block holding one row of six cartridges, and faced on the inner side with a steel plate securely riveted to the body of the block, and containing a dovetail-groove, corresponding to the bolster on the lock-plate. When fixed, the block is locked in place by a rotary cam on its inner surface, connected with a thumb-piece on the outside and turned by it so as to engage against the lower edge of the bolster. The cartridges are held in the block, in case of its being accidentally overturned, by copper bushings with which the holes are lined.

This block is intended to be issued as a part of the soldiers' equipment, and to be carried full in the cartridge-box. To this end, additional protection against dropping the cartridges is afforded by a leather strap, fastened at the forward end of the block and passing over the heads of the cartridges to a button on the other end of the block. Colonel Benton also proposed that the portion of the stock just to the left of the receiver of a Springfield gun might be enlarged so as to accommodate five cartridges, caliber .45. They were to be held in place by a lip on the side of the breech-block when the breech was closed, and when opened by the copper bushings. See *Hare* and *Metcalfe Cartridge-block.*

BENTON DYNAMOMETER.—This instrument, invented by Lieutenant-colonel James G. Benton, Ordnance Department, U. S. Army, is designed to be used in connection with the Rodman pressure-gauge, for the purpose of determining the presence per square inch exerted within the bores of cannon and small arms by the ignition of powder. It may also be used for testing the tensile strength of materials or for measuring their compression within certain limits. The size of the specimens would necessarily have to be small. When used for either of the latter purposes, special forms of housings have to be made to fit between the guide-blocks. In testing for tensile strength, provision must be made to check the sudden reaction of the springs at the instant of rupture, by interposing a block of rubber, or some other yielding substance, in order to break the force of recoil.

This machine consists essentially of—1. The frame; 2. The springs; 3. The cylindrical casing; 4. The guide-blocks; 5. The screw; 6. The graduated scale. The frame is rectangular in form and made of cast-iron. It rests upon a wooden pedestal formed of two thick cheek-pieces into which a transverse piece of timber is mortised and securely held by two long wrought-iron bolts. The frame is fastened to this pedestal by four bolts, also of wrought-iron. The steel springs are comprised in two systems, or nests, of concentric spiral springs, consisting of three springs each. The outer is a left-handed spiral and has the greatest cross-section; the middle one is a right-handed, and the central a left-handed, spiral. The two systems are placed one above the other between the uprights of the cast-iron frame, with a thin steel plate between them. The cross-sections of all the springs are rectangular, that of the central ones being the least. They are inclosed by a hollow cast-iron cylindrical casing, concentric with but not touching them. This casing does not rise to the level of the nests by nearly three inches, to allow space for their compression. The lower guide-block has on its under surface a flat disk of iron with a diameter equal to the exterior diameter of the springs, which rests upon the upper base, in order to give a good bearing surface. These nests of springs are those used for the ordinary car-buffers, with the exterior and interior cylindrical surfaces turned smooth.

so that the springs of each system are concentric without being in contact. Each nest is 7.68 inches in length, measured on the axis. The lateral deflection of the axis of the entire system due to compression is obviated by using two systems, or nests, as described above, with a steel disk between them, and by grinding the limiting bases of the springs to plane surfaces perpendicular to their axes, and inserting small steel blocks under the tapering terminal ends of the spirals, thus insuring the rigidity and stability of position of the basal planes of each system of springs. This blocking up and squaring the ends, while diminishing the amount of their compressibility, allow the power applied to the screw to be transmitted more uniformly to the springs, as they come to a bearing almost simultaneously. The guide-blocks are two rectangular pieces of cast-iron, with planed surfaces, accurately fitted to move between the planed surfaces of the uprights of the frame. In front they are confined to their positions by steel side plates screwed to them, and projecting shoulders retain them on the rear side of the frame. The lower block rests on the upper set of springs, and carries a cylindrical cap of nickel-plated brass, which conceals that portion of the springs which projects above the cylindrical casing. This cap is slotted at the sides to allow it to slide up and down the frame. Its diameter is a little greater than that of the casing, to admit of its passing over the latter during compression. The upper guide-block is attached to the screw by a shoulder which turns easily in a recess in the let surface of the block, and is covered by a steel plate into its upper side flush with the surface, and held by six screws. The screw is of steel, 1.6 inches in diameter, with eight threads to the inch; it engages a female screw in the upper cross-piece of the frame. The motion of the screw is limited in the direction of the axis by a metallic collar attached to the newel just below the wheel. The power is applied to a cast-iron wheel attached to the upper end of the screw. The length of the screw and the position of the collar are so correlated that when the machine is not in use, should the screw, by accident or design, be depressed to its fullest extent, no initial tension can be brought to bear upon the springs, provided the housing and block have been removed from between the guide-blocks, as they invariably should be except when in legitimate use. A graduated scale 6 inches long, made of a small square steel bar, is attached to the frame by two small blocks. These blocks are slotted to receive the ends of the scale. A screw inserted through each block and into the ends of the scale-bar furnishes the means of a longitudinal adjustment. A small sliding-block upon the scale, whose upper plane surface serves as a pointer, has a toe projecting from one side to receive the pressure of the lower edge of the side plate of the lower guide-block during its descent. This index or pointer is held in any position on the scale by the action of a gib, whose pressure is regulated by adjusting screws. The scale upon its four sides is graduated into sixteenths, fiftieths, sixty-fourths, and hundredths of an inch respectively.

When the dynamometer is used for finding pressures, the appendages are: 1. The block; 2. The housing; 3. The copper block or disk; 4. The cutter; 5. The limit-gauge. The block is of cast-iron, planed and fitted by narrow overhanging lips to the upper surface of the upper guide-block. A pin projecting from the latter into a small hole countersunk in the bottom of the block centers it, and a corresponding pin set in its upper surface performs the same function for the housing, thus insuring the coincidence of the line of direction of the pressure with the axis of the screw. The housing is made of tempered steel, and its form and dimensions must conform to the object in view. Fig. 1 shows the usual form. The side screws (two on each side) project internally far enough to bring the edge of the cutter, when in position, upon a line one third of the width of the copper block from its longer side. By shifting the copper block, a second cut may be made in the same block. The widths of metal between the cuts and edges will be equal. The side screws serve to adjust the copper blocks in the housing and offer no serious obstruction to the flow of the metal, the places of contact being mere points. The position of the cutter is invariable, laterally. There is a stop on the back of the housing to facilitate the longitudinal adjustment of the copper block and cutter. The cutter-block is of tempered steel and is rectangular in shape. The cutting or *indenting* edge is an arc of a

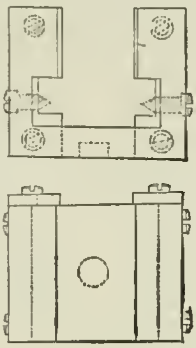


Fig. 1.

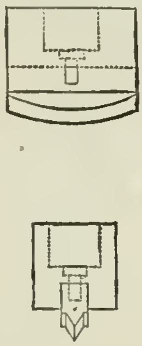

Fig. 2.

Fig. 3.

circle; the two surfaces whose intersections form the edge are two right cones with circular bases. The form and dimensions are shown in Fig. 2. The limit-gauge, shown in Fig. 3, consists of two parts. The lower part has on its upper end a screw which fits into a corresponding female screw upon the interior cylindrical surface of the upper part. This arrangement gives a longitudinal motion by which the length of the gauge can be adjusted. The planes of the ends of the gauge are parallel to each other. A collar on the upper part, and the base on the lower, are either milled or checked, for ease of turning while adjusting. See *Dynamometer* and *Pressure-gauge*.

BENTON THREAD VELOCIMETER.—A gravity instrument in which the weights are suspended by the tension of a cord, and it may be worked with common thread in place of the usual electro-magnetic currents. The principle involved in this arrangement is that the loosening effect of cutting a taut thread is transmitted to equal distances along the thread from the point of rupture, in equal, or sensibly equal, times. It is a principle that can be applied to others of the large class of machines for measuring small intervals of time. The peculiar advantages found in the use of threads over electricity are simplicity and cheapness of the apparatus, freedom from acid and water for the batteries, and the certainty and ease with which it can be operated by a single person, and that person the one who fires the gun.

Fig. 1 represents the front and end views of the Benton Electro-ballistic Machine, originally devised for the use of the Military Academy, and since modified and adopted by the Ordnance Department, for proving powder, etc. *a* is a bed-plate of metal, which supports a graduated arc, *b*. This arc is placed in a vertical position by means of *thumb-screws* and *spirit-levels* attached to it; and it is graduated into degrees and fifths, commencing at the lowest point of the arc and ending at 90°. *p p'* are two pendulums having a common axis of motion, passing through the center and perpendicular to the plane of the arc. The bob of the pendulum, *p'*, is fixed, but that of *p* can be moved up and down with a thumb-screw, so as to make the times of vibration equal. *m* and *m'* are two electro-magnets attached to the horizontal limb of the arc, to hold up the pendulums when they are deflected through angles of 90°. *s* and *s'* are pieces of soft iron attached to the prolongations of the suspension-rods, in such way as to be in contact with the lower poles of the magnets when the pendulums are deflected. *d* is an apparatus to record the point at which the pendulums pass each other, when they fall by the breaking of the currents which excite the magnets. It is attached to the prolongation of the suspension-rod, *p'*, and consists essentially of a small pin inclosed in a brass tube; the end of the pin near the arc has a sharp point, and the other is terminated with a head the surface of which is oblique to the plane of the arc. As the pendulums pass each other, a blunt steel point attached to the lower extremity of the suspension-rod, *p*, strikes against the oblique surface of the head of the pin, which presses the point into a piece of paper clamped to the arc, leaving a small puncture to mark the point of passage. An improvement to the foregoing consists in attaching to the pendulum, *p'*, a delicate bent lever, which carries on its point a small quantity of printer's ink; the pendulum, *p*, presses upon this lever, causing the point to touch the arc and leave a small dot opposite to the point where the pendulums pass each other. The magnets are also so arranged that they can be transposed from one pendulum to the other, thereby affording the means of correcting errors arising from inequalities of magnetic power, by taking a mean of two observations. *c c* and *c' c'* represent the wires which conduct the two electric currents to the magnets *m* and *m'*.

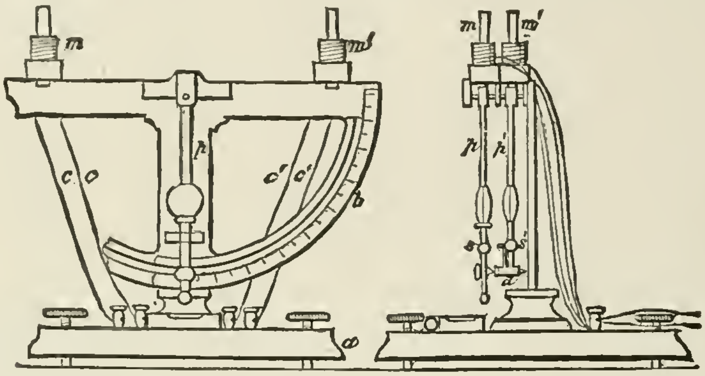

Fig. 1.

The targets, two in number, are designated as No. 1 and No. 2, in the order of their distance from the piece. *For cannon* the targets are similar in construction; each consists of a post fixed in the ground, to which are well secured two horizontal arms. A thread, *d d*, Fig. 2, is stretched vertically between these arms, to which is attached the thread leading to the pendulum at one side. The point of attachment of this thread should be a little below where the projectile cuts the vertical thread, and is shown at *b*. Both threads to the pendulum pass through the loops of the compressors, and are fastened to posts set in the ground, in such relative positions to each other and the pendulum that the compressors will sustain the pendulums when the threads are tightened, and will relax their hold when broken. When cannon are carefully aimed, the projectile will cut both vertical threads directly; but in the case of small-arms it is found difficult to insure the cutting of the thread of No. 2 target without a special arrangement. Target No. 1, for *small-arms*, consists of a piece of board with a vertical opening to serve as a rest for the muzzle of the gun. Across this opening, and directly in front of the muzzle, is stretched a short horizontal thread secured to two leather washers. The thread to pendulum No. 1 is drawn around the middle of the horizontal thread, and secured at the leather washer. The muzzle of the piece is in contact with the intersection of the threads, which should be a little below the center of the bore. The thread is cut the instant the bullet reaches the muzzle, and the other thread slackens, generally without breaking. Target No. 2, for small-arms, Fig. 3, is composed of

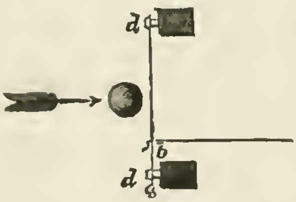

Fig. 2.

an iron target-plate, B, 1 inch thick, which swings freely on horizontal trunnions at its upper edge. The lower back edge of the plate rests lightly against the back of a sharp knife-blade, D, hinged at E. The thread, I, leading to pendulum No. 2 is wrapped around the slitted part in which the knife-blade operates, and fastened to the leather washer, F. C, C are two flat iron bars bolted to a post of wood let into the ground, and serve as supports of the trunnions of the target-plate, B. When the bullet strikes the plate, B, the knife-blade, D, is pressed backwards, cutting the thread, I, and releasing the pendulum. C and H are screens of boiler-plate to protect the thread and knife from fragments of the bullet. The target-plate, B, is made of tough wrought-iron about 6 inches wide, 6 inches deep, and 1 inch thick. The

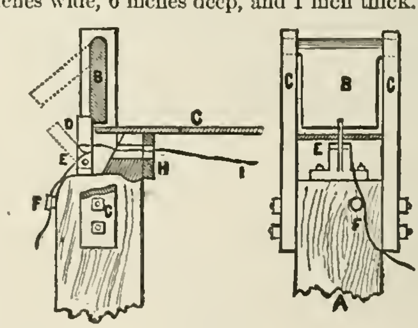

Fig. 3.

knife should be made as sharp as possible, so that a slight tap of the finger on the target-plate will suffice to cut the thread.

For use with small-arms, the graduated arc of the machine should be placed in or near the plane of fire; for cannon, the arc should be parallel to and at least 100 feet to one side of the plane of fire, beyond the jar due to the discharge, and in every case equidistant from the targets. If it be desired to use a table of calculated velocities, the distance between the targets must correspond to that used in the table; but any distance may be taken and the tabular velocity modified by multiplying it by the ratio of the actual and tabular distances. The machine and the targets having been located and the threads laid, the operator, before commencing to work, levels the machine by means of the thumb-screws and spirit-levels, and tests the pendulums and compressors to see that they work freely; then, 1st, deflects the pendulums; 2d, tightens the compressors and secures the threads at the targets; 3d, covers the point of the marker with printer's ink; 4th, fires the piece; 5th, notes the reading of the arc; 6th, wipes out the ink-mark. Assuming that each pendulum, whether held deflected by an electro-magnet or by a thread and compressor, begins to move at the instant the projectile cuts the target, then the interval of time between the rupture of the two targets will correspond to the difference of the arcs described by the pendulums up to the time of meeting. To determine a formula for the time that it takes for one of the pendulums to pass over a given arc, let l be the length of the equivalent simple pendulum, v the velocity of the center of oscillation, y the vertical distance passed over by this point, x the variable angle which the axis of the pendulum makes with the horizontal, and t' the time necessary for the point to pass over an entire circumference, the radius of which is l, with a uniform velocity v. We have

$$v = \sqrt{2gy}.$$

Substituting for y its value in terms of the constant angle of half-oscillation and the variable angle x, the above expression becomes

$$v = \sqrt{2gl \cos. (90^\circ - x)}.$$

The time t' is equal to the circumference of the circle, the radius of which is l, divided by the velocity v; again divide this by 360; we have the time of passing over each degree, or

$$t = \frac{2\pi l}{360 \sqrt{2gl \cos. (90^\circ - x)}}.$$

To determine l it is necessary to change the points of suspension from cylinders to knife-edges, in order to determine the time of vibration through a very small arc. The mean of 500 vibrations will be very near the exact time of a single vibration. Denoting this time by t'' and substituting it in the preceding expression for its value $\pi \sqrt{\frac{l}{g}}$, there results

$$t = \frac{t''}{180 \sqrt{2 \sin. x}}.$$

As t'' is constant for any one place, $\frac{t''}{180\sqrt{2}} = A$, will be constant, and we have $t = \frac{A}{\sqrt{\sin. x}}$. By assigning values to x, a table can be formed giving the times corresponding to different arcs. The length of the equivalent simple pendulum in all velocimeters is made 5.558 inches, and tables calculated on this length will answer for practical purposes in all altitudes and latitudes in the United States where they are likely to be used. To find the velocity for a given reading take the corresponding time from the table, double it, and subtract its logarithm from the logarithm of the distance between the targets. The remainder will be the logarithm of the required velocity. By constructing a "table of velocities" calculated for degrees and tenths of degrees, from 10° to 29° inclusive, and for the distance between the targets used, velocities may be readily obtained by inspection.

The peculiar advantages found in the use of this velocimeter are simplicity and cheapness of the apparatus, freedom from acid for the batteries, and the certainty and ease with which it can be operated by a single person, the one who fires the gun. If electricity be employed with this machine, two galvanic batteries will be required. These should be as nearly as possible of the same strength and constancy, in order that any remaining magnetism in the magnets may be as uniform as possible. The currents from the batteries pass to the electro-magnets and the targets, each magnet having its own battery and target; the circuit of each current must, however, include the *disjunctor*. This latter is a small auxiliary instrument by which the currents may be broken simultaneously. Each pendulum is held deflected through an angle of 90° by its electro-magnet and is released and allowed to oscillate when the current is broken by the rupture of its target, or by the disjunctor. The point at which the pendulums meet, when falling, is noted by the *marker*. This consists of a bent lever attached at the lower end of the inner pendulum. As the pendulums pass each other, an arm on the outer one presses upon the lever, drives it against the arc, and leaves thereon a dot made by printer's ink, carried on the point of the lever. The *error* of the machine is determined by making a rupture of the wires by the disjunctor, and observing the point of passage of the pendulums with reference to the zero of the arc. See *Chronoscope*.

BERDAN TELEMETER.—It is proposed with the Berdan range-finder, as with the majority of instruments intended for the same use, to determine the side of a right-angled triangle BAC whose base, CA, is known by measuring the angle at the apex. Let b be the base. One can measure on the side AB a certain number of distances, of which the constant difference is m, corresponding in range to *successive notches* of the sight. If $AB = c$ is the smallest distance, the following results: $c + m$, $c + 2m$, . . . and the greatest, $c + nm$. The angles at the apex corresponding are given by their tangents:

$$\text{tang. } B = \frac{b}{c};$$

$$\text{tang. } B_1 = \frac{b}{c + m};$$

$$\text{tang. } B_2 = \frac{b}{c + 2m};$$

. . . .

$$\text{tang. } B_n = \frac{b}{c + nm}.$$

One is able to measure in practice these different angles by prolonging to the rear of the point C the hypothenuse of each triangle as far as the arc of a circle described from the point C with a radius l. We obtain in this way the points 0 . 1, 2 . . . h, and the arcs 0D, 1D, 2D — nD, or X, X_1, X_2 — X_n, measuring the angles B, B_1, B_2 — B_n. If it is desired, for example, to measure some infantry distances:

$$C = 300 \text{ meters};$$
$$m = 50 \text{ meters};$$
$$c + nm = 1600 \text{ meters}.$$

If we take $b = 2$ meters and $l = 0.4^m$, we have

$$\text{tang. } B = \tfrac{2}{300} = 0.00666, \quad B = 22' 55'';$$
$$\text{tang. } B_n = \tfrac{2}{1600} = 0.00125, \quad B_n = 4' 17'';$$
$$\text{angle} (X - X_n) = B - B_n = 18' 38''.$$

Upon a circumference whose radius is 1 this angle intercepts an arc of 1118×0.000004848, which is 0.00542; for a radius of 400 millimeters,

$$X - X_n = 0.00542 \times 400 = 2.168^{mm}.$$

These arcs are, moreover, sufficiently small to enable one to substitute for their lengths those of their tangents, and to form the following table without recourse to trigonometrical tables:

Distances in meters. $c, c + m, \ldots c + nm$.	Tangents. tang. $B, B_1, \ldots B_n$.	Arcs. $X, X_1, X_2, \ldots X_n$.	Differences. $X - X_1, X_1, X_2 \ldots - X_{n-1} - X_n$.

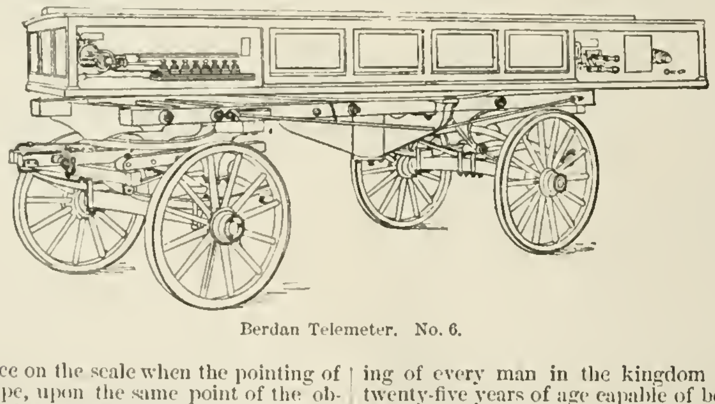
			2.167

One sees definitely that while rapidly measuring the arcs X, X_1, X_2, the corresponding distance will be at the same time determined. Among instruments already known a great number measure, in the same way, angles by a single observation, unfortunately too long to be practically possible on the field of battle. The essential conditions are great rapidity and accuracy in connection with the graduation of the sight. The range-finder invented by General Berdan satisfies these conditions by reason of the advantages which it presents. So far it does not seem to be objected to in Germany, where it is very much appreciated, either by its net cost (about 25,000 francs) or by its large size, which it owes in part to its two telescopes, astronomical instruments of great power, about five feet long ($1^m.52$), and provided with object-glasses 4 inches ($0^m.10$) in diameter. Some improvements in details have been made in it, however, which have not so far been made public. The apparatus consists essentially of two telescopes, connected by a fixed base, one of which can be moved without altering the length of the base. This displacement can be measured by a micrometer which gives immediately the distance on the scale when the pointing of the second telescope, upon the same point of the object at which the first one is directed, is completed. The micrometer-screw which produces and measures the displacement of the movable telescope has a movement equal to the total arc $X - X_n$. It is provided with a large head or drum, the circumference of which is divided in n parts proportionately to the arcs $X - X_1$, $X - X_2$, . . . $X_{n1} - X_n$. Each division corresponds, therefore, to one of the distances c, $c + m$, $c + 2m$, . . . $c + nm$. General Berdan has recently modified his telemeter for garrison and sea-coast service, and constructed a new model intended for field and mountain artillery. This last instrument is constructed upon the same optical principle as that which was applied in the telemeter of great range. The inventor rightly thought that his first telemeter was too heavy for field and mountain batteries, and endeavored to make this instrument lighter, more easily handled, and cheaper. The telemeter represented in the drawing is the old instrument modified; it is called No. 6 in the series of General Berdan's essays. In this model the box can be turned in all directions independently of the wagon. The instrument has a fixed base of 4 meters; two telescopes of $1^m.50$, with object-glasses 90^{mm} in diameter, and a reckoner which indicates directly distances up to 10,000 meters. The author asserts that it only takes 30 seconds on an average to estimate distances, and that the errors of observation are less, even for movable objects, than the average error in range resulting from the precision of fire of artillery. This instrument, although more powerful than the one described previously, and more easily handled, in consequence of the rapidity with which the first telescope can be directed upon the object to be sighted, is still too cumbersome for service with field-batteries, and should be reserved for garrison and sea-coast batteries. Telemeter No. 7 is of smaller dimensions; it is quite portable. It has a base of $1^m.33$; the telescopes are $1^m.12$ long, and the reckoner is graduated up to 6000 meters. For transportation the telescopes are packed in the direction of the length of the instrument. The power of this telemeter is one half that of No. 6; one operation occupies about 30 seconds. The weight of No. 7 is only 70 kilometers (154 pounds), while that of No. 6 is about 1000 kilometers (2200 pounds). No. 7 is therefore suited to field and mountain batteries, as well as for observation on shipboard. General Berdan thinks that the very high price of his instrument ought not to be considered in the choice of a telemeter, in consequence of the advantages which result from the *exact* determination of distances. It is impossible, in his opinion, to construct a practical instrument smaller and cheaper, for he thinks it absolutely necessary to have a fixed base and a reckoner; now the fixed base being always tolerably small (4 meters at the most), involves necessarily the employment of powerful telescopes. See *Pratt Range-finder* and *Telemeter*.



Berdan Telemeter. No. 6.

BEREUNG.—A kind of Swedish militia, consisting of every man in the kingdom from twenty to twenty-five years of age capable of bearing arms.

BERG BARTHE.—A variety of battle-axe used in the seventeenth century. This arm was seldom used for war purposes, but mostly by miners on the festival-day processions of miners' corporations.

BERM.—Between the parapet and ditch of a field-fortification a narrow zone is usually left on the natural surface of the ground which is termed the *berm.* This is a defect in field-works, because it yields the enemy a foothold to breathe a moment, before attempting to ascend the exterior slope. It is useful in the construction of the work for the workmen to stand on; and it throws the weight of the parapet back from the scarp, which might be crushed out by this pressure. In firm soils the berm may be only from *eighteen inches to two feet wide;* in other cases, as in marshy soils, it may require *a width of six feet.* In all cases it should be *six feet below the exterior crest*—to prevent the enemy, should he form on it, from firing on the troops on the banquette. See *Field-fortification.*

BERNARD SYSTEM OF FORTIFICATIONS.—This system proposes a double enceinte covered by counterguards and ravelins, having high and low faces. The outer bastions can be isolated, after the enemy has opened a breach, by blowing up the flanks. Bernard proposes two other methods, which are based upon excellent principles.

BERNER RIFLE.—An early two-grooved rifle, firing a belted ball, and of which the Lancaster rifle is a modification.

BERSAGLIERI.—The name given to the Riflemen or Sharpshooters of the Italian army. After the disastrous campaign of Charles Albert against the Austrians in 1848–49, and the abdication of that monarch, his son, Victor Emmanuel, commenced a remodeling of the Sardinian army. One improvement, brought about by General Alessandro della Marmora, was the formation of a Corps of Bersaglieri. These were light active soldiers, dressed in a picturesque but serviceable dark-green uniform, and armed with long rifles. Two battalions of these Riflemen formed part of the Sardinian army during the Crimean War. On the 16th of August, 1855, they took part in the battle of the Tchernaya. During the Italian War of 1859 the Bersaglieri were engaged in many operations requiring dash and brilliancy. There are over 40,000 Bersaglieri in the regular army.

BESIEGE.—An army, to undertake the siege of a fortress, must have superiority in the field, so that while some of the corps are occupied in besieging the place, others are employed in *covering* this operation, or in repulsing the enemy whenever he endeavors to succor the place. The army covering the siege is called an *Army of Observation*, and that which endeavors to give aid to the place is called the *Succoring Army.* The *Besieging Army* is that which, protected by the army of observation, throws up all the works necessary to take the place, such as trenches, batteries, etc. It begins its operations by investing the fortress; that is, it will advance with the greatest secrecy and rapidity, and occupy positions on every side, to cut off all communication with the adjacent country, and confine the garrison entirely to their own resources. The positions thus occupied are strengthened by field-works, and a sure communication is kept up between them. It is absolutely necessary to invest the fortress attacked, so as to prevent the garrison holding any intercourse with the neighboring country; for if this precaution be not taken, the defenders will be able to draw fresh supplies of men, provisions, and ammunition from the country, increasing greatly the duration of the siege, and reducing the chances of ultimate success. At the late siege of Sebastopol, the ground being intersected by the inlet of the harbor of Sebastopol, the allied army was unable to complete the investment. Thus the fortress on the northern side was left open to receive all the reinforcements of men and *materiel* which could be furnished by the resources of Russia. Fresh officers, fresh troops, fresh provisions were continually poured in; the defenses were enlarged and multiplied; and the besiegers, attacked in their own lines, held at one period a very critical position. The siege was thus prolonged beyond that of any other of modern times, and success was ultimately attained by a loss of men and *matériel* altogether unprecedented. Ground was broken on the 10th October, 1854, and on the 10th September, 1855, the Russians, having sunk their ships, retreated from the southern to the northern side of the harbor, leaving the works on the southern side in the hands of the allies, exactly eleven months after the commencement of their attack. A place may sometimes be reduced by investment or blockade alone, and where it is possible suddenly to blockade a place ill provisioned and filled with a numerous garrison and population, it may be the most ready and bloodless mode of proceeding. Indeed, many other circumstances may render it desirable to endeavor to reduce a place by blockade. When the defenders have been driven within their works, and the place invested, the ground before the fronts to be attacked is carefully examined, and the most suitable situations selected for the park of artillery, and the Engineers' park: the former to receive all the ordnance stores and ammunition; the latter all the Engineers' stores and materials to be used in the construction of the trenches, batteries, etc. These parks should be placed in secure localities, behind the slopes of hills or in ravines, beyond the general range of the guns of the fortress, but with a ready access to the trenches and batteries of attack, for the use of which they are formed.

The artillery and Engineer parks having been duly established, and an adequate supply of ordnance, ammunition, and materials collected in them, for a week's or ten days' consumption, the actual work of the siege begins. The objects of the besiegers are three: 1st. By a superior fire of artillery to dismount the guns and subdue the artillery-fire of the place. 2d. To construct a secure and covered road by which his columns may march to assault the defensive works, so soon as they are sufficiently destroyed to justify the attempt. 3d. To breach or batter down the escarp revetments of the fortress in certain spots, causing the fall of the rampart and parapet supported by them, and thus exposing the interior of the place to the assaulting columns. Now, before any means can be taken to attain any one of these objects, a strong force must be placed under cover, close at hand to the spots on which the necessary operations are to be commenced, whose duty it is to repel any sortie of the enemy, and drive back any parties which issue from the place to destroy or interrupt the works of the attack. The cover provided for this guard of the trenches is usually a trench and parapet called the first parallel, formed around the whole of the fronts attacked: its distance from the advanced-works has usually been between 600 and 700 yards. In the late siege of Sebastopol, the first parallel was opened at a distance of 1200 yards; and doubtless, in future sieges, owing to the increased range of fire-arms, the first parallel will seldom be less, and may probably be considerably more distant. This parallel is formed by approaching the place secretly in the night with a body of men; part carrying intrenching-tools, and the remainder armed. The former dig a trench in the ground parallel to the fortifications to be attacked, and with the earth excavated from the trench raise a bank on the side next the enemy, while the latter remain under arms, usually in a recumbent posture, in readiness to protect the working party, should the garrison sally out. During the night, this trench and bank are made of sufficient depth and extent to cover from the missiles of the place the number of men requisite to cope with the garrison, and the besiegers remain in the trench throughout the following day, in despite of the fire or of the sorties of the besieged. This trench is afterwards progressively widened and deepened, and the bank of earth raised till it forms a covered road, called a parallel, embracing all the fortifications to be attacked; and along this road, guns, wagons, and men securely and conveniently move, equally sheltered from the view and the missiles of the garrison. So soon as the first parallel is established, the Engineers select positions for the batteries to silence the defensive artillery. In the positions of these batteries lies one of the principal advantages of the besiegers. Batteries of guns and mortars are now constructed a little in advance of this parallel, in positions such that their guns enfilade all the faces of the works attacked. The crest-lines of these batteries are therefore made perpendicular to the prolongations of the faces of the ravelins and bastions of the fronts attacked, and so great is the advantage to the besieger arising from such positions of his batteries, that with an equal or sometimes smaller number of guns he is able speedily to subdue the artillery-fire of the defense. These enfilading batteries on the first parallel should be completed and ready to open fire on the third morning after breaking ground.

After the fire of the defensive artillery has been sufficiently subdued, the approaches are commenced. These, like the first parallel, are trenches dug in the ground and protected by a parapet formed of the excavated earth, thrown up on the side of the enemy's works. The approaches are made on the capitals of the ravelins and bastions attacked, but not in a straight line directly towards the salients, as in that case they could be enfiladed from end to end, but in a zigzag direction, alternately to the right and to the left of the capitals, in such a manner that their prolongations fall clear of the fortress, and the possibility of enfilading them is entirely removed. The heads of these approaches are pushed forward by small parties of men, who, from their great numerical inferiority, are quite unable to contend with sorties issuing from the place. To prevent the repeated destruction of the approaches, and the continual loss of the working parties engaged in their construction, a guard of sufficient strength must always be stationed within a distance from these works not exceeding the distance of these works from the covered-way of the place: so that a sortie issuing from the place for the purpose of destroying the approaches may be met and repulsed by the guard of the trenches before they can have time to carry their object into effect; and as the approaches themselves, from their limited dimensions, afford no accommodation for a guard of the trenches, a parallel must always be established at least as near to the head of the approaches as the heads of approaches to the covered-way of the place. It may then be considered a general principle of the attack that a new parallel or place of arms becomes necessary when the approaches have advanced half-way between the last-formed parallel and the covered-way of the fortress. So soon, therefore, as the approaches have advanced half the distance between the first parallel and covered-way of the fortress, a second parallel must be established to accommodate a guard of the trenches, or the working parties at the heads of the approaches will be liable to be swept off by parties of cavalry issuing from the covered-way, before aid can reach them from the first parallel. The approaches are then pushed forward, parallels being made according to the principles just laid down, wherever required, until they reach nearly the crest of the covered-way. Here a trench of greater magnitude is formed, and in it batteries of heavy guns are constructed to silence the remaining artillery of the defense, and to breach in certain selected spots the escarp revetment-wall, thus destroying the formidable obstacle to assault presented by the high perpendicular sides of the ditches of the fortress. The order for the assault is given when the breach has been rendered practicable by the overthrow of the parapet upon the ruins of its walls; and after a gallery has been opened for descending into the ditch, across which a good epaulement has been made joining the breach to the gallery. The troops for the assault are held in the ditch, in the crowning of the covered-way, and in the third parallel. These detachments are to sustain each other and to do it with strong arms. At the concerted signal, the first detachment mounts the breach, driving back the defenders, and seeking to establish itself firmly upon the height by constructing with gabions a lodgment in the angle of the bastion. This is a little intrenchment, called by the French *nid de pie*, which crowns the breach, and under shelter of which the soldiers fire upon all who present themselves. The sappers are charged with its construction, and, in sufficient numbers for this purpose, accompany the assaulting party, each carrying a shovel, a pickaxe, and a gabion. The second detachment aids the first in surmounting the breach, and relieves it if the struggle is obstinate. The third detachment lines the trenches upon the glacis, and sweeps with its fire the parapets and top of the breach, and wherever else there is resistance; but care must also be taken, before coming to close quarters, to facilitate the assault by directing upon the work attacked as many pieces of artillery as possible. When the close combat begins, the artillery ceases, as it would otherwise fire upon friend and foe.

Frequently the taking of the first works brings about the surrender of the place, but again it often happens that the irresistance is but a foretaste of the obstinate defense to be made, and it is necessary to grasp, step by step, the fortifications of the besieged. Sometimes, again, the possession of the ramparts does not put an end to the fighting, but courageous citizens, willing to sacrifice their property to the honor and independence of their country, dispute inch by inch the possession of the streets and houses. The defense of Saragossa in 1808 is a heroic instance of such devotedness. The Spaniards, after losing their fortifications, sustained during twenty-three days attacks in streets and from houses. They capitulated for want of powder, and only after the enormous loss of fifty-four thousand persons of all ages and sexes. A Commanding Officer *defending the approaches of a fortress* threatened by armed enemies declares it in a *state of siege*, and from that moment martial law prevails; or, in other words, the military authority alone governs. Everything is brought into the place necessary for defense, in the shape of wood, fascines, gabions, animals, grain, and eatables of all kinds. All useless mouths are sent out of the place, and those inhabitants who remain are required to provide themselves with wheat, dried vegetables, oil, salt meats, etc., for many months, in order that the garrison may not be obliged to share their provisions with them. The place is put in a state of defense by arming and repairing the fortifications, planting palisades, clearing away the incumbrances in the communications, etc., etc. When the garrison is sufficiently numerous, and that is the case here supposed, it guards against being entirely shut up in the place, by disputing all approaches. Positions are taken in advance of the suburbs, and, far from destroying the suburbs as a smaller garrison must do, they should be covered by intrenchments, in the double aim of preserving them, and sparing the rear as long as possible. Besides the preceding intrenchments, advantageous points are selected for solid redoubts and small posts. The most exposed passages are closed by abatis or deep cuts. Walls are pierced with embrasures, the different stories of houses made defensible, and all means whatsoever resorted to that can prolong the defense. Upon a field of battle thus prepared a long resistance may be expected, and the attacking force will experience great losses before they can open their trenches and begin the ordinary labors of the siege. Perhaps even during this exterior struggle political events or other warlike operations may extricate the garrison from the impending siege, and its glorious struggle will then have freed the place committed to it from many horrors. If the moment at last comes when it is necessary for the garrison to shut itself up, then follows that series of operations properly called a siege. The defense has a thousand means of prolonging its duration, because his exterior defense has given time to prepare them. Knowing the point of attack indicated by the first operations, the defense will have redoubled his intrenchments. The garrison will have been made warlike by frequent combats.

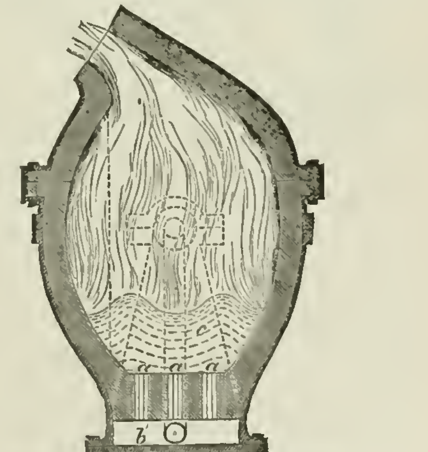
It occupies, it is true, a post hard pressed, but its force is the more concentrated from that cause, and is still imposing notwithstanding the losses that it has experienced. It is by *sorties* that we retard the operations of the besiegers. Large sorties are executed by numerous corps, and are generally made by day to avoid confusion. Small sorties are made at night, and consist of but few men. The first are designed to overthrow the trenches, fire the batteries, and spike the pieces, and they are consequently always followed by a sufficient number of workmen, provided with the necessary instruments. The smallest sorties are only directed against the workers of the sap; they present themselves unexpectedly, and frequently drive away the workmen and break up the gabions. The sap thus interrupted progresses but slowly.

Defensive mines are also a powerful means of prolonging the defense, as they force the besieger to make works that require much time in their preparation. As soon as the point of attack is known the besieged prepare under the glacis chambers of mines, which threaten the batteries of the besieger and constrain him to dig under the ground. The defense has in this subterranean war a great advantage, as he expects the attack in galleries previously prepared. The attack has no other resource than to prepare his chambers at a great distance in order to destroy those of the defenders, and for this purpose *globes of compression* are employed. These overcharged chambers, however, require a great deal of powder, and also much time for their preparation. The besieged has also an advantage in the defense of breaches, because the attacking force may be surrounded, and can only reach their object by a narrow and difficult ascent. In defending a breach, therefore, all the energies of the defense should be brought into action. Preparations should be made in advance for this period of the siege, and some pieces of artillery should be carefully preserved, to arm at the moment of the assault these works which take in flank and reverse the columns of attack. At the top of the breach loaded shells are kept ready to roll down upon the assailants; a large fire should be lighted at the foot of the breach, and kept up by fagots. Or, if the enemy has only partially beaten down the wall, the foothold may be cleared away during the night in such a manner as to make the breach impracticable. Mines may be dug under the ruins by which the assailants may be overthrown. Long arms, as pikes, may be given to the soldiers who defend the breach, and those in the front ranks may be protected by cuirasses. If the work attacked has much capacity, reserves may be held in the interior to charge the enemy when he shows himself, and cavalry may also be brought up at this decisive moment. Such are, in general, the steps to be taken to defend a work; but success will at last depend upou the character, firmness, and skill of the Governor, and upon the intrepidity of his soldiers. The army of observation ought not to be too far from that engaged in the siege, because it may be necessary to call for reinforcements from the latter, and they should be able to return to their camps after the action. Such aid furnished at the opportune moment is precious, and may contribute powerfully to defeat or repulse an enemy. When Napoleon covered the siege of Mantua he did not confine himself to drawing battalions from the besieging army, in order to fight the numerous troops striving to surround him, but he marched the whole besieging army, and uniting it with the army of observation, he gained the celebrated battle of Castiglione. Besides, if the army of observation be too far off, there is nothing to prevent the enemy from unexpectedly attacking the besieging army, which, occupying a long line of investment, is rarely in a condition to repulse such an attack, and may therefore, without aid, be compelled to raise the siege, with the loss of ordnance and other material. General rules cannot be laid down for the position to be taken by an army of observation. It must possess mobility of action, and seek concentration as much as circumstances admit. It must not consider itself tied to the besieging army, and yet be always ready to succor the latter as well as repel a succoring army: conditions which demand much consideration, and which will be fulfilled only by varying dispositions according to circumstances. See *Siege*.

BESSEMER SHOT FOR SMOOTH-BORES. — The plan of this projectile is similar to that of the *Mackay*. Channels formed in the exterior of the projectile conduct the powder-gas to the front. The forward ends of these channels are sharply inclined so that the gas escapes nearly at right angles with the bore, and thus causes the shot to *recoil* in an opposite direction.

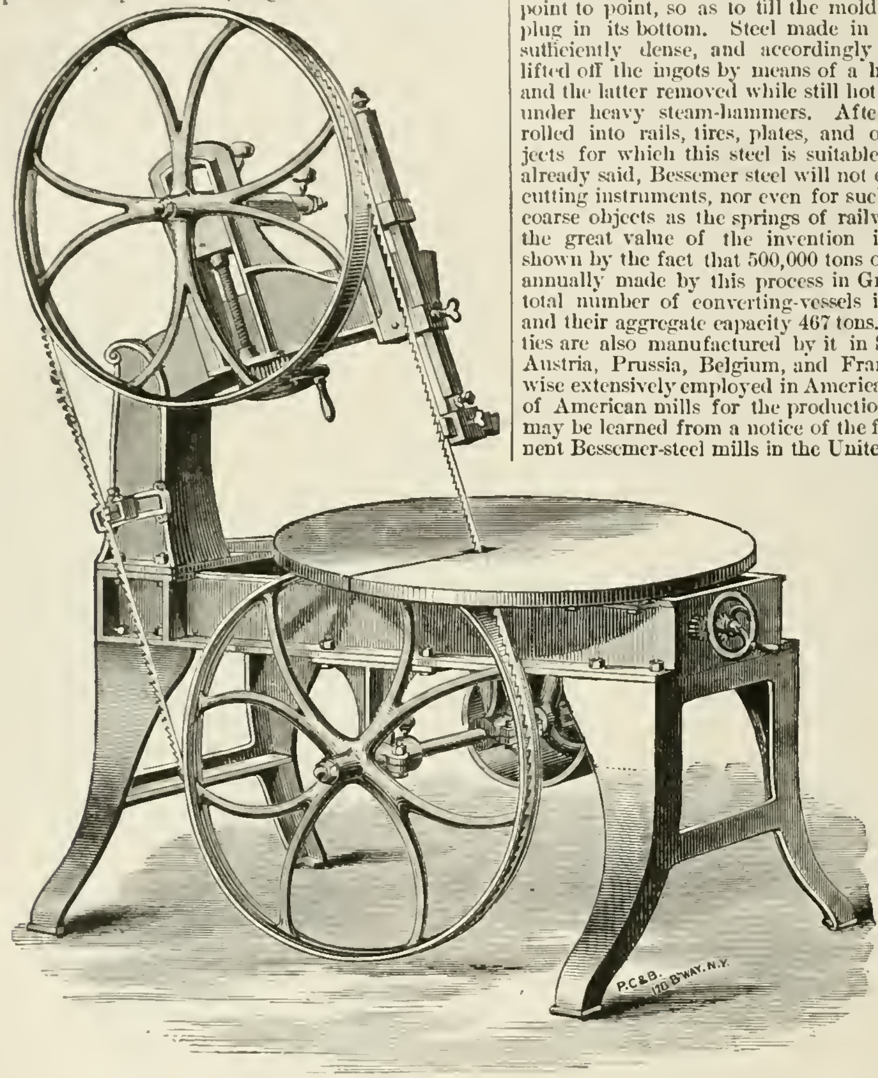
BESSEMER STEEL.—The boldest and most noted attempt which has yet been made to improve on the older methods of making both malleable iron and steel is that of Mr. Henry Bessemer, whose process was patented in 1856. Bessemer's first idea was to blow air through molten cast-iron till the whole of the carbon was oxidized when malleable iron was required, and to stop the blowing when a sufficient degree of decarburization was effected in order to produce steel. He has hitherto failed to produce malleable iron of the least service by his process, so that, as a metallurgical operation, it is at present confined to the manufacture of steel. But neither can serviceable steel be made by the plan first specified by Bessemer, except from the best charcoal-iron, such as the Swedish. In England, where charcoal-iron is not used for this purpose, the process can only be successfully conducted by first oxidizing the whole of the carbon and silicon, and then restoring the proper amount of carbon by the addition of a small quantity of a peculiar cast-iron of known composition, called *spiegeleisen*. Moreover, until recently hæmatite pig was the only kind of English iron which could be employed, as that made from clay ironstone contained too much phosphorus and sulphur; but by the Thomas-Gilchrist modification of the Bessemer process impure ores can now be employed.

The various steps in the Bessemer process, as at present conducted, are as follow: Pig-iron is melted either in a cupola or reverberatory furnace, and run



Converter, on Trunnions.

in the liquid state into a converting-vessel, such as is shown in the drawing, where *a*, *a*, *a* are tuyeres; *b*, the air-space; and *c*, the melted metal. This converter, or "kettle" as it is called in Sheffield, is of wrought-iron, lined either with fire-brick or with a siliceous material called "ganister," and is suspended on trunnions, so as to admit of its being turned from an upright to a horizontal position by means of hydraulic apparatus. The capacity of a converter varies from three to ten tons. In the bottom there are seven tuyeres, each with seven holes of one-half inch in diameter, through which atmospheric air is blown with a pressure of 15 to 20 lbs. per square inch by a blowing-engine. The molten iron



Bevel Band-saw Machine.

in the converter is therefore resting, from the first, on a bed of air, the strength of the blast being sufficient to keep it from falling through the tuyeres into the blast-way. During the blowing off of the carbon at this stage, a striking and magnificent effect is produced by the roar of the blast, and the volcano-like shower of sparks and red-hot fragments from the mouth of the converter, as well as by the dazzling splendor of the flame. In about 15 or 20 minutes the whole of the carbon is dissipated. The first " blow" being over, the converter is lowered to a horizontal position, and presently a red stream of molten spiegeleisen is run into its mouth, till it amounts to from 5 to 10 per cent of the whole charge. As already stated, the spiegeleisen restores the proper amount of carbon to produce steel; and after it is added, the blast is again turned on for a few minutes to secure its thorough incorporation. There is a circular pit in front of every two converters, with a hydraulic piston in its center, and on its counter-poised arm a large ladle is hung, so that it can sweep the whole circumference. Round this the ingot-molds are arranged, and the hydraulic machinery is so conveniently planned that, simply by moving levers, a man standing on a small platform can empty the contents of the huge converters into the ladle, raise or lower the ladle itself, and turn it round from point to point, so as to fill the molds by means of a plug in its bottom. Steel made in this way is not sufficiently dense, and accordingly the molds are lifted off the ingots by means of a hydraulic crane, and the latter removed while still hot, and condensed under heavy steam-hammers. After this they are rolled into rails, tires, plates, and other heavy objects for which this steel is suitable. Although, as already said, Bessemer steel will not do for tools and cutting instruments, nor even for such comparatively coarse objects as the springs of railway wagons, yet the great value of the invention is unmistakably shown by the fact that 500,000 tons of steel are now annually made by this process in Great Britain, the total number of converting-vessels in use being 91, and their aggregate capacity 467 tons. Large quantities are also manufactured by it in Sweden, Russia, Austria, Prussia, Belgium, and France. It is likewise extensively employed in America. The capacity of American mills for the production of this metal may be learned from a notice of the following prominent Bessemer-steel mills in the United States.

See *Iron* and *Steel*.

BETON.—A French term for concrete. It is much used in permanent fortifications. *Béton aggloméré* is a species of concrete invented by M. Coignet. This is used in building arches, aqueducts, cellar-walls, etc. It differs from ordinary béton, having much greater strength and hardness—qualities derived from the ramming to which it is subjected. See *Concrete*.

BETRAY.—To deliver perfidiously any place or body of troops into the hands of the enemy; to discover that which has been intrusted to secrecy.

BETTY.—An ancient machine used for forcing open gates and doors. See *Petard*.

BEVEL BAND-SAW MACHINE.—A machine designed to avoid the instability of inclined tables supported by siegments, pivots, etc., and the difficulties encountered in holding and guiding work upon such tables. The saw is inclined, and the table simultaneously set to correspond with the inclination, by turning a single hand-wheel, it being unnecessary even to clamp the parts in place, as all remain locked in any position in which they are left. When a varying bevel is desired on work, it can be easily produced by turning the hand-wheel while the work is being fed to the saw.

The drawing shows the form of the machine used in the arsenals, which combines all the general features of the band-saw machine—having tension spring; rubber-covered wheels; adjusting-screw for inclining the upper shaft, accessible to the operator from his position in front of the machine, and so arranged that the adjustment can be made while the wheels are in motion; and self-oiling loose pulley. The machine is suitable for general work as well as for bevel sawing. For the latter it will be found of great value in carriage-factories, dock-yards, and for pattern-making.

The weight of the machine is about 1875 pounds; the diameter of the wheels, 40 inches; the total height, 8 feet; the width, 6 feet; the depth, 2¾ feet; the height of the sawing space, 15 inches; the tight and loose pulleys, 16 inches diameter, 4 inches face. The speed is 400 revolutions per minute. See *Band-saw Machine*.

BEVELED HANDSPIKE.—A handspike made of wood, the end of which is sloped off at an obtuse angle.

BHEESTIE.—An Indian term for a water-carrier. Bheesties are attached to all regiments in India, whether in barracks or on the march.

BHIL.—A native tribe in Central India, friendly to the English, which has done good service in suppressing the predatory habits of its neighbors. In common with other hill-tribes, the Bhil are supposed to have been aborigines in their region. They are of dark complexion and diminutive stature, but active and capable of enduring much fatigue. It is with much difficulty that they are reconciled to the life of agriculturists.

BHOOSA.—An article of forage fed to bullocks in India. It is a finely-chopped straw, 14 pounds of which with 6 pounds of grain constitute the ration.

BIACOLYTES.—A military organization in the Grecian Empire, whose duty was to prevent the committal of any excesses against life or property. Their service was analogous to that of the French Gendarmes.

BIANCHI DENSIMETER.—The density of the smaller-grained gunpowder is found by the *Bianchi densimeter*, which consists of a strong glass vessel provided with stop-cocks at each end. The lower end can communicate with a cistern of mercury, and the upper end with an air-pump. This vessel is attached to the apparatus and filled with mercury by exhausting the air from it; both stop-cocks are then closed. The vessel is then removed, weighed (suppose W the weight found), and emptied. One hundred grams of powder are then put in, it is again attached to the apparatus, and mercury is forced in by atmospheric pressure; the stop-cocks are again closed, and the vessel is detached and the weight (w) found. Then if S and d are the densities of the mercury and gunpowder respectively at the time of the experiment,

$$d = \frac{100S}{W - w + 100}.$$

See *Densimeter* and *Mallet Densimeter*.

BIBAUDIERS.—A name anciently given to the foot-soldiers armed with *cranequins*.

BIBAUX.—In ancient times, soldiers who fought on foot with cross-bow and lance. Also written *Petaux*.

BICKER.—A word formerly used in the sense of to skirmish; to fight off and on; to make repeated attacks.

BICKFORD FUSE.—An English patent fuse intended for miner's use. It consists of a cylinder of gunpowder or other explosive matter covered by a double layer of cord and varnished. A similar fuse covered with a water-proof composition was designed for submarine blasting. See *Fuse*.

BICOQUE.—A term used in France to signify a place ill fortified and incapable of much defense. It is derived from a place on the road between Lodi and Milan, which was originally a gentleman's country-house surrounded by ditches. In 1522 a body of imperial troops were stationed in it, and stood the attack of the whole French army, during the reign of Francis I. This engagement was called the Battle of Bicoque.

BICORNEURS.—An ancient name given to the militia of Valenciennes.

BIDARKEE.—A skin-boat of peculiar construction, used by the Aleuts; light and portable.

BIDAUTS—BIDAUX.—An ancient French corps of infantry; according to some authorities they were armed with two javelins.

BIGA.—A Roman term applied in ancient times to vehicles drawn by two horses abreast, and commonly to the Roman chariot used in processions or in the circus. In shape it resembled the Greek war-chariot—a short body on two wheels, low and open behind, where the charioteer entered, but higher and closed in front.

BIGHT.—The name applied to the bent or doubled part of a rope. Thus, one anchor may "hook the bight" of the cable of another, and thereby cause entanglement. In geography, bight has much the same sense as "bay."

BIGLES.—A military corps of Rome, whose particular duty was to furnish sentinels; the bread which these troops received was called *bigliaticum*.

BILBO.—1. A flexible-bladed cutlass from Bilboa. —2. A form of fetters for prisoners, named from Bilboa, Spain, where they were manufactured in large quantities and shipped on the vessels of the Spanish Armada. Bilboes consist of long bars or bolts of iron, with shackles sliding on them, and a lock at one end. When an offender on shipboard is put "in irons," it implies that bilboes are fastened to him, more or less ponderous according to the degree of his offense. The bilboes clasp the ankles in some such way as handcuffs clasp the wrist.

BILBOQUET.—A small 8-inch mortar, whose bore is only half a caliber in length. It throws a shell of 60 pounds about 400 toises.

BILDARS.—A name given to a certain class of natives in India who are entertained as a part of the establishment of a camp or of a siege-train on the march, for the purpose of clearing the camp of filth and dirt, or cutting down brushwood in and around the camp.

BILL—BROWNBILL.—The main offensive weapon of English infantry until the substitution of fire-arms; a two-edged, sickle-shaped knife or sword, weighing from 9 to 12 pounds, on a handle 3 or 4 feet long, and wielded with both hands. It had terrible power, sometimes taking off a person's head or cutting a man in two in spite of the strongest armor. It was also called a "glaive." The bill or bill-hook, under the name of *falx* or *falcula*, was a common weapon among the Romans. A similar implement was used by the Greeks. The figures of Perseus and Saturn are represented thus armed. With this weapon Jupiter wounded Typhon, and Hercules slew the Lernæan Hydra.

BILLED.—A term exclusively confined to the Foot-guards. It means that a man's name is placed in the list or bill of those who are to undergo drill and confinement to barrack. Hence a "billed man," "seven days' bill," "billed up," etc.

BILLET.—1. A document requiring a householder to receive a soldier or soldiers, including officers, with their horses. Only innkeepers and licensed victualers are liable to have troops billeted on them. See *Billeting*.—2. In Heraldry, billets are small oblong figures, sometimes taken to represent bricks, but more commonly *billets-doux*. The latter interpretation, which is that of Guillim, is generally adopted by English heralds, and is supported by the authority of Colombiere. The former again, which has the *Trésor Heraldique* and Sir George Mackenzie on its side, is further strengthened by the fact that in German they are called *Schindeln*, shingles.

BILLETING.—A mode of provisioning and lodging soldiers when not in camp or barrack. It is one of the many vexed questions connected with the organization and administration of the British army. When in camp or barrack, the soldier is supplied with hot food daily by the Commissariat Officers; or rather, with undressed food, and the means for cooking it. But when it is necessary to keep soldiers for one or more days in a town unprovided with barracks, a difficulty occurs which has never yet been properly surmounted; a burden is sure to rest on some one who is unwilling to bear it. In early times, monarchs were often wont to quarter their troops on the monasteries. In later times, the soldiers often compelled the inhabitants of towns to receive and support them; and the authorities were either unable or unwilling to prevent this. The Mutiny Act, passed for the first time in 1689, put a stop to this pernicious practice, by declaring that no housekeepers should be compelled to accommodate soldiers except on some recognized and fairly administered system. The Chief Civil Magistrate of a town, on requisition from the military authorities, quartered the soldiers on the inhabitants as fairly as he could. This continued in England until 1745, when all kinds of persons were exempted from this burden except certain traders; and the new system has been maintained with minor alterations ever since. The alteration was not made in Scotland until 1857. At present, the persons liable to have soldiers billeted on them are the keepers of public-houses, hotels, inns, ale-houses, beer-shops, wine-shops, spirit-vaults, livery-stables, and such-like licensed houses. There are certain exceptional cases provided for; and in and near London there are special regulations concerning the billeting of the Guards; but the general rule is as here stated. The persons liable are bound to accommodate soldiers, under a system that may be described in a few words. When troops are on the march from one barrack or station to another, and cannot cover the distance in one day's railway or foot traveling; or when they are to remain for a few days in a town unprovided with barrack accommodation, or where the barracks are already occupied—the Commanding Officer sends previously to the Chief Civil Magistrate, and demands *billets* for a certain number of men for a certain time. The Magistrate has a list of all the houses subjected to the billeting system, and he quarters the men on those houses as fairly as he can. Rules are laid down to prevent the Magistrate from billeting too many soldiers on one house; any excess in this way is remediable at the hands of a Justice of the Peace. On the evening before the arrival of the troops, two or three Non-commissioned Officers enter the town, and present an order for the delivery of the billets to them, in order that no delay may arise when the main body enter. After the arrival, the soldiers go to the houses on which they are billeted: all those belonging to one company being quartered as near together as may be, for convenience of muster; and the sick are billeted near headquarters. The licensed victualer, or other person, is bound to provide each billet-holder with food, drink, bed, and accommodation, either in his own house or somewhere near at hand. A specified sum of 10*d*. per day is allowed for this; or, under other circumstances, a trifling sum per day is allowed for fire, candles, cooking-utensils, salt, and vinegar. The sum per day allowed for hay and straw for a horse varies with the price of forage. The officers visit the houses, to see that the men really have one hot meal per day, instead of taking the value of it in money. The soldier may demand facilities for cleaning his arms and accouterments. The financial officer of the regiment makes the payments. There are often unpleasant disputes between the innkeeper or others, on the one side, and the officers of the regiment on the other, concerning the occupancy of the "best room," and on minor details. The militia are frequently billeted like the regulars. There being many untoward circumstances connected with this system, a Committee of the House of Commons, in 1858, sought how best to remove them. In their report, the Committee could not recommend the cessation of the billeting system altogether, but they pointed out certain possible ameliorations; and since that, by camping out the troops and other means, great efforts have been made to reduce billeting to a minimum. In the United States, the law declares that no soldier shall in time of peace be quartered in any house without the consent of the owner, nor in time of war but in the manner to be prescribed by law.

BILLETTE FUSE.—This fuse consists of a wrought-iron fuse-plug to which is attached the explosive apparatus. The plug is screwed into the eye of the shell, stopping it completely, the rest of the apparatus being inside the shell. In two side-channels are fixed by friction, by means of pieces of parchment, two small tubes of hard wood, one filled with chlorate of potassa, the other with sulphuret of antimony. Through these tubes pass two hard woolen cords, terminated at the upper ends by rubbers of copper. The other ends pass down through the cup and breaker of the fuse, and are tied together in a groove of the latter. In order to load the side-channels, they are left open at the bottom; that part of the apparatus being afterwards closed by means of the two halves of a hollow truncated cone, which are fixed to the body of the fuse by means of a screw. These half-envelopes are made of bronze, and leave between them two openings through which the flame is transmitted to the charge. The breaker is fixed to the cup by means of a steel screw through its center. The shells with which these fuses are used are fixed to sabots, the fuse being placed in the hollow and exactly in the axis of the sabot. When the shell strikes, the shock breaks off the steel screw connecting the cup and breaker at the point where they join; the weight of the breaker and strength of the screw being so regulated as to insure this effect. The weight and motion of the breaker act on the cords, producing the deflagration of the fulminates.

BILL-HOOK.—An intrenching tool used for cutting down and clearing jungle, branches of trees, stuff for gabions, fascines, etc. The bill-hook is much used in European armies, the pioneers of infantry always being provided with them. See *Bill*.

BILL OF LADING.—Officers of the Quartermaster's Department in charge of the transportation of public property issue bills of lading for the same. When transportation is required from one distant point to another, or over more than one road forming a through line, they ascertain from the proper representatives of the through line the lowest through rate, or any special rate less at which the transportation will be performed and cause the same to be inserted in the bill of lading. The following is a form of bill of lading as used in the United States Army:

No. . MARINE.

ORIGINAL BILL OF LADING.

————, 18—.

Received from ——, United States Army, on board of the —— of ——, whereof the undersigned is master or agent for this present voyage, now lying in the port of ——, and bound for ——, the following articles of public property as specified below (contents and value unknown), in apparent good order and condition, to be forwarded to ——, the dangers of the seas only excepted, and there to be delivered in like good order and condition unto ——, for which I have signed a bill of lading in duplicate. Freight to be paid on the original bill of lading by ——, Quartermaster, U. S. Army, at ——, and at the rates named below, and to the order of ——.

————.

————

—— QUARTERMASTER'S OFFICE,

————, 18—.

I certify that I have shipped this day by the ——, the stores specified in this bill of lading, and that the weight is —— pounds, and the measurement —— cubic feet.

————.

—— *Quartermaster, U. S. Army.*

Marks.	Nos.	No. packages	Contents.	Weight	Meas-ure't.	Rate.
				Lbs.	*Cb.ft.*	

The bill of lading consists of two parts, the *original* and *duplicate*, each to be certified by the shipping officer and receipted by the carrier. The original is given to the carrier at the time of making the shipment, and upon delivery of the property in good order and condition is receipted by the consignee and returned to the carrier, with such further indorsement as may be necessary to insure settlement for the service. The duplicate is promptly transmitted by mail or otherwise to the officer to whom the stores are shipped, and upon delivery of the property is receipted by him in like manner as the original and retained, if he is the paying officer; if not, it is forwarded to the paying officer, to be used in settlement for the service. If the shipping officer is not the paying officer, he is notified by letter of the receipt of the stores, in good or bad order as the case may be, as per bill of lading.

BINARY THEORY.—This theory in chemistry takes cognizance of the mode of construction of salts. It assumes that all salts contain merely two substances, which either are both simple, or of which one is simple, and the other a compound playing the part of a simple body. The best and most familiar illustration of the binary theory is common salt or chloride of sodium (NaCl), which is constructed of the metal sodium (Na) and the non-metal chlorine (Cl), and is at a glance seen to be a *binary compound* (a compound of two). In like manner, fluor-spar, or the fluoride of calcium (CaF), consists of the metal calcium (Ca) and the non-metal fluorine (F); iodide of potassium (KI), largely employed in photography, of potassium (K) and iodine (I); and bromide of silver (AgBr), also useful in photography, of silver (Ag) and bromine (Br). Considerable difficulty is experienced in including all salts under the binary theory, but in many cases the apparent difficulty may be got over. Thus, saltpeter, or the nitrate of potash (KO,NO_5), according to the ordinary mode of representing its composition in symbols, naturally breaks up into potash (KO) and nitric acid (NO_5); but in this form it cannot be correctly included in the binary theory. If, however, the same elements be arranged differently, as when the nitrate of potash (KNO_6) is represented as containing the metal potassium (K) and the compound non-metal nitrationide (NO_6), the latter playing the part of chlorine or other simple substance, the apparent barrier to the introduction of such salts into the list of those comprehended under the binary theory to a great extent disappears. The following table will represent this more clearly:

	Symbols. Ordinary Way.	Binary Theory
Chloride of sodium....	Na,Cl	Na,Cl
Nitrate of potash......	KO,NO_5	K,NO_6
Sulphate of soda......	NaO,SO_3	Na,SO_4
Carbonate of lime.....	CaO,CO_2	Ca,CO_3

Much, however, remains to be cleared up, and in very many cases the binary theory does not answer the purpose of including all salts under one class.

BINOCULAR MICROSCOPE.—A microscope adapted to be used by both eyes at the same time. It has only one set of object-glasses, but the pencil of light, after passing these lenses, is divided, and the parts are sent to the eyes separately. The division is caused by a trapezoidal prism that is pushed laterally into the pencil of light, cutting off one half; the other half goes on directly to one eye. That part of the pencil which is obstructed enters the lower face of the prism normally and is not there changed; it meets the second face internally at such an angle as causes it to be wholly reflected and to pass back through the glass to the third face; here it is again totally reflected, and it passes thence out of the glass normally through the fourth face. The result at all these changes of direction is to give it a path, slightly oblique to that of the unchanged ray, that will carry it through an oblique tube to the second eye. The rays of light cross in the objective; hence, to obtain a stereoscopic effect—that is, to cause the object to stand forth as a solid, its three dimensions being properly appreciated—the light which comes from the left side of the object must enter the right eye, and *vice versa*. Should the light from the right side enter the right eye, a pseudoscopic effect follows; projections seem hollows, and hollows look like elevations. The binocular microscope has two eye-pieces. It is restful to the eyes, and with low powers gives information not to be had otherwise, showing the depth, as well as the length and breadth, of the thing observed. The binocular telescope has two tubes and two sets of lenses throughout. A pair of opera-glasses is a familiar example. See *Field-glass*.

BINOMIAL.—In algebra, a quantity consisting of two terms or parts—e.g., $a + b$ or $9 - 5$; a *trinomial* consists of three terms, as $a + b + c$, or $10 + 5 - 8$. The Binomial Theorem is that remarkable series of analytical formulæ by which any power of a binomial can be expressed and developed. Thus, the eighth or any other power of $a + b$ can be at once written down without going through the actual multiplication of $a + b$ by itself for the given number of times. The older mathematicians were acquainted with this theorem in the case of integral exponents, though the actual discoverer is unknown. Newton was the first to demonstrate its truth for all exponents—fractional and negative, as well as integral. It is one of the finest of his discoveries, and is engraved on his tomb. Among its many applications, it affords the means of finding any root of any number much more conveniently than by the usual method of extraction.

BIPENNIS.—A war-axe used by the Phrygians. It was double-edged, having the edges set back to back, and between them the long shaft or handle is produced until it ends in a point. Sometimes the axe had but one edge, while on the other side it had either a hook or a hammer.

BIPORUS.—With the ancients this word signified a double-prowed boat, so that it could change its course to the opposite direction without turning.

BIRAGO BRIDGE.—A trestle-bridge, of which the supports are, for a depth of water less than 12 feet, a peculiar kind of adjustable horse. For water deeper than this, pontons made in several pieces joined together, or any large flat-bottomed boats, may be used. It may be so laid as to form several passage-ways in the same bridge, by joining a larger number of the parts of pontons together, and placing several rows of the horses. The horse is formed of a movable cap sustained at each end by a single foot. The cap is of spruce or pine, 17 feet long, 8⅝ inches deep, 6½ inches wide in the middle, and 8½ inches wide at the ends for a distance of 3 feet. A mortise 3½ inches wide by 10½ inches long is cut in each head of the cap for the passage of the foot, the bottom of the mortise being inclined 22°. The floor of this bridge is composed of planks 10⅝ feet long by 11½ inches by 1½ inches, with a notch at each end ½ inch deep and 18½ inches long, to receive the balks at the side of the bridge.

BIRD'S-EYE VIEW.—A term applied generally to modes of perspective in which the eye is supposed to look down upon the objects from a considerable height. If the eye is considered as looking perpendicularly down while it sweeps over each point of the scene in succession, we have an exact ground-plan; no object covers another, horizontal angles and distances are exactly represented; while, on the other hand, no vertical angles or side-views appear. In sketching or drawing a locality for military or economical purposes, this kind of perspective is always used. The great difficulty is to represent at the same time the relative heights of mountains and steepness of acclivities. But the more usual kind of bird's-eye views differ from common perspective only in the horizontal line being placed considerably above the picture. In the sixteenth century the only kind of views known were of the nature of ground-plans, and the artists of the seventeenth century tried to combine this method with side-views.

BISCAIEN.—A name formerly given to a long-barreled musket, the range of which was greater than the ordinary musket. At present this appellation is given to a leaden ball about the size of an egg, which is used for canister or case-shot.

BISCAYAN FORGE.—A furnace in which malleable iron is obtained direct from the ore.

BISCUITS.—Small flat bread rendered dry and hard by baking, in order to their long preservation. They are divided into two classes—the *unfermented* and the *fermented*. *Unfermented* or *unleavened* biscuits, generally known as *common sea-biscuits* or *ship-bread*, are made of wheaten flower (retaining some of the bran), water, and common salt. The materials are kneaded together, either by manual labor—that is, by the hands and feet of the workmen—or by introducing the materials into a long trough or box, with a central shaft, to which a series of knives is attached, and which is made to revolve rapidly by machinery. The mass of dough so obtained is then kneaded and thinned out into a sheet the proper thickness of the biscuits, by being passed and repassed between heavy rollers. This sheet being placed below a roller with knife-edge shapes, is readily cut into hexagonal (six-sided) or round pieces of dough of the required size of the biscuits. The indentation of the slabs of dough, in the case of the hexagonal biscuits, is not complete, so that all the biscuits cut out of each slab remain slightly adhering together. These slabs of biscuits are then introduced into an oven for about fifteen minutes, and are placed in a warm room for two or three days to become thoroughly dry. The more modern oven is open at both ends, and the biscuits being placed in a framework are drawn by chains through the oven. So rapidly is this operation conducted that about 2000 lbs. weight of biscuits are passed through one of these ovens every day of ten hours. The extent to which biscuits are now consumed may be learned from the fact that several of the largest biscuit-manufactories each prepare and throw into market every week from 30,000 to 50,000 lbs. weight of biscuits of various kinds. One of the largest and most complete biscuit-manufactories in England is that of Carr at Carlisle, whose biscuits, sold in tin boxes, are well known. Another bakery of this kind is that of Harrison of Liverpool. See *Hard-tack* and *Meat-biscuit*.

BISET.—A member of the National Guard who performed his duty in civilian's dress, before the wearing of uniform on duty was made obligatory.

BISHOP'S MANTLE.—A Venetian mail cape, with which the Doges were armed; it was also worn in Germany during the fifteenth and sixteenth centuries, and over the cuirass in Italy during the fifteenth century.

BISTER—BISTRE.—A pigment of a warm brown color, prepared from the soot of wood, especially beech. It is used in water-colors after the manner of Indian ink.

BITUMEN.—A mineral substance, remarkable for its inflammability and its strong peculiar odor; generally, however, supposed to be of vegetable origin. The name, which was in use among the ancient Romans, is variously employed, sometimes to include a number of the substances called *mineral resins*, particularly the liquid mineral substances called *naphtha* and *petroleum* or mineral oil, and the solid ones called *mineral pitch*, *asphalt*, *mineral caoutchouc*, etc.; sometimes in a more restricted sense it is applied by mineralogists only to some of these, and by some mineralogists to the solid, by others to the liquid ones. All these substances are, however, closely allied to each other. Naphtha and petroleum consist essentially of carbon and hydrogen alone, 84 to 88 per cent being carbon; the others contain also a little oxygen, which is particularly the case in asphalt, the degree of their solidity appearing to depend upon the proportion of oxygen which they contain, which amounts in some specimens of asphalt to 10 per cent. Asphalt also contains a little nitrogen. Bituminous substances are generally found in connection with carboniferous rocks, in districts where there is, or evidently has been, volcanic agency. See the articles already referred to. Indeed, most kinds of coal contain bitumen, and a substance essentially the same is produced from all kinds of coal by distillation; and whether before existing actually formed in the coal, or produced at the time by the action of heat, bitumen may often be seen bubbling from pieces of coal after they have begun to burn on an ordinary fire. Some of the shales of the coal-measures are very bituminous, as is also a kind of marl-slate abundant in some parts of the Continent of Europe. One of the most interesting of the bituminous minerals is that called *mineral caoutchouc* or *elastic bitumen*, and for which the new name of *elaterite* has been devised, as if to support the dignity of its exaltation to the rank of a distinct mineral species. It is a very rare mineral, only three localities being known for it in the world—the Odin lead-mine in Derbyshire; a coal-mine at Montrelais, near Angers, in France; and a coal-mine near South Bury, in Massachusetts. It is elastic and flexible like caoutchouc, and may be used, like it, for effacing pencil-marks. It is easily cut with a knife. Its color is blackish, reddish, or yellowish brown; and its specific gravity is sometimes a little less and sometimes a little more than that of water. It has a strong bituminous odor, and burns with a sooty flame. See *Coal*.

BIVOUAC.—The encampment of soldiers in the open air, without tents, where every one remains dressed and with his weapons by him. Even during the Seven Years' War it was no uncommon thing for the whole army, when in the vicinity of the enemy, to pass the night in their ranks, each lying down in his place, in order to be ready to stand to their arms at a moment's notice. But the French revolutionary armies introduced the practice of dispensing with tents altogether, and regularly passing the night *en bivouac*. Hence in a great measure that rapidity in their motions which long made them uniformly successful. The practice was afterwards imitated by the other armies of Europe, though less by the English. Soldiers in bivouac light fires, and improvise, where it is possible, huts of straw, branches, etc. But this mode of encampment, though favorable to celerity of movement, is purchased at the expense of the soldiers' health, besides being destructive of discipline, by leading to plundering and destroying of houses, fruit-trees, etc., in the vicinity. Accordingly, the tent is again coming into use, and for permanent encampments regularly constructed wooden huts have been introduced. There are still, however, many cases where the bivouac is the only resource.

The bivouac is formed as follows: A regiment of Cavalry being in order of battle, in rear of the ground to be occupied, the Colonel breaks it by platoons to the right. The horses of each platoon are placed in a single row, and fastened as prescribed for camps; near the enemy, they remain saddled all night, with slackened girths. The arms are at first stacked in rear of each row of horses; the sabers, with the bridles hung on them, are placed against the stacks. The forage is placed on the right of each row of horses. Two stable-guards for each platoon watch the horses. A fire for each platoon is made near the color line, twenty paces to the left of the row of horses. A shelter is made for the men around the fire, if possible, and each man then stands his arms and bridle against the shelter. The fires and shelter for the officers are placed in rear of the line of those for the men. The interval between the squadrons must be without obstruction throughout the whole depth of the bivouac.

An Infantry regiment going into bivouac forms its line of battle and then breaks into companies, like when it goes into camp. The arms are then stacked, and the fires made. These fires are on the ground that would be occupied by the tents in camp, and are sufficient in number to allow one for every eight or ten men. If possible, shelters are constructed; these are easily built in a wooded country. If liable to surprise, the infantry should stand to arms at daybreak, and the cavalry mount, until the return of the reconnoitering parties.

The Artillery can have no fixed rule for its bivouacs, being obliged to suit itself to localities; but in no case should the fires be near the park. The following arrangement is generally observed: In a single platoon of a mounted battery, the pieces and caissons are parked at eight yards' interval; the horses are tied to the prolonges (twenty-four feet long) stretched between the hind-wheels of the pieces, the distance between the pieces and caissons being increased; the harness, etc., is placed on the carriages, and any implements which could be injured by the horses are removed. If there be no forage on the caissons, the prolonges may be stretched between the hind-wheels of these carriages, the spare wheels being taken off. The men bivouac at a convenient distance in rear of the caissons; the guard is on the flank; the cook-fire is near the guard-tent. In a single platoon of a *horse-battery*, the carriages are parked in one line with ten yards' interval; the prolonges are lengthened by lariats doubled or trebled. If platoons are liable to be often detached, a rope should be provided for the cannoneers' horses. A battery bivouacs in a similar manner; the battery-wagon and forge are in line with the pieces; the picket-rope is ordinarily used instead of the prolonges. When practicable, the picket-rope, or prolonges, should be stretched between trees, etc., so as not to run the risk of having the carriages gnawed by the horses. See *Camp*, *Field-service*, and *Winter Quarters*.

BLACK.—In Blazonry, under the name of sable, denotes constancy, wisdom, and prudence.

BLACK-BAND IRONSTONE.—An ore of iron found very extensively in Scotland and elsewhere. It occurs in the carboniferous system of geologists, in regular bands, layers, or strata, and generally associated with coal and limestone. It is mainly a carbonate of iron accompanied by much coaly matter. The following is the composition of several samples:

	A.	B.	C.	D.	E.	F.
Carbonate of iron*.....	51.58	50.40	40.62	29.14	53.38	63.80

* Metallic iron, per cent	25.20	25.79	19.61	14.06	25.77	30.80

The black-band ironstone is easily reduced. It does not, however, yield a first-class iron when smelted by itself, and is therefore generally mixed with a small quantity of hæmatite (red iron-ore), which communicates strength and hardness to the iron obtained. See *Iron*.

BLACK-BOOK.—An ancient book of English Admiralty Law, compiled in the reign of Edward III. It has always been deemed of the highest authority in matters concerning the Admiralty in England.

BLACK-COATS.—Mercenary troops employed in the religious wars in the sixteenth century. Their appointments were black throughout, and they were armed with swords and pistols. They desolated the countries in which they were employed, and overwhelmed the humbler classes of the populations with their cruelties and depredations.

BLACK FLAG.—A flag of a black color, displayed as a sign that no mercy will be shown the vanquished, or that no quarter will be given.

BLACK FLUX.—A material used to assist in the melting of various metallic substances. Black flux is prepared by heating in a covered crucible ordinary or crude cream of tartar, or the bitartrate of potash ($KO,HO,C_8H_4O_{10}$), when the tartaric acid ($C_8H_4O_{10}$) is decomposed and charred, forming carbonic acid (CO_2), which remains in combination with the potash (KO) as carbonate of potash (KO,CO_2), accompanied by much free carbon. This very intimate mixture of carbonate of potash and carbon, otherwise called black flux, is a fine black powder of great service in the fluxing of metallic ores, as of lead and the separation of the metal therefrom. The black flux is likewise employed as the raw material from which, on the application of heat in iron vessels, the metal potassium can be obtained.

BLACK HOLE.—An appellation familiarly given to a dungeon or dark cell in a prison, and which is associated in the public mind with a horrible catastrophe in the history of British India—namely, the cruel confinement of a party of English in an apartment called the "Black Hole of Calcutta," on the night of the 18th of June, 1756. The garrison of the fort connected with the English factory at Calcutta having been captured by the Nabob Suraja Dowlah, this barbarian caused the whole of the prisoners taken, 146 in number, to be confined in an apartment 20 feet square. This cell had only two small windows, and these were obstructed by a veranda. The crush of the unhappy sufferers was dreadful; and after a night of excruciating agony from pressure, heat, thirst, and want of air, there were in the morning only 23 survivors, the ghastliest forms ever seen on earth.

BLACKING.—The material employed for producing a black glazed shining surface on leather. The main ingredient in the various kinds of blacking is bone-black, which is mixed with an oil, some sugar, and a little sulphuric acid. The materials in Day & Martin's blacking are finely powdered bone-black ground with sperm-oil, raw sugar or molasses, a little vinegar, and some concentrated sulphuric acid (specific gravity 1.850). The substances are incorporated together one by one in the order in which they are stated, and the action of the sulphuric acid is to convert much of the lime in the bone-black into sulphate of lime, which causes a thickening of the mixture, and a tenacious paste results. This paste, diluted with weak vinegar, is put, while warm, in stone-ware bottles, and is then ready for the market.

Blacking for shoes, belts, etc., consists of three parts of white wax, seven and a half parts essence of turpentine; one and a half parts of ivory-black. The wax is cut into small pieces and put into a glazed vessel. Spread the turpentine over it, and leave it for twenty-four hours. Then mix it by degrees with ivory-black. To use it, spread it with a rag in a thin layer on the leather, and afterwards rub with a soft brush.

Blacking for harness consists of yellow wax, four parts in weight, six parts essence of turpentine, one part of mutton-suet, and one part of ivory-black. Cut the wax into small pieces, and leave it to soak twenty-four hours in the essence of turpentine; grind in separately the ivory-black and suet until there is a perfect mixture of the whole mass. When the leather has lost its color, it may be restored by the mud of ink, or by sulphate of iron in a thick solution, spread upon the edges.

BLACKWALL HITCH.—A bend to the back of a tackle-hook or to a rope, made by passing the bight round the object and jamming it by its own standing part. See *Cordage*.

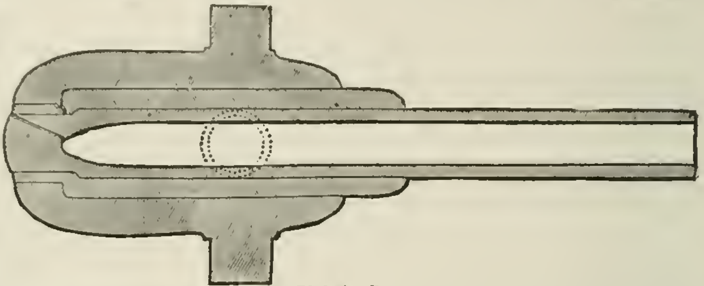
BLACK WATCH.—The appellation given to certain armed companies employed to watch the Highlands of Scotland. The term *black* arose from the dress of this species of militia, which was composed of tartans of dark colors. Some Highlanders had been armed by Government as early as 1725, when General Wade was appointed Commander-in-Chief in Scotland; but it was not till about 1729 or 1730 that the companies assumed a regular form. The companies were six in number—three comprising 100 men each, commanded by a Captain; and three of 70 men each, commanded by Lieutenants, acting as Captains. Stationed in different parts of the Highlands, and acting independently of each other, they were styled the Independent Companies of the Black Watch. The body was raised chiefly from the Whig or loyal clans—Campbells, Grants, Munros, etc.—and many men of good station in society joined it, not only for the sake of good pay, but for the valued privilege of bearing arms. The duties of the Black Watch were to enforce the Disarming Act, to overawe the disaffected, to prevent political meetings of a seditious kind, and to check depredations among the clans, or on the Lowland frontier. After being of considerable use for these local purposes, the whole of the companies were formed into the 42d Regiment, under the command of the Earl of Crawford, in 1739—their removal giving facility, no doubt, for the outbreak of the Rebellion in 1745. Retaining its original Highland character, the 42d Regiment became one of the most distinguished Corps in the British army; the whole of its history, for which we would refer to the work of Colonel Stewart on Highland Regiments, being a series of brilliant achievements. Embodied under the Earl of Crawford, the regiment would have adopted the tartan of that nobleman, if he had possessed such a cognizance; the Earl, however, being a Lowlander, it was necessary to adopt an arbitrary pattern of tartan, which has ever since been known as the 42d or Black Watch tartan.

BLACKWOOD.—A tree growing in Southern India in the Annamallay Forest, and in other parts of India and Burmah. The wood is close-grained, strong, flexible, fibrous, durable, and of a very deep purple color. It is used in the Bombay Gun-carriage Agency for beams, cheeks, axle-beds, and poles of field-carriages.

BLAISE.—A military order instituted by the Kings of Armenia, in honor of St. Blaise the Martyr, anciently Bishop of Sebasta, and the Patron Saint of Armenia. Justinian calls them Knights of St. Blaise and St. Mary, and places them not only in Armenia, but in Palestine.

BLAKELY GAS CHECK.—This consists of a taper breech-screw, devised to realize the advantages of a plug parallel with the bore, and yet to withdraw the plug without unscrewing its whole length. After the plug is unscrewed two or three turns, it may be withdrawn longitudinally, on a prepared slide, without further turning. The thin end of the screw forms a kind of gas-check.

BLAKELY GUN.—The most approved pattern of the Blakely gun combines in its construction the principles of "initial tension" and "varying elasticity," the object of which is to bring the strength of all the metal of the piece into simultaneous play, to resist explosion. The drawing shows the general features of the gun. The inner tube, or barrel, is made of low steel, having considerable but not quite enough elasticity. The next tube is made of high steel with less elasticity, and is shrunk on to the barrel with just sufficient tension to compensate for the insufficient difference of elasticity between the two tubes. The outer cast-iron jacket, to which the trunnions are attached, is the least elastic of all, and is put on with only the shrinkage attained by warming it over a fire. The steel tubes are cast hollow and hammered over steel mandrels, under steam-hammers: by this process they are elongated about 130 per cent; at the same time the tenacity of the metal is increased. All the steel parts are annealed.



Blakely Gun.

Captain Blakely uses other combinations of these metals, the simplest of which is a cast-iron gun with hoops of steel surrounding the reinforce. He objects to the use of wrought-iron on account of its tendency to stretch permanently. Blakely guns are rifled with one-sided grooves, and are fired with expanding projectiles. The following are the dimensions, etc., of Blakely all-steel guns:

Guns.	Weight.	Diam. of Bore.	Length of Bore.	No. of Grooves.	Twist.	Weight of Projectile.	Weight of Powder.
	Lbs	In.	In.		1 turn in Calibers.	Lbs.	Lbs.
100-pdr....	8,000	6.4	96	8	48	100	10
120-pdr....	9,000	7	100	8	48	120	12
200-pdr....	17,000	8	44-156	12	48	200	20
250-pdr....	24,000	9	do.	12	48	250	25
350-pdr....	30,000	10	do.	15	48	350	35
350-pdr...	35,000	11	do.	12	36	550	55
700-pdr....	40,000	12	do.	12	36	700	70

See *Ordnance*.

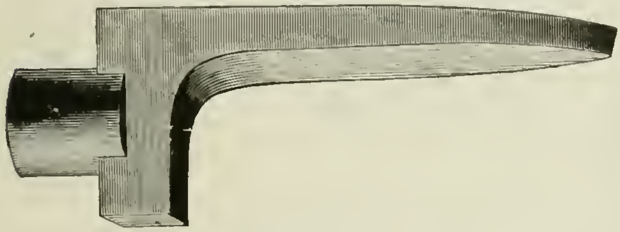
BLAKELY PROJECTILE.—This projectile has an expanding copper cup attached to its base by means of a single tap-bolt in the center, or other simple means. It is prevented from turning by radial grooves cast on the surface of the bottom of the projectile, into which the cup is pressed by the charge. The angle between the curved sides of the cup and the bottom of the projectile is filled with a lubricating material. On the forward part of the body are soft metal studs, more numerous than the grooves of the bore of the piece, that some of them may always form a bearing surface for the projectile against the lands. The driving sides of the grooves are deeper than the other. See *Expanding Projectiles.*

BLANCHARD LATHE.—A lathe for turning irregular forms, invented by Mr. Thomas Blanchard. It was the first successful lathe for turning gun-stocks, axe-handles, etc. The idea was partly elicited in Brunel's block-turning machine. The art of turning is most applicable in all the mechanical arts; for the hardest metals, and the most ponderous articles, as well as the softest wood and the most delicate pivots. See *Lathe.*

BLANCHARD PONTONS.—Tin cylinders terminated by hemispheres, 19½ feet in length, 2¾ feet in diameter, weighing 565 pounds, and with a buoyancy of 7110 pounds. They are divided into nine water-tight compartments, each provided with a screw-plug for the insertion of a sucker-pump. When placed at open order, 12½ feet apart, they bear infantry, cavalry in sections, or light field-artillery; when placed 8 feet apart they will bear siege-artillery. The heaviest guns may be towed on a raft of three or more pontons. The bridge formed with these pontons can be boomed out from the shore at the rate of five minutes per ponton.

BLANCH-LYON.—A title of one of the English pursuivants-at-arms. See *Pursuivant.*

BLANK.—1. A piece of metal brought to the required shape and ready for the finishing operation, whatever it may be. A planchet of metal, weighed, tested, and milled, is a *blank* ready for the die-press, which converts it into a coin. A strip of softened steel made into the required shape is a *blank*, which cutting and tempering transform into a *file.* A



Rifle Breech-pin Blank.

piece of iron with a flaring head, and otherwise properly shaped ready for nicking and threading, is a screw-blank, which with the final operations becomes a screw. The drawing shows the *blank* from which is made the rifle breech-pin.—2. The point of a target at which aim is taken, marked with a white spot; hence the object to which anything is directed.

BLANK CARTRIDGE.—The blank cartridge consists of a copper case, 70 grains of musket-powder, a cup-anvil, ½ grain percussion-powder, and a patch of black wax. The copper for blank cartridges is rolled in strips 35 inches long, 3.2 inches wide, and .024 of an inch thick; each strip will cut forty-two disks. The process of manufacture of the cases, etc., is the same as for the ball-cartridges up to the point of loading. This is done by boys, by hand, the case being loaded by a charger, and closed by pressing a

piece of soft black wax upon the open end. The cartridges are then wiped clean and the waxed end touched with shellac varnish. They are afterward put up in suitable paper boxes, which are packed in wooden boxes for transportation. The black wax, which is entirely dissipated by firing, is made by boiling for two hours 15 lbs. beeswax and 1 lb. rosin in one gallon of pine-tar. The following materials are required for 100,000 blank cartridges: 2390 lbs. sheet-copper, scrap one third, .03 inch thick; 575 lbs. sheet-copper, scrap one third, .045 inch thick; 1145 lbs. musket-powder (80 grains to each cartridge); 7¼ lbs. percussion-powder; 32 lbs. nails, 8d.; 4 lbs. nails, wrought; 15 lbs. paint; 1 pound twine; 1028 lbs. tarred boards, scrap 10 per cent; 1 quart varnish; 800 feet lumber; 4¼ gross screws; 25 lbs. paste; 1¼ lbs. putty; 45 lbs. paper covers; 3 lbs. glue. See *Center-fire Metallic-case Cartridge.*

BLANKET.—A course, heavy, open, woolen fabric, adapted for bed-covering, and usually napped. It may be twilled or otherwise. The name is applied to any coarse woolen robe used as a wrapping. The *poncho* is a blanket with a hole in the center for the head to go through. It is worn by the South Americans, Mexicans, and Pueblo Indians.

BLANKET-BAG EQUIPMENTS.—The blanket-bag now supplied by the United States Ordnance Department is a substitute for the clothing-bag formerly issued, and is designed to be worn without the "carrying-brace." Two "clothing-bag straps" are supplied in lieu of the brace system, each 23 inches long, 2 inches wide at one end, and 1½ inches wide at the other. On the wide end is sewed a standing leather loop, open, on the undressed side of the strap, and having a small brass-wire loop, to receive the coat-strap, on the blackened side, attached by a chape sewed and riveted under the leather loop. A double brass-wire hook is attached to the small end of the strap, which is passed through its eye (the back of the hook toward the undressed side) and secured by another hook riveted on and passing through holes punched in the strap to regulate the length. A sliding loop slipped over the fold in the strap keeps the double-wire hook in place. The straps are attached to the bag by means of two rectangular brass-wire loops at the top. To attach the strap, remove the double-wire hook and the sliding leather loop; pass the strap through the rectangular brass loop at the top of the bag from the back of the bag toward the side of the flap, holding the blackened side of the strap toward the bag and observing that the straps are "rights" and "lefts." The straight edges of the straps should be toward the middle of the bag. Next, pass the small end of the strap through the standing leather loop at the wide end and draw the noose thus formed up close to the rectangular wire loop on the bag. The small brass loop on the strap should be drawn through the brass loop on the bag so as to remain on the outside. Next, put on the sliding leather loop and then the double-wire hook. Adjust the strap to the desired length by means of the hook at the end, and pass the sliding loop over the fold in the strap. To attach the coat-strap, slip the sliding loop down to the buckle and pass the billet end through the small brass loop on the blanket-bag strap, holding the blackened side of the coat-strap toward the bag; pull the strap through to within one foot of the buckle; pass the billet through the sliding leather loop and push the latter down close to the brass loop through which the strap passes. The coat-strap should be inserted in same direction with regard to the bag as the blanket-bag straps—that is, so that when the strap hangs double over the flap of the bag the buckle end will be outside. To sling the bag, first hook the left-hand strap to the D ring on the lower left-hand corner of the bag, pass the left arm through this strap, grasp the end of the other strap with the right hand, swing the bag over the shoulders, carrying the right-hand strap over the head; bring this strap down over the right shoulder and hook it into the D ring at the lower right-hand corner of the bag. The webbing loop with button and button-hole at the bottom of the blanket-bag is designed to carry the tin cup. When the bag is filled, the flap is fastened down by passing the leather loops at the corners over he buttons on the gussets. A haversack-strap is also made of leather and supplied with double-wire hooks at each end like those on the blanket-bag straps. These hooks are inserted into the buckles at the top of the haversack. No change has been made in the haversack except to enlarge the pocket for the meat-

ration can. It can be used with either the carrying-brace or the haversack-strap now provided. A leather strap similar to the haversack-strap (only narrower) is now provided for the canteen. Iron-wire loops are attached to the sides of the canteen to receive the double-wire hooks on the strap.

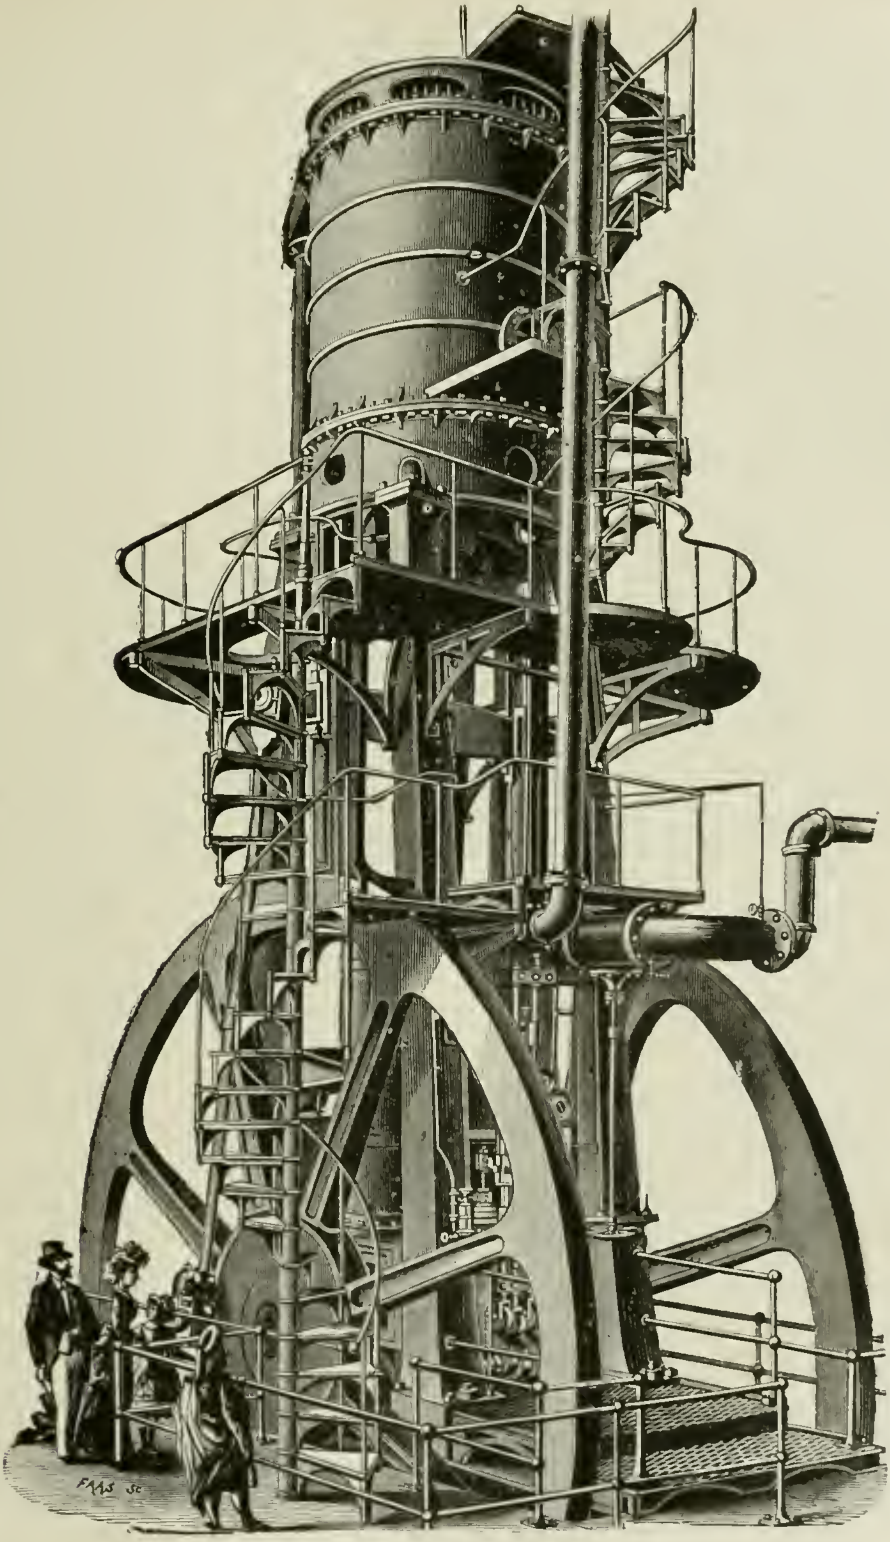
BLANKET-BOATS.—A practical and highly useful plan for crossing streams is by means of boats constructed of a single rubber blanket, capable of carrying a soldier, knapsack, arms, and accouterments, with only 4 inches of flotation. The size of some of the ordinary blankets is 6 feet long and 4¾ feet wide; but 7 feet by 5 feet would be preferable. If the height of the boat be made 1 foot, the length will be 4 feet and the width 2¾ feet, so as to be completely covered by the blanket. The frame may be made of round sticks, 1 inch and 1½ inch in diameter. In using these boats it will be convenient to lash several together, side by side, upon which soldiers can be transported. The frames are abandoned or used for fuel when the army has crossed over. See *Canvas-boats*.

BLANKETEERS.—A number of operators who, in 1817, met in St. Peter's Field, near Manchester, England, many of them having blankets, rugs, or great-coats rolled up and fastened to their backs. This was termed the "Blanket Meeting." They proceeded to march towards London, but were dispersed by the Magistracy. It is stated that their object was to commence a general insurrection. Eventually the ring-leaders had an interview with the Cabinet, and a better understanding between the working classes and the Government ensued.

BLAST.—The long flash from the muzzle of a piece of ordnance, and the rapid rush of the suddenly produced powder-gas, cause a very powerful *blast*, which acts destructively on objects close at hand lying in its path. In siege-batteries the parapets become damaged from the effects of their own fire. When the *blast* is confined in a narrow embrasure (temporary work the sides soon crumble away after repeated firing, entailing constant repair. Not only, however, is the embrasure gradually destroyed, but frequently the revetment of its sides catches fire or smoulders, rendering great care necessary in taking out fresh cartridges in loading.

BLAST-ENGINE.—For smelting and refining furnaces, where a blast with a pressure of some pounds per square inch is required, blowing-engines of large size are usually employed. Such an engine consists of a steam-engine, with the ordinary steam-cylinder at one end and a blast-cylinder at the other end of the beam. Such, at least, is the construction preferred for the larger-sized engines; but sometimes a horizontal arrangement of the cylinders is adopted for those of smaller size. The blowing-cylinder is of cast-iron, with an air-tight piston, which, as it ascends and descends with the motion of the engine, alternately inhales and expels the air at each end. A blast-engine at Shelton Iron-works, of which the blowing-cylinder is 8 feet 4 inches in diameter, and has a 9-foot stroke, working with 186 horse-power, and making 32 single strokes of the piston per minute, inhales 15,700 cubic feet of atmospheric air per minute; but this is compressed by the blowing-cylinder to a pressure of 3 lbs. per square inch above the atmosphere, which reduces the volume supplied by the cylinder to 13,083 cubic feet. Its volume, however, is largely increased again, when raised to the hot-blast temperature, before entering the furnace. In the Catalan forges of Spain and the south of France there is a very ingenious water-blowing machine in use, called a *trompe;* but it can only be advantageously employed where a fall of a few yards of water is available. The height from which the water falls determines the tension of the blast; but the height seldom exceeds 27 feet, which gives a pressure of from 1½ to 2 lbs. to the square inch. It is asserted that no other blowing-machine gives so equable a blast as the trompe, and it is the least costly of any; but it has the serious defect of supplying air more or less saturated with moisture. The theory of this singular machine has never been satisfactorily explained, although one or two able philosophers, who have specially studied the matter, incline to the belief that much of the air is carried down the pipe by becoming entangled in water. It is found that the separation of the air from the water is greatly promoted by allowing the falling current to impinge on a narrow platform, about midway of the wind-chest.

The engraving on the opposite page represents the blast-engine exhibited at the U. S. International Exhibition, in 1876, by the I. P. Morris Company, and which is constructed after a style now much in favor with many American furnace-managers. In its design the following points were sought to be obtained: compactness, without sacrifice of accessibility to moving parts; self-adjustment of parts liable to inequalities of wear; steadiness of the whole structure, and preservation of alignment by being self-contained. All the parts are proportioned to the work of supplying blast of 10 lbs. pressure steadily, if needed; and though the ordinary working of anthracite-coal-burning furnaces does not demand that high pressure, it has been exceeded in one case, 13½ lbs. having been blown off for a considerable period of time without damage to the engine. The Wanich equilibrium valve with which this engine is fitted was applied first about eight years ago to an engine at the Lebanon Furnaces, and soon after it was applied to a second engine at the same furnaces, on both of which it has proved highly satisfactory, saving steam and being entirely manageable. Double-beat valves will leak even if ground in, under steam, owing to unequal expansion between themselves and the chamber containing their seats. The single-beat valve with a "pilot" or supplementary valve is not easily handled on blast-engines, where it is found best, in order to promote regularity of motion, to set the steam-valves late, sometimes so much that the piston has moved one twelfth of its stroke before steam is admitted; consequently the passage,



Blast-engine.—I. P. Morris Company.

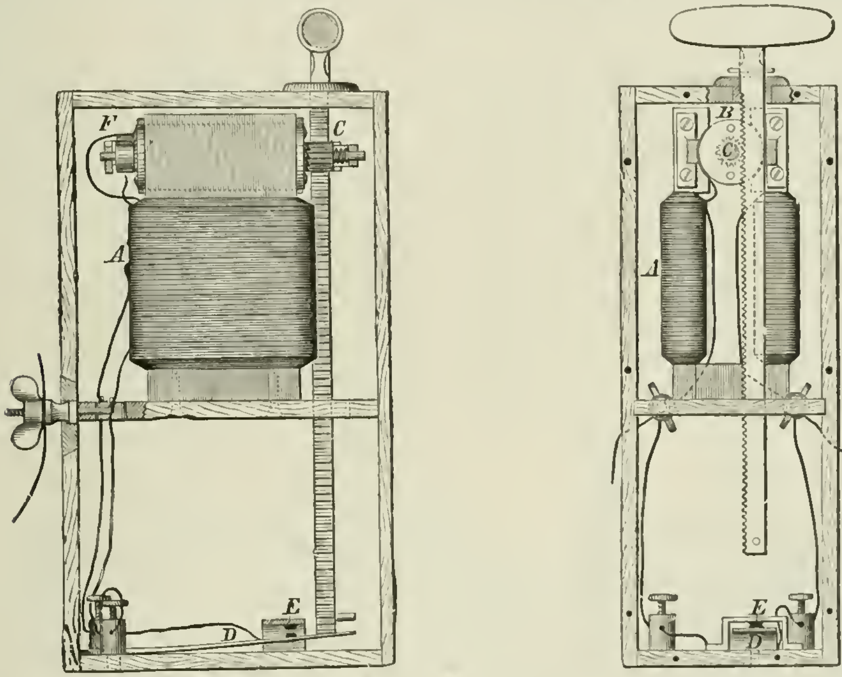
and space within the cylinder to be filled are proportionately so great and rapidly increasing that steam cannot pass by the pilot-valve fast enough to equalize the pressure on the upper and under sides of the main valve unless the pilot-valve be increased largely in area, when it becomes unmanageable by hand. To overcome this, Mr. Wanich, foreman of the machine-shop of the I. P. Morris Company, designed the valve illustrated, and found its action to realize what was anticipated of it. It consists in the use of a ring cast on the back of the main valve, extending upward, and bored out so as to envelop and slide freely upon the outside of another ring cast on the steam-chest bonnet, dropping downward and turned off. The rings are, of course, concentric, and the annular space between them is quite small in area, very much less than the aggregate area of the holes for the passage of steam below the pilot-valve; consequently any steam passing the annular opening when the pilot is raised goes freely through into the cylinder, exerting no appreciable pressure on the back of the main valve, and permitting it to rise easily. This absence of pressure has been proved by connecting with the space inclosed by the rings an ordinary steam-gauge, which showed the pressure when the pilot was seated to be, say, 35 lbs., and when the pilot was raised the pressure suddenly fell to almost zero until the main valve opened, when it rose again to 35 lbs. The blast-valves are of selected thick sole-leather backed with plate-iron; blast-piston fitted for either metal, wood, or bag packing; steam-piston fitted with metal double rings held out by springs; valves are lifted by cams operating directly against rollers fitted into the bottom ends of the lifting-rods. The cams are adjustable, but not variable, and give facilities for experimenting to determine the best distribution of steam without interference with each other. The cam-shaft is driven by spur-gears fitted to the main shaft. The fly-wheels are large, and weigh nearly 18 tons. The rim on the side in line with the crank-pin is cored out so that the preponderance of the opposite sides will counterbalance weight of pistons, rods, cross-heads, etc. The shafts are of wrought-iron with ample bearing-surface. The cross-head swivels in the yoke connecting the two piston-rods, and is provided with spherical journals for the connecting-rods, so that it may accommodate itself to any inequalities of wear in the main shaft or crank-pins. The height of the engine compared with its base is suggestive of instability, but that defect does not exist. A foundation of hard bricks or good stone, long and wide enough to take the bed-plate, and 10 feet deep, is known to be quite sufficient to sustain the engine without perceptible swaying of the top. This height is mainly due to length of stroke compared with diameter of blast-cylinder, whereby a given quantity of air can be supplied by a lesser number of revolutions —usually in engines of this stroke not exceeding twenty—and with fewer beats of the blast-valves; and as with fixed diameter of blast-cylinder the loss in delivery due to piston-clearance and space in the passages is a certain quantity, it is clear that the percentage of loss of useful effect from this cause diminishes as the stroke increases. The dimensions of the principal portions of the engine are as follows: blowing-cylinder, 90 inches diameter, 7 feet stroke; steam-cylinder, 50 inches diameter, 7 feet stroke; two fly-wheels, each 24 feet diameter; bed-plate, 13 feet by 8 feet; total height of engine, 36¼ feet; capacity, 10,000 cubic feet of air per minute.. See *Blower* and *Iron*.

BLASTING.—Before gunpowder was invented, the separation of masses of stone from their native rock could only be effected by means of the hammer and wedge, or by the still slower method of fire and water. In soft and stratified rock, wedges are still used for quarrying stones for building purposes, but in hard rock, or where regularity of fracture is no object, gunpowder is universally employed. Blasting is either accomplished by the *small-shot* system, or by large blasts or *mines*. Small shots may be fired, even under water, by inclosing the charge in a tin case, with a tube of powder reaching to the surface; or in a canvas bag, well tarred, and tied at the neck round a length of Bickford's fuse, which burns under water. The charge is inserted in the drill-hole, and the weight of the superincumbent water acts as tamping. In removing the wall between the old and new Shadwell basins of the London docks, shots were fired under water within a few yards of vessels lying in the basin, by using moderate charges, and by keeping a raft of timber floating over the hole, as a shield to prevent anything flying upwards. The Voltaic battery has been used for firing shots, chiefly under water, since 1839, in which year it was employed at the wreck of the Royal George and at the Skerryvore light-house.

When a large mass of rock has to be removed at once, recourse must be had to large blasts or *mines*. The greatest isolated example of this kind of blasting was the overthrow, in 1843, of the Rounddown cliff at Dover, by 18,500 pounds of powder, in three separate charges, fired simultaneously by voltaic electricity. These large blasts are of two kinds: either *shafts* sunk from the top of the rock, or *headings* driven in from the face. The shaft-holes are 6 feet long by 4 feet wide, of various depths, according to the height of the rock, but seldom much exceeding 60 feet. The deal-box, with the charge of powder, is placed in a chamber cut at one side of the shaft, so that the tamping may not be in the direct upward line of fire. The tamping consists of the stone and débris which have come out of the shaft; and the wires from the battery are protected from injury by being laid in a groove cut in a batten placed up one angle of the shaft. It is evident that the same point in the rock may be reached as well by a heading or gallery driven in from the face of the rock as by a shaft from the top, and often by a shorter route. Headings are made 5 feet high by 3 feet 6 inches wide, and are driven, if possible, along a natural joint in the rock. The direction of the gallery is changed and sunk at parts, to prevent the tamping from being blown out. Four men can, on the average, drive 5 feet run of heading per week; but cannot sink above 3 or 4 feet of shaft, which has a greater sectional area, and is more inconvenient to work in. The charge of powder may be divided and placed in two or more separate chambers, and it is better thus to spread a heavy charge over a length of face than to have it in one spot, at a greater distance from the face than about 30 feet. The charges for these mines vary from 600 to 13,000, and even more, pounds of powder; and the produce is from 2 to 6 tons of stone to the pound of powder, according to the density of the rock and the position of the mine. In military blasting, or where total destruction is aimed at, an excess of powder is little or no objection. Of late years great improvements have been effected in the production and application of explosive agents other than gunpowder, which latter, until lately, may be said to have been exclusively used for the purpose of blasting. Nitro-glycerine and gun-cotton were discovered within two years of each other; but while gun-cotton was immediately applied to industrial purposes, nitro-glycerine was destined to remain a chemical curiosity for about 16 years. Dynamite is a preparation of nitro-glycerine and porous earth, in the form of a pasty mass, which, without materially impairing its explosive properties, has the effect of rendering it perfectly safe to handle.

A great variety of electric blasting apparatus has been devised and tested in the last few years; but a remarkably simple and effective magneto machine made by the Laflin and Rand Powder Company possesses more points of merit than any other single machine made. It is constructed on the Wheatstone and Siemens principle, having a magnet of the horseshoe character, of iron, wound about with coils of insulated copper wire; between the poles of the magnet there is fitted to revolve an armature of cylindrical construction carrying in its body other insulated wire coiled longitudinally, as to the cylinder. The rapid revolution of the armature, by suitable means, generates and sustains in the machine an accumulative current of voltaic electricity of great power, which at the moment of its maximum intensity is, practically, switched off to the outside circuit in which are the fuses, and in the interior of each fuse the ignition is accomplished instantly. The drawings show the interior arrangement of the machine: *A*, the principal magnet; *B*, the armature revolving between the poles of the principal magnet; *C*, the loose pinion, its teeth engaging with the rack-bar, and by clutching also engaging with the spindle of the armature on the downward stroke (only) of the rack-bar; *D*, the spring which, when struck by the foot of the descending rack-bar, breaks the contact between two small platinum bearings, and this causes the whole current of electricity to pass through the outside circuit,—the leading wire and fuses; *E*, the two platinum bearings, one on the upper face of the spring, the other on the under side of the yoke over the spring; *F*, the commutator.

Platinum-fuses are specially made for this machine, and the manner of using is very simple. A fuse should be used with the wires attached, of such length that the ends may protrude from the surface after the hole is charged, the fuse-head being in the center of the charge. Tamp with dry sand, or in such a manner that the wires may not be cut or the insulated covering upon them be injured. When all the holes to be fired at one time are tamped, separate the ends of the two wires in each hole, joining one wire of the first hole with one of the second, the other or free wire of the second with one of the third, so proceeding to the end or last hole. If the wires attached to the fuses should not be long enough, use connecting wire for joining. All connections of wires should be by hooking and twisting together the bare and *clean* ends, and it will be best if the parts joining be bright. The charges having all been connected as directed above, the free wire of the first hole should be joined to one of the "leading" wires, and the free wire of the last hole with the other of the two leading wires. The leading wires should be long enough to reach a point at a safe distance from the blast—say two hundred and fifty feet at least. All being ready, and not until the men are at a safe distance, connect the leading wires, one to each of the projecting screws on the front side of the machine, through each of which a hole is bored for the purpose, and bring the nuts down firmly upon the wires. Now, to fire, taking hold of the handle for the purpose, lift the rack (or square rod toothed upon one side) to its full length and press it down, for the first inch of its stroke with moderate speed, but finishing the stroke with all force, bringing the rack to the bottom of the box with a solid *thud*, and the blast will be made. Platinum-fuses are not in any case to be fired by a spark or by the effects of free electricity, needing a current of sufficient strength and persistence that in its passage through the circuit it shall heat to redness a small bridge of fine platinum wire in the body of the fuse.



Magneto Machine.

The most extensive operation of blasting ever witnessed in the United States was, perhaps, the removal of the reefs in the East River, at Hallett's Point, near New York, known as the "Hell Gate Improvement." The rock to be removed extended more than 100 yards into the river, greatly narrowing the channel and rendering navigation extremely difficult. The plan of operation was to sink a large square shaft on the Long Island shore from which the rock projected, and to run into the rock at a proper depth long galleries radiating from the place of entrance like the lines of an expanded fan. The entrance-shaft was nearly 100 feet square, and its bottom was 32 feet below low water. Nearly 20 tunnels were bored in all directions, extending from 200 to 240 feet, and all were connected by lateral galleries. All the excavated rock was hauled to the entrance and hoisted to the surface. The work was completed in September, 1876, and made ready for blasting with more than 52,000 pounds of explosive material in many thousands of holes drilled for the purpose. The explosives were dynamite, rendrock, and vulcan powder. On the given day a quarter of a million people found their way to points on land and water where the explosion could be seen. When the eventful moment arrived, General Newton, the Engineer in charge, took the hand of his little girl, a mere infant, and with it pressed down the key by which the battery was fired. There was a rumbling or shaking of the ground, the rising of a great mass of water from 20 to 40 feet in the air, a few small stones thrown a little higher, an immense mass of smoke, and all was over. Millions of tons of rock had been shattered, and yet the noise and the shock were less than would have attended the simultaneous discharge of half a dozen field-pieces in the open air. There was so much doubt and ignorance about the possible effect of this explosion that many people living one, two, and three miles away left their houses and took positions in the open air, through fear of wide-spread ruin. The work was completed successfully, and after dredging out the broken stone the navigation of the channel was greatly improved. In previous years much has been done in the harbor of New York by surface-blasting, i.e., lowering to the face or to some crevice of a rock cans filled with nitro-glycerine and exploding it by electricity, the effect being to gradually wear away the rock. The great work of the Sutro Tunnel was another triumph for American engineering. See *Mines*.

BLASTING-FUSE.—The common *blasting-fuse* is merely a tube filled with a composition which will burn a sufficient length of time to allow the person firing it to reach a place of safety before it is burnt out. The safety-fuse, by which the charge can be fired by a man at a considerable distance, is also much employed. Some of these consist of a tape of soft material saturated with a highly inflammable compound (fulminates are employed in some to increase the speed of the flame), and covered with an envelope of water-proof material. Firing by electro-battery is much safer. See *Fuse* and *Platinum-fuse*.

BLASTING-POWDER.—An explosive, in the form of powder, used for blasting. The most powerful blasting-powders in common use are made by adding certain substances to nitro-glycerine which, by absorbing it, reduce it to the form of powder, and thus render it comparatively safe against the shocks and jars of use. The term *blasting-powder* is also specially applied to a powder analogous to gunpowder, but which contains sodium nitrate in place of potassium nitrate, or saltpeter.

There are two grades of *blasting-powder*, branded "A" and "B." "A," the best grade in quality, is packed in wood or metal kegs of twenty-five pounds each, and is branded as to size, "CC," "C," "F," "FF," "FFF," "FFFF," "FFFFF," "FFFFFF," and "glazed" or "unglazed" as may be desired. "CC" is the coarsest size, the others being finer, in the order as given above. "B," of which the greater

"CC" Blasting-powder.

quantity is sold, it being best adapted to most work, is packed in the same manner as the "A" The sizes are from "C," coarsest, to "FFFF," finest, "glazed" or "unglazed." "B" *blasting-powder* was first successfully made at one of the mills of the Laflin & Rand Powder Company, and to that success the country is indebted for a cheaper grade of powder than had ever been known before, and one as well adapted to most of the rock-excavation to be done as the higher grade, while for military mining it is entirely superior. It is a slower-burning powder than the "A," but produces a greater volume of expansive gases, and in soft rock lifts a large mass, rather than shatters to small fragments a less quantity.

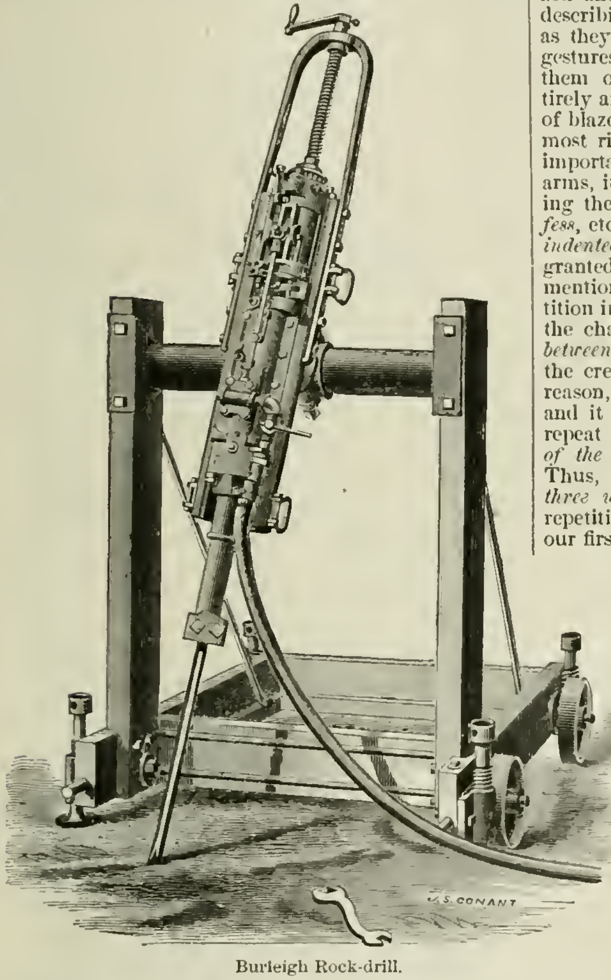
The drawing fairly shows the size of "CC" blasting-powder, either "A" or "B." See *Gunpowder* and *Mines*.

BLAST-METER.—An anemometer applied to the nozzle of a blast-engine. The Colliau meter is at present used by most furnace-managers. The following are the directions for its use:

1st. Place the meter in vertical position and as close as possible to the blast-gate, connect it with air-box by means of a half-inch gas-pipe and a short piece of India-rubber pipe between gas-pipe and meter. 2d. Pour into the meter about one half-pint of water. The water will stand at the same height in both tubes, at about mark 4. 3d. When the blast is put on, the water will descend on one side of the gauge; then loosen the screws of the sliding gauge so that it moves easily and slide the gauge downward until the 0 mark of the gauge reaches the level of the water of the descending side. Fix the gauge there by means of the lower screw. 4th. The mark on the gauge corresponding with the level of water in the ascending side will then represent the pressure in ounces per square inch. 5th. The amount of water put in is sufficient for a pressure of 7 to 8 ozs. Should a greater pressure be required, pour in a little more water. 6th. When the water on the lower side descends below the zero, slide down the gauge so that the zero of the gauge is level with the water. 7th. In cold weather it would be better to use spirits instead of water. To let the liquid out, open the small valve at the bottom. 8th. This blast-meter is calculated for sea-level. When the altitude is much greater a special gauge is required. See *Foundry*.

BLASTS.—Small chambers or holes made in rock or masonry, and charged with powder. The forming of blast-holes requires the use of particular tools, called *borers, jumpers, scrapers, needles*, and *tamping-bars*. To form the blast-hole, two or three men are required. One holds the borer with both hands, while the head of it is struck with sledge-hammers by one or two others. The first turns the borer at each stroke so that the hole may be circular, and from time to time clears it out with the scraper. When the hole required does not exceed 15 inches in depth, it may be excavated in the above manner; but if 20 inches, or more, deep, the jumper is generally made use of. The miner holds the jumper in both hands, raises it, and lets it fall in the hole, turning it continually; he also clears the hole with the scraper. When the stone is of a very hard description, it is usual to pour water occasionally into the jumper-hole.

Blast-holes are seldom made by hand nowadays, when the use of the rock-drill is possible. The drawing shows the Burleigh rock-drill mounted on a frame for surface and quarry work. When in operation, the drill may be raised from the wheels by means of the jack-screws represented. There are two sets of journals, and by shifting the wheels it can be moved in different directions. By the use of this machine great works become easy that could hardly be undertaken with the appliances of hand labor. Having the hole bored to a suitable depth, to load it, fill about one fourth or one third of it with powder, according to the nature of the stone. The charge for a depth of 18 inches is from 8 to 12 ounces. To tamp and prime the blast-hole, the needle is first introduced, plunging it well into the powder and placing it on the smoothest side of the hole; then a layer of clay is laid on the powder, and is closely pressed down with the tamping-bar. Other similar layers are then laid, or layers of brick reduced to small bits, the needle being turned repeatedly. It is usual to press down the first layers with a bar of wood, the helve of a tool, for instance, and the latter ones with the iron tamping-bar. When the hole is thus filled up, a small shell of clay is formed round the needle, which is then withdrawn, the hole left by it is filled with fine powder, and it is fired with a monk or a piece of port-fire. The use of the needle is often dispensed with, in which case the priming is rolled up in a sheet of brown paper, or it is introduced in straw-stalks thrust into one another. This priming is placed in the hole at the same time as the charge, so that it may penetrate well into the latter. The tamping is then executed as before. The use of the tamping-bar and the ordinary tamping may also be dispensed with, the hole being filled over the charge with very fine dry sand, poured in without any pressure.



Burleigh Rock-drill.

The many accidents that have happened in priming blasts have led to the invention of priming-fuses, which are made to burn somewhat in the same way as the fuse in the small Chinese fire-cracker. Their use is far safer than any of the former methods. For blasts under water, the charge is inserted in a water-tight tin case and fired either by a galvanic current or a priming-fuse, which is protected from the water by a small tube connected with the charge, and leading to the surface of the water. The result of many experiments has shown that in blasting rock a large portion of the powder—nearly half—may be saved, by mixing with the remaining part fine, dry sawdust of elm or beech. In blasts exploded in this way the effect is not the same as when the full charge of powder is used; the rock splits into fewer and larger pieces, and to finish dividing them a more frequent use of the sledge-hammer is required.

BLAZING-OFF.—Tempering by means of burning oil or tallow spread on the spring or blade, which is heated over a fire.

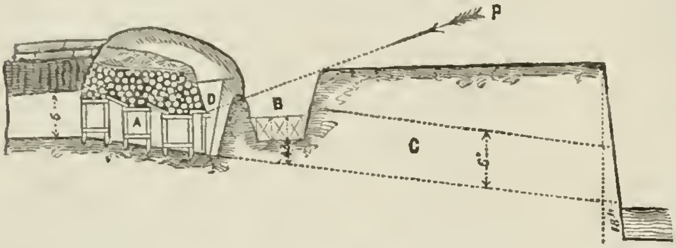
BLAZON — BLAZONRY.— These heraldic terms originated in the custom of blowing a trumpet to announce the arrival of a knight, or his entrance into the lists at a joust or tournament. The blast was answered by the heralds, who described aloud and explained the arms borne by the knight. Blazon and blazonry thus came to signify the art of describing, in technical terms, the objects (or charges, as they are called) borne in arms—their positions, gestures, tinctures, etc., and the manner of arranging them on the shield. As Heraldry, though an entirely arbitrary, is a very accurate science, the rules of blazoning are observed on all occasions with the most rigid precision. The following are the most important: 1. In blazoning or describing a coat of arms, it is necessary to begin with the field, mentioning the lines by which it is divided—*per pale, per fess*, etc., if such there be—and noticing if they are *indented, engrailed*, or the like, it being taken for granted that they are straight, unless the contrary be mentioned. 2. There must be no unnecessary repetition in blazoning; thus, where the field is blue, and the charges yellow, we should say, *azure, a crescent between three stars, or*, thereby implying that both the crescent and the stars are *or*. 3. For the same reason, where a color has been already mentioned, and it is necessary, in order to avoid ambiguity, to repeat it in describing a subsequent charge, we say, *of the first*, or *of the second*, as the case may be. Thus, we should say, *azure on a saltire argent, three water bougets of the first*, thus avoiding the repetition of the word azure. 4. Again, recurring to our first example, it would be an error to say, *three stars with a crescent between them*, because we must always begin with the charge which lies nearest the center of the shield. 5. Where the charges are of the natural color of the objects or animals represented, in place of describing the color, you simply say *proper*—i.e., of the proper or natural color. 6. Another general rule in blazoning, or rather in marshaling coat-armor, is, that *metal shall never be placed upon metal, nor color upon color*. The rules for blazoning separate charges, whether animate or inanimate, are indicated in the descriptions which will be found of them under their respective heads. See *Heraldry*.

BLECHSCHIENEN.—Thin metal plates which the ancient Gauls placed upon the buff coats of the infantry, between the buff and the lining. Also written *Blechstreifen*.

BLEUS.—A name given to the soldiers of the Republic, by the Royalists, during the wars of La Vendée, on account of their uniform.

BLINDAGE.—When a trench has to be pushed forward in a position where the command of the dangerous point is so great that it cannot be sheltered from the plunging fire by traverses, it is covered on the top and on the sides by fascines and earth supported by a framework, and is termed a *blindage*. The frames used, termed *blindage-frames*, are composed of two uprights or stanchions of 5-inch scantling, each 8 feet 6 inches long and pointed at both ends; and two horizontal pieces of the same-sized scantling, each 3 feet 4 inches long. The horizontal pieces are notched upon the stanchions at 12 inches from each end. The width of the frame from out to out is 3 feet 4 inches; the distance between the horizontal pieces from out to out, 6 feet.

This method of obtaining cover is principally requisite in trenches which descend towards the dangerous point; like the passages which lead from the trenches on the glacis into the covered-way, or to the bottoms of shallow ditches. The manner of forming the blindage is to set up a row of blindage-frames along each side of the trench or passages; to connect the two rows at top by like frames laid across the line of the trench; to cover the top frames by fascines and earth; and to fill in between the side frames and the sides of the trench with fascines. The trench is made by the double sap. Its width at bottom is 7 feet 6 inches; the width between the frames, 6 feet. The frames and fascines of the blindage are gradually placed as the trench advances, the latter preceding the former about 5 feet. The work is begun by placing an upright frame on each side; the two are



Longitudinal Section of Blindage Descent into Covered-way. A, Blindage-frames; B, Covered-way; C, Gallery Descent to Ditch; O, P, Direction of besieged fire coming over end of Traverse.

next connected by a frame on top, one side of which is lodged on the top cross-pieces of the upright frames, and the other supported by two auxiliary frames until the next two upright frames are placed; the fascines are then thrown over the top frame to the depth of about 2 feet, and these are covered with earth or raw hides, to prevent their being set on fire. Fascines are at the same time placed in on the sides.

The slope given to the bottom of a blinded descent should not be greater than one perpendicular to four base. When the descent is to a covered-way, the bottom of it should come out in the covered-way at 43 inches below its terre-plein; this will serve to determine the point of departure, the slope being fixed, which should be five feet below the surface of the glacis, so that when the blindage is put up at this point the top of it shall not be above the level of the parapet of the trench. A horizontal landing about 8 feet in breadth is made at the entrance of the blindage; and this is connected with the bottom of the trench by two ramps of one sixth.

The point selected for a blinded descent into a covered-way is usually at the end of a traverse of the covered-way; as the traverse will thus serve to cover the outlet of the blindage into the covered-way from a plunging fire in front.

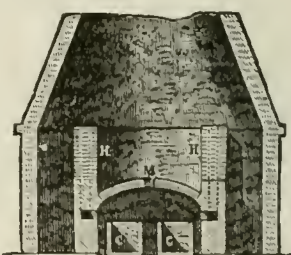
BLINDED BATTERIES.—In view of the great improvement in range, and the accuracy of fire of rifled guns, and of the greatly increased amount of both guns and mortars shown in the more recent sieges, the question of armored parapets and of bomb-proof blinds for the protection of the guns of the batteries in the position of the second parallel is one demanding consideration. When the batteries are not exposed to flank or very oblique slant views, chambers or casemates of timber, with strong bomb-proof roofs and sides with sufficient cover and strength to resist any chance shots, might be easily constructed, restricting the dimensions of each casemate to what will be strictly requisite for the maneuvers of the gun in it.

The entire front of the battery might be guarded from direct shot, particularly of elongated projectiles, by laying heavy logs or iron rails in an inclined position against the exterior slope and covering them with sand-bags, leaving only enough embrasure opening in front, both horizontally and vertically, for the field of fire wanted. Considering the range of these batteries at this distance of the second parallel, they might be sunk, so as to place them in greater security and to effect their construction more readily. See *Batteries*.

BLINDS.—Shutters of an embrasure; they are musket-proof, and at a siege, at the discretion of the Officer Commanding the Artillery, are made up by the Engineer Department from materials available on the spot. In the Crimea, coils of rope run round the chase of the gun were used in addition to the ordinary blind, to protect the gunners from the fire of riflemen when laying the gun.

BLIND SHELLS.—Shells which do not explode on impact, or at the time it is intended they should. Several causes are attributed to this defect, among them the imperfect manufacture of the fuse, the insecure manner of fitting it in the shell, shrinkage of the composition, whereby the fuse is unable to act and consequently does not ignite, and various other causes.

BLISTERED STEEL.—This variety of steel is prepared by exposing alternate layers of bar-iron and charcoal in a close furnace for several days. The purpose for which this steel is to be used determines the degree of carbonization. The best qualities of iron (Russian and Swedish) are used for the finest kinds of steel. This is the kind of steel from which, by hammering, rolling, etc., certain qualities of tools and files are fashioned. When broken up, piled, and welded under the hammer, it forms *shear-steel*, from which a finer class of tools is made, and when melted in crucibles it forms the finest kind of *cast-steel* for cutlery. Blister-steel is made from bar-iron of superior quality by a process of *cementation*, and the furnace employed for the purpose is termed a converting-furnace. This furnace is dome-shaped and inclosed in a conical jacket of brick-work, which serves to carry off the smoke from the flues, as shown in the drawing. The hearth of the furnace is divided in two parts by the grate, G, traversing the whole length of the furnace, in which a coal-fire is maintained, the flame of which is made to circulate around the fire-clay chests or pots, C, placed one on each side of the grate, before escaping through the flues in the wall, H, and through the opening, M. Into each of these pots layers of the purest malleable iron bars and layers of powdered charcoal are packed horizontally, one upon the other, to a proper height and quantity, according to the size of the pots, leaving room every way for the expansion of the metal when it becomes heated. The bars are cut to certain lengths, according to the lengths of the pots. After the packing of the pots is completed, the tops are covered with a bed of sand or clay, to confine the carbon and exclude the air. All the open spaces of the furnace are then closed, and the fire kindled. The heat is kept up for a week or ten days, according to the degree of hardness required, the hardest quality for melting purposes requiring the longest time. When the bars are removed after cooling, they are found to have undergone a remarkable change. They are no longer tough, but quite brittle and fusible, and covered over with blisters. During the process the iron absorbs and combines with from a half to one and a half per cent of carbon. The blisters are supposed to be due



Converting-furnace.

to the evolution of carbonic oxide arising from the combination of carbon with a trace of oxygen existing in the iron.

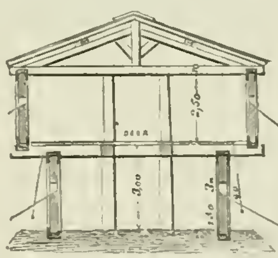
Several bars of *blistered steel* being welded together, and the process being repeated, *shear-steel* is the result; this being broken in pieces, and melted in a crucible, forms *cast-steel*, which possesses equality of texture and a capability of being rendered extremely hard, as well as of taking a fine polish. The Bessemer process of making steel consists in blowing atmospheric air into the melted pig-iron in the converting-vessel, and this operation is continued until the oxygen has effected a combination with all the carbon, except the quantity required to form steel. It has also been manufactured in such a way that the bars contain cores of iron, this gives all the hardness of steel and the tenacity of iron; and prevents articles made of it from breaking off short, as they frequently do, when formed only of hardened steel. See *Cementation* and *Steel*.

BLOCKADE.—1. In a military point of view, blockade is an operation for capturing an enemy's town or fortress without a bombardment or regular siege. The attacking party throws up works on the neighboring heights and roads; these works may be redoubts, for 200 or 300 men each, raised around at distances of 1000 or 1500 yards asunder; or they may assume other forms, according to the circumstances of each case. The rest of the besieging force remains under cover in villages, or in a temporary camp, ready to repel any sortie attempted by the besieged. The whole purpose in view is to prevent the besieged from receiving supplies of any kind, in order that, when the food or the ammunition is exhausted, they may be compelled to surrender. Fortresses situated on steep and rocky eminences, difficult to conquer by bombardment or assault, may often be reduced by blockade; because the roads or paths for the reception of supplies are few, and can be watched by a small number of troops. Towns situated on a plain are less frequently invested. If the inhabitants be numerous and commercial, they will soon be impatient of the restraint produced by a blockade, and may compel or induce the Governor to adopt a plan opposed to his wishes as a soldier. If, however, a resistance be determined on, the Governor sends out of the town as many non-combatants as possible; all the stores are collected in bomb-proof receptacles; economy is observed in the consumption of food; all the people within the walls are placed under military rules; and the Governor endeavors, by frequent sorties, to prevent the besiegers from making too close an investment of the place.

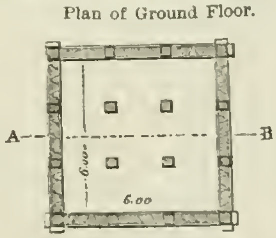
2. In international law, blockade is the right, in time of war, of rendering intercourse with an enemy's port unlawful on the part of neutrals; and it is carried into effect by an armed force (ships of war), which blocks up and bars export or import to or from the place blockaded. This right is described by all writers on the law of nations as clear and incontrovertible, having its origin in the soundest principles of maritime jurisprudence, sanctioned by the practice of the best times. It is explained on the reasonable theory that if a potentate or government lays siege to a place, or simply blockades it, such potentate or government has a right to prevent any other power, or representative, or subject of such power, from entering, and to treat as an enemy any one who attempts to enter the blockaded place, or in any way assists the besieged, for such a person opposes the undertaking and contributes to the miscarriage of it. To be valid, a blockade must be accompanied by actual investment of the place, and it may be more or less rigorous, either for the purpose of watching the operations of the enemy, or, on a more extended scale, to cut off all access of neutral vessels to that interdicted place, which is strictly and properly a blockade; for the former is, in truth, no blockade at all, as far as neutrals are concerned. But to be binding on neutrals, it ought to be shown that they have knowledge or may be presumed to know of the blockade; and this knowledge may arise in two ways—either by such a public and formal notification as we have already described, or by the notoriety of the fact. Yet it is at all times most convenient that the blockade should be declared in a public and distinct manner, instead of being left to creep out from the consequences produced by it; and the effect of such notification to the neutral government is clearly to include all the individuals subject to the latter. The breach of blockade may be either by coming out of the blockaded port or going in; such breach, however, may sometimes be excusable. It has been decided that intoxication on the part of the master of a ship will not be received as an excuse. That breach of blockade subjects the property employed for that purpose to confiscation is an established rule of the law of nations, and is universally acknowledged by all civilized governments. The violation of blockade by the master, however, affects the ship, but not the cargo, unless the cargo is the property of the same owner, or unless the owner of the cargo is cognizant of the intended violation. On the proclamation of peace, or from any political or belligerent cause, the continuance of the investment may cease to be necessary, and the blockade is then said to be *raised*. The blockading force then retires, and the port is open as before to all other nations.

BLOCK-BATTERY.—In gunnery, a wooden battery for two or more small pieces, mounted on wheels, and movable from place to place: adapted to fire *en barbette*, in the galleries and casemates, etc., where room is wanted.

BLOCK-HOUSE.—In inclosed works a place of retreat, into which the troops may retire in safety after a vigorous defense of the main work, will remove the



Plan of Ground Floor.



Block-house.

fears of the garrison for the consequences of a successful attack of the enemy, and will inspire them with confidence to hold out to the last moment. This interior work, which may very properly be termed the *keep*, can only be applied to works of large interior capacity. It may be formed of earth, or consist simply of a space inclosed by a defensive stockade, or palisading. In either case it should be about four feet higher than the main work, to prevent the enemy from obtaining a plunging fire in it from the parapet of the main work. The best arrangement for the keep is the construction termed the *block-house*. This work is made of heavy timber, either squared on two sides or four; the pieces which form the sides of the block-house are either laid horizontally, and halved together at the ends, like an ordinary log-house, or else they are placed vertically, side by side, and connected at top by a cap-sill. The sides are arranged with loop-hole defenses; and the top is formed by laying heavy logs, side by side, of the same thickness as those used for the sides, and covering them with earth to the depth of three feet.

The plan of a block-house is selected by the same general rules which are used for selecting the trace of a field-work. It may be square, rectangular, octagonal, and even cruciform in plan, according to the locality in which it is placed and the fire which it has to deliver. The dimensions should be sufficient to allow sleeping accommodations for the men who are to occupy it; and in some cases allowance should be made for other accommodations. Its interior dimensions should give at least a height of six feet in the clear for the rooms; a height of eight or nine feet gives better accommodations and better ventilation. The width of the interior should not be less than nine feet in the clear, as this is the least distance which can be used and give room for a passageway and a row of bunks. The length will depend upon the number of men it has to accommodate, after the width has been assumed. Block-houses must be made strong enough to resist the projectiles which may strike them, and should be proof against fire and splinters. They should be free from dampness, and should be well ventilated. The conditions given for a bomb-proof are applicable to the block-house, with the additional one of arranging its walls for defense.

It has been proposed to place a slight parapet of earth on top of the block-house. It is thought that this accumulation of earth would be too heavy for the timbers, independently of leaving but little space for the defense. Perhaps a better arrangement might be made on top, similar to a defensive stockade, the uprights being secured at bottom, between two pieces resting on the top pieces, and held firm by an arrangement of riband pieces and braces. It has also been proposed to place the interior and exterior rows of uprights three feet apart, and to fill in between them with closely packed earth, for a defense against artillery. This method has been tried, and was found to be less solid than the one here laid down, independently of being more difficult to construct. The top pieces should in no case project more than twelve inches beyond the sides, to admit of logs, etc., being rolled over on the enemy.

Timber block-houses were used frequently in the War of 1861–5 in isolated spots, as independent works. In these places they were, as a rule, exposed to attack only from infantry or cavalry, or a few pieces of field-artillery. It was found from experience that it required a thickness of forty inches of solid timber to resist the projectiles of field-guns. These isolated block-houses were frequently built two stories high. The upper story was usually placed so as to have its sides make an angle with the sides of the lower story. By this arrangement the corners of the upper story projected over the sides of the lower. This arrangement of the upper story removed the dead space near the sides of the lower story, and the sector without fire in front of the angles. Block-houses exposed to artillery-fire should not have a second story.

The drawing shows the construction of a block-house, with dimensions in meters, used by the French in Algiers; or it may be built of logs 18 inches square on the ground-floor and 12 inches square in the upper story. Height of each story 10 feet; loop-holed; the upper story projecting all round, beyond the ground-story, as machicoulis. Hatches are made in the roof for the escape of smoke, and are grated. See *American Block-house*.

BLOCKS.—1. *Blocks* are of two kinds, *made* and *mortised*. A *made* block consists of four parts—the *shell*, or outside; the *sheave*, or wheel on which the rope turns; the *pin*, or axle on which the wheel turns; and the *strap*, either of rope or iron, which encircles the whole and keeps it in its place. The sheave is generally strengthened by letting in a piece of iron or brass at the center, called a *bush*. Nearly all heavy blocks for ordnance purposes are made with iron shells and brass sheaves. A *mortised block* is made of a single block of wood, mortised out to receive a sheave. All blocks are single, double, or threefold, according to the number of sheaves in them. There are blocks that have no sheaves, to wit: a *bull's eye*, which is a wooden thimble without a sheave, having a hole through the center and a groove round it; and a *dead-eye*, which is a solid block of wood made in a circular form, with a groove round it, and three holes bored through it, for the lanyards to reeve through. *Snatch-blocks* are single blocks, with a notch cut in one cheek, just below the sheave, so as to receive the bight of a fall

Mortised Block.

without the trouble of reeving and unreeving the whole. They are generally iron-bound and have a hook at one end. A *tail-block* is a single block, strapped with an eye-splice, and having a long end left, by which to make the block fast temporarily to the rigging. This tail is usually selvaged, or else the strands are opened and laid up into sennit, as for a gasket.

Blocks were made by hand until about a century ago. But mere workers in wood could not produce them; it required unusual skill and practice to fashion the several pieces and put them together so as to possess the requisite strength and facility in working. In 1781 a Mr. Taylor began to make the sheaves and shells of blocks by a process which he had invented. He made all the blocks for the Royal navy until the expiration of his patent-rights. The Admiralty then commenced the manufacture on their own account. In 1801 Mr. (afterwards Sir) Mark Isambard Brunel submitted to the Admiralty a working-model of a very beautiful system of machinery for block-making; it was accepted, and the inventor engaged to set up the apparatus at Portsmouth. So intricate was the machinery, and so great the difficulty in procuring the several working-parts from the machinists of those days, that it was not until the year 1808 that the system was put into effective operation. It was then, however, so perfect that very few additions or improvements have since been needed. The machinery made blocks more accurately than they had ever been made by hand, and with the aid of ordinary workmen only. It could effect £50,000 worth of work in a year, or 140,000 blocks, by the assistance of ten men attending the machine. Duplicate machinery was made for Chatham. Brunel received £20,000 for his invention and for his personal superintendence until the machinery was brought into working-order; this sum was money well laid out, for the machine saved to the country more than £20,000 a year, in the busy warlike period from 1808 to 1815. The machinery itself is too complicated to be described except at a length incompatible with the limits of this work; but it may be stated in a general way that the system is made up chiefly of saws and lathes, combined with great ingenuity. The blocks are made of elm, and the sheaves of lignum vitæ; the pins are of iron, carefully prepared to avoid friction as much as possible.

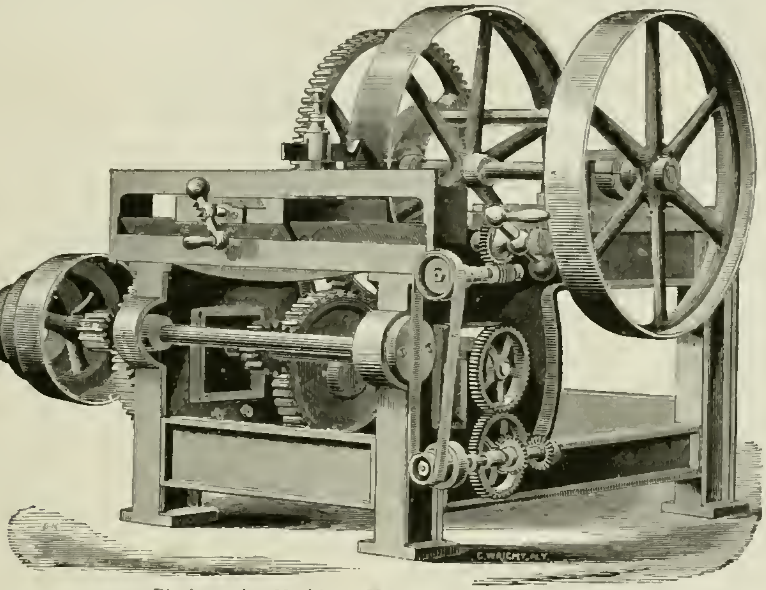
The drawing shows a most excellent block-turning machine manufactured by Messrs. Manning, Maxwell & Moore, New York. It is generally employed at the armories, and has a capacity for blocks up to 50 inches diameter. The latest designed block-turning lathe has a large cone-pulley, with 6 steps for a wide belt, which transmits the power through tangent gearing (accurately cut) to the main spindle; this is an extraordinarily steady and powerful method of driving, and is held in high estimation in England, where it has been tested through a range of work that demands the utmost steadiness, such as cylinder-boring, etc. The carrier-plate is of the equalizing type, obviating unequal and lateral strains. On each side of the solid bed-piece are placed rests which slide in and out on graduated surfaces to suit the diameter of the pulley to be turned; these rests can be set angularly to get any desired degree of "crown"; tools are thus operated on both sides of the machine. The feeds are continuous, not intermittent (a ratchet and a pawl give an intermittent feed). The feeds can be instantly engaged, disengaged, or changed. Another admirable feature of this tool is that the spindle of the cone-pulley runs at so much higher velocity than the main spindle that its speed is suitable for polishing when the latter is turning; a steel mandrel and a suitable rest are provided for polishing. This arrangement secures a combination of machines. The counter-shaft has two pulleys 20 inches in diameter, 5¼ inches face, which should run 130 revolutions per minute. See *Mechanical Maneuvers* and *Tackles*.

2. Rectangular prisms of wood employed extensively in all operations connected with the movements of heavy artillery. They are usually 8 inches square and 20 inches long.

BLOCK-SHIP.—A ship of war too old or too slow in sailing to render efficient service in action out at sea, but useful as a defense in great ports and naval arsenals. Since war-steamers have almost superseded the old sailing men-of-war, the latter are of little service except as block-ships, or for training-ships. The number of block-ships in the British navy in 1859 was about ten.

BLOCK-TIN.—Tin which has undergone refining, either by *liquation* or *poling*, when it is run into blocks, each weighing about 3 cwt. Tin thus treated is found to form in the melting-basin three strata, of which the top stratum is most pure, the bottom most impure, and the middle of average purity. The best qualities of this metal are the Banca, the Cornish, and the Spanish tin. This metal is mixed with copper to form bronze.

BLOCK-TRAIL.—In artillery, that pattern of gun-carriage the trail of which is formed of one beam, or two beams tabled one into the other. It is stated in Lieutenant-colonel Owen's *Modern Artillery* that this nature of carriage was invented in 1792 by Sir W. Congreve. It has now been superseded in lately constructed wrought-iron carriages by the bracket-trail.



Block-turning Machine. Manning, Maxwell & Moore.

BLOMARY—BLOOMARY.—A furnace for transforming pig-iron to wrought or malleable iron, or for making such iron directly from ore. When ore is used, a mass of iron called a "bloom" is produced, instead of the impure pig-iron that runs from the melted metal in a blast-furnace. The blomary process is one of the oldest in iron-working, and is used in rude forms in some still barbarous countries. The best of modern blomaries are the German and the Catalan (Spanish) furnaces, in which ores are reduced chiefly by means of charcoal. The best of ore should be used, as the waste is much greater in poor ore. In the Catalan, the charcoal, with a large part of the iron, is heaped on a square hearth opposite to the tuyere, charcoal and fine ore being added from time to time, while a moderate blast is kept up and the mass occasionally stirred. In about six hours the iron settles to the bottom, is taken out in a mass, and forged into a bloom. For the German or more common bloom, the ore is pounded fine and thrown in small quantities upon a charcoal-fire, with either hot or cold blast, hot being much the better. The metal settles to the bottom, and is drawn off at intervals, and hammered into blooms. The process is available in places where wood (for charcoal) and good iron-ore are found near each other. Iron so made is of the best quality, and is very desirable for converting into steel.

BLONDEL SYSTEM OF FORTIFICATION.—In this system the bastions are large and acute; their flanks are long and triple. The bastions are covered by counterguards, whose ditches, like those of the ravelins, are defended by low batteries. Small ravelins are substituted for the reduit of the re-entering place of arms. It is weak in outline and costly in masonry. See *Fortification*.

BLOOD-HOUND.—A variety of hound remarkable for its exquisite scent and for its great sagacity and perseverance in tracking any object to the pursuit of which it has been trained. It derives its name from its original common employment in the chase, either to track a wounded animal or to discover the lair of a beast of prey. It was also formerly called, both in England and in Scotland, *sleut-hound* or *sleuth-hound* from the Saxon *sleut*, the track of a deer. The poetical histories of Bruce and Wallace describe these heroes as occasionally tracked by blood-hounds, when they were skulking from their enemies. The blood-hound was at a later period much used to guide in the pursuit of cattle carried off in border raids; it has been frequently used for the pursuit of felons and of deer-stealers; and latterly, in America, for the capture of fugitive slaves and prisoners of war—an employment of its powers which has contributed not a little to render its name odious to many philanthropists. Terrible ideas are also, probably, suggested by the name itself, although the blood-hound is by no means a particularly ferocious kind of dog, and when employed in the pursuit of human beings can be trained to detain them as prisoners without offering to injure them. The true blood-hound is taller and also stronger in proportion and of more compact figure than a fox hound, muscular and broad-chested, with large pendulous ears, large pendulous upper lips, and an expression of face which is variously described as "thoughtful," "noble," and "stern." The original color is said to have been a deep tan, clouded with black. The color appears to have been one of the chief distinctions between the blood-hound and the talbot, but it is not improbable that this name was originally common to all blood-hounds. Many interesting anecdotes are recorded of the perseverance and success of blood-hounds in following a track upon which they have been set, even when it has led them through much-frequented roads.—The Cuban blood-hound, which is much employed in the pursuit of felons and of fugitive slaves in Cuba, differs considerably from the true blood-hound of Britain and of the Continent of Europe, being more fierce and having more resemblance to the bull-dog, and probably a connection with that or some similar race. Many of these dogs were imported into Jamaica in 1796, to be employed in suppressing the Maroon Insurrection, but the terror occasioned by their arrival produced this effect without their actual employment. It was this kind of blood-hound which was chiefly introduced into the former Slave States of North America.

BLOOD'S PONTONS.—Flat-bottom boats, made of light wooden frames covered by coatings of canvas, wood, cork, and leather, cemented together. Their length is 21 feet, breadth 5½ feet, weight 850 lbs., and buoyancy 5½ tons. The bridge will readily bear a 64-pounder gun. One wagon conveys one ponton and the superstructure for 15 feet of bridge. The bridge can be constructed at the rate of 200 yards per hour. See *Blanchard Pontons*.

BLOOM CAMPAIGN EQUIPMENT.—The difficult problem of drawing the proper line between the number of articles that should be in hand, when the engagement ensues, and the weight that should be transported on the person, has received much attention of late. The excellent campaign equipment devised by J. E. Bloom, Esq., late of the United States Artillery, is the nearest approach to perfection, as yet. By this device the center of gravity of the soldier remains nearly normal, and the strain falls upon those portions of the body which can best bear them. It seems that the principal objection to the "roll" as worn during the late war was that the weight fell upon one side of the body, thus heating it, etc. In Mr. Bloom's system of equipment this objection is entirely overcome, and the soldier is enabled to transport the following with great facility: one hundred cartridges (cal. 45), one blanket, one shelter-tent, one overcoat, one pair pants, one pair drawers, one undershirt, one woolen shirt, one pair socks, one pair shoes, towel, soap, etc., in addition to his rifle. The equipment consists in a system of supporting straps, by means of which the weight to be carried is directly transferred to and supported equally by the shoulders, without producing any horizontal pressure upon the chest. This object is accomplished by means of a yoke, composed of two leather straps, passing over the shoulders and joined by the same rivets at their ends—front and rear (opposite to the extremity of the sternum bone)—both to plates or stirrups, and also to a double blanket-strap, for securing the blankets and articles rolled therein. The blanket-roll is adjusted so as to fully clear, by an inch, the shoulder over which it passes, being thus suspended from a central point front and rear, upon a line passing through the center of gravity of the body—thus causing such a disposition of these articles as not to disturb the equilibrium of the body.

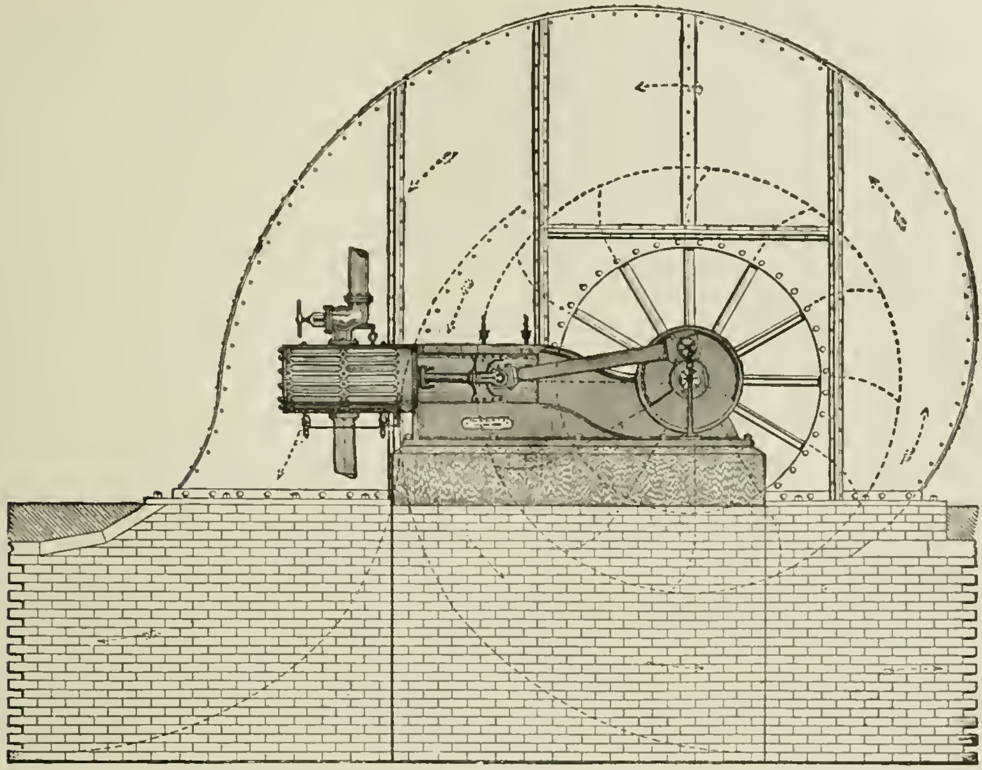
The weight of the cartridge-belt, of any variety, is supported from stirrups, both at front and back, by means of hooks, or hook-plates, which are connected with the belt through adjustable straps and snap-hooks. The haversack, canteen, gamebags, etc., are likewise suspended from side slots in the stirrups by means of straps. The blanket-roll, when firmly made and adjusted, exerts more than sufficient *outward thrust* to counteract all inward strains (which would otherwise fall upon the chest) due to the weight of the "roll," ammunition-belt, etc. This should be passed over the left shoulder when the soldier is right-handed or fires from the right shoulder, and *vice versa*. The following advantages of such an equipment are apparent: 1. Lightness and simplicity; and, being practically in one piece, there are no parts to be lost by the most careless. 2. Facility and quickness of slinging and unslinging. 3. It does not interfere with the action of the soldier, or the natural equilibrium of his body. 4. It does not heat the soldier; but allows him to sleep with all accouterments upon the person—the upper part of the "roll" forming a pillow for the head. The European soldier, on going into action, is allowed the following ammunition: France, 92; Germany, 117; Russia, 120; England, 100; Austria, 119. The equipment described will enable him to carry 100 rounds, in addition to his kit, etc., with ease and safety. See *Equipments*.

BLOOMFIELD GUN.—An ordinary cast-iron gun, with a charge of one third the weight of the shot. It has from 1¾ to 4 cwt. of metal to every 1 lb. of shot. The 32-pdr., of 56 cwt., and 24-pdr., of 50 cwt., are still in the English service, as well as some other guns of this pattern.

BLOUSE—BLOWSE.—A part of the undress uniform. It is usually employed for fatigues, marches, squad and company drills, and other drills when authorized by the Commanding Officer, and for ordinary wear. In the United States army, it is a sack-coat of dark blue cloth or serge; falling collar; single-breasted, with five buttons in front, same as those worn on the dress-coat. The skirt extends from one third to two thirds the distance from the hip-joint to the bend of the knee. The shoulder-straps are always worn with this coat. A Chaplain wears a plain black frock coat with standing collar; one row of nine black buttons on the breast, with "herring-bone" of black braid around the buttons and button-holes. Officers are permitted to wear a plain dark blue body-coat, with the button designating their respective corps, regiments, or departments, without any other mark or ornament upon it. This coat, however, is not to be considered as a dress for any military purpose. Enlisted men wear a dark blue blouse of navy flannel, according to the pattern deposited in the Quartermaster-general's Office. Blouses for winter wear are lined. See *Dress-coats*.

BLOWER.—A machine for creating an artificial current of air by pressure. A *plenum* engine, as contradistinguished from a *vacuum* engine, such as an aspirator. Blowers are used to increase draughts in furnaces; to furnish vital air to close and fetid places, as mines, poorly ventilated casemates, etc.; to furnish a current of warmed, cooled, moistened, or medicated air to hospitals or closely occupied barracks; to furnish a drying atmosphere in powder-mills and lumber-kilns; to raise fluids on the principle of the Giffard injector, etc.

The earlier modern forms of machine-blowers consist of cylinders with pistons, the differences between them consisting principally in the means for communicating motion and for securing a uniform blast. In the blowers at Woolwich, England, the air is forced from the blowing-cylinders into a reservoir,



Sturtevant Blower.

whence it issues by the force of its compression. The beams of the pistons are so connected that when one is at the top of the stroke another is midway of its cylinder and the third at its lowest point, maintaining very nearly uniform pressure in a wind-chest below with which each cylinder communicates. Blowers on the fan-principle are the favorite subjects of the exercise of the ingenuity of modern inventors in this line. In these the air is admitted through an aperture at or near the axis of the rotating fan, whence it is driven toward the periphery by means of curved arms, and discharged through an opening in the case. The Sturtevant blower, in its many varieties, is acknowledged to be superior to all others of its kind, and is much used by the United States Government, as also in foreign armories. The drawing shows a form of this blower especially adapted for use where air is to be carried any distance in underground ducts, and is much used for forcing fresh air into and taking foul air out of hospitals and apartments needing ventilation. These blowers are of all descriptions to suit every possible situation and kind of work, In nearly all cases where the blast-pipe leads directly upward from the blower it is better to have the blower built with upward blast, with the mouth pointing upward instead of horizontally. It saves making an elbow, which would have to be used in the case of a horizontal-blast blower; and in most cases where elbows are put on to the horizontal blast, contractors try to economize room, and by so doing make a very short elbow, which in some cases reduces the force of the blast about one fifth, necessitating nearly double the power to do the same work as would be required with the up-blast blower and straight pipe. These blowers may, for example, be used with advantage where the space under the floor is to be ventilated, and the foul air discharged upward through the roof or into a chimney, or when the blower is attached to a heater and located where floor-space is very valuable, and the hot blast used in dryers overhead or on the next floor above.

The pressure-blowers for cupola-furnaces and forges are made of steel, and are built very strong and heavy. The following table shows the melting capacities, speeds, etc., of blowers of various sizes:

No. of the blower.	Diam. in inches inside of cupola.	Melting capacity per hour in pounds.	Number of square inches of blast.	Cubic feet of air per minute.	Speed.	Pressure in ounces of blast	Horse-power req'ired	Power Saved by Reducing the Speed and Pressure of Blast.					
								Speed.	Oz. Pres.	H. P.	Speed.	Oz. Pres.	H. P.
1........	22	1,200	4 (One square inch of blast is sufficient for one forge-fire, or ninety square inches area of cupola-furnaces.)	324	4135	5	0.5						
2........	26	1,900	5.7	507	3756	6	1	3445	5	0.8	3100	4	0.6

10........	84	33,300	60	8,880	1815	16	48	1700	14	39.6	1566	12	31.7

The speed given is regulated so as to give the pressure of blast stated in ounces per square inch. The number of cubic feet of air per minute given against each size cupola is the result of numerous tests taken on cupolas. The term "square inches of blast" refers to the area of a proper-shaped mouth-piece discharging blast into the open air. The melting capacity per hour in pounds of iron is made up from an average of tests on a few of the best cupolas found, and is reliable in cases where the cupolas are well constructed and driven with the greatest force of blast given in the table. That portion of the table headed "Power saved by reducing the speed and pressure of blast" shows that in foundries, where a strong blast is not desirable, the blower can be run and do good work with very much less power. See *Fanner*, *Iron*, and *Steam-fan*.

BLOW-GUN.—A sort of air-gun used by the Barbados Indians of Brazil and other aborigines of South America. A similar contrivance is employed by some of the Malays, by whom it is called "sumpitan." The arrows are about fifty inches long, made of a yellow reed, and tipped with hard wood, which has a spike of cocourite wood poisoned. The spike is cut half through, so as to break off in the wound, that the arrow-shaft may drop and be recovered.

BLOWING-BAGS.—Bags filled with a small charge of gunpowder and coal-dust, and placed inside a common shell when it is not intended to burst the shell. The charge is ignited by means of a fuse. Blowing-bags are used in artillery-practice, to show where, if the shell had been a live shell, it would have burst.

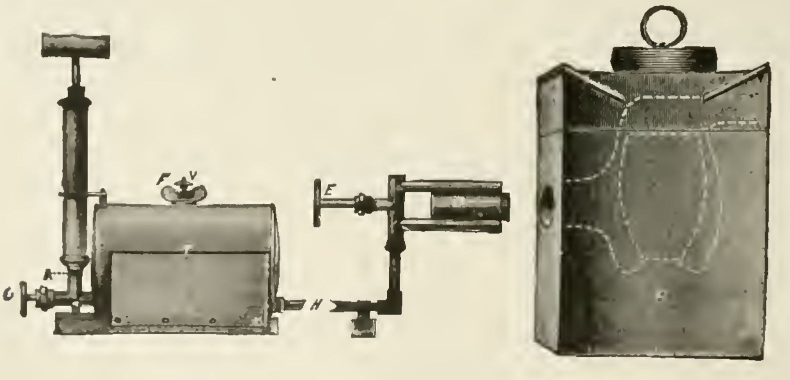
BLOWING-CHARGES.—Charges used for different natures of common shells; they are a mixture of gunpowder and coal-dust. The object of using the blowing-charge is when it is not desirable or safe to burst the shell.

BLOWING-CYLINDER.—A form of blast-engine. Smeaton introduced the blowing-cylinders at the Carron Iron-works, and by the power and volume of blast made effective the earnest and repeated attempts of the English to smelt iron by the use of the coke of pit-coal. This was in 1760, and utilized the invention of Abraham Darby, of Colebrookdale, in 1735.

BLOW-PIPE.—A small instrument used in the laboratory for soldering metals, and in analytical chemistry and mineralogy for determining the nature of substances by the action of an intense and continuous heat, its principle depending on the fact that when a jet of air or oxygen is thrown into a flame the rapidity of combustion is increased, while the effects are concentrated by diminishing the extent or space originally occupied by the flame. The blow-pipe generally consists of a conical tube of metal, about 8 inches long, closed at the wider or lower end, but open at the narrow or upper end, which latter constitutes the mouth-piece, and is turned over to admit of the lips closing perfectly round it. Near the lower end, a small tube, fitted with a finely perforated nozzle, is inserted at right angles to the large tube, the space below being intended as a chamber for condensing the moisture of the breath. Through this nozzle a fine current of air can be projected against the flame experimented with.

When a current of air from the blow-pipe is directed against a candle or gas-jet, the flame almost entirely loses its luminosity, owing to the perfect combustion of the gases evolved from the source of heat, and is projected in a lateral direction, as a long-pointed cone, consisting of three distinct parts. The first or central cone is of a dark blue color, and there the combustion is complete from the excess of air thrown in from the small nozzle. The second cone, or that immediately surrounding the first, is somewhat luminous; and here, the oxygen being insufficient for the combustion of the carbon, any metallic oxide subjected to the action of this portion of the flame is deprived of its oxygen and reduced to the condition of metal; for this reason the luminous cone is generally termed the *reducing flame* of the blow-pipe. Beyond the second cone, or where the flame comes freely in contact with the atmosphere, and abundance of oxygen is present to effect complete combustion of the gases, is a third or pale yellow envelope, containing excess of atmospheric air at a very high temperature, so that a portion of metal, such as lead or copper, placed at this point, becomes rapidly converted into its oxide: this outer part of the flame is on this account called the *oxidizing flame* of the blow-pipe.

Hoskins' Hydro-carbon Blow-pipe and Furnace are represented in the drawing. In this apparatus, much used in the armory, P is an ordinary force-pump, at the bottom of which (at A) is a valve which closes automatically upon releasing the pressure from the pump. C is a check-valve which closes the inlet to the tank, T, completely. F is the filling-screw. H is the pipe leading from the tank to the burner, D. E is the burner-regulator, terminating in a fine point, closing the orifice of the burner. B is the crucible-furnace. Upon pumping a few strokes, a pressure is created in the tank, which forces the fluid through the pipe, H, and the tubes of the burner, when it is vaporized by heating the burner, and finally issues from the fine orifice at the end of E as a highly heated gas, and burns as such with a powerful blast. After once being started, the heat of the flame passing through the burner evaporizes the fluid in the tubes, and hence it is automatic in its action. The air which is forced in is not used, and therefore it is only necessary to occasionally use the pump to maintain the pressure lessened by the consumption of the fluid, to keep up the blast.



Hoskins' Hydro-carbon Blow-pipe and Furnace.

The following are exemplifications of the difference of color communicated to the flame by different substances: salts of potash color the flame *violet;* soda, *yellow;* lithia, *purplish red;* baryta, *yellowish green;* strontia, *carmine;* lime, *brick-red;* compounds of phosphoric acid, boracic acid, and copper, *green.* The commonly occurring metallic oxides reducible by heating on charcoal alone in the inner flame of the blow-pipe are the oxides of zinc, silver, lead, copper, bismuth, and antimony; the principal ores not so reducible are the alkalies and alkaline earths, as also the oxides of iron, manganese, and chromium. The fluxes generally used in blow-pipe experiments are either carbonate of soda, borax (biborate of soda), or the ammonia-phosphate of soda, otherwise called *microcosmic salt.* The carbonate of soda, when heated on platinum wire in the oxidizing flame, forms with silica a *colorless glass;* with oxide of antimony, a *white bead*, etc. The following metals are reduced from their compounds when heated with carbonate of soda on charcoal in the inner flame of the blow-pipe, viz.: nickel, cobalt, iron, molybdenum, tungsten, copper, tin, silver, gold, and platinum. When compounds of zinc, lead, bismuth, arsenic, antimony, tellurium, and cadmium are similarly treated, these metals are also formed, but being volatile, they pass off in vapor at the high temperature to which they are exposed.

Borax, as a flux, is generally mixed with the substance under examination, and placed on platinum wire. When thus heated in either of the flames, baryta, strontia, lime, magnesia, alumina, and silica yield *colorless beads;* cobalt gives a *fine blue color;* copper, a *green;* etc. With microcosmic salt the results obtained are generally similar to those with borax, and need not be specially mentioned, as the test is applied in the same way. The blow-pipe has been long used by goldsmiths and jewelers for soldering metals, and by glass-blowers in fusing and sealing glass tubes, etc.; it has also been applied in qualitative analysis for many years, but more recently chemists (especially Plattner) have devoted their attention to its use, and have even employed it with great success in *quantitative* chemical analysis; the advantages being that only a very small quantity of material is required to operate upon, whilst the results may be obtained with great rapidity and considerable accuracy.

BLOW-PIPE AND ARROW.—A kind of weapon much used by some of the Indian tribes of South America, both in war and for killing game. It consists of a long straight tube in which a small poisoned arrow is placed and forcibly expelled by the breath. The tube or blow-pipe, called *gravatina pocuna*, etc., is 8 to 12 feet long, the bore not generally large enough to admit the little finger. It is made of reed or of the stem of a small palm. Near Pará it is in general very ingeniously and nicely made of two stems of a palm (*Iriartea setigera*) of different diameters, the one fitted into the other, in order the better to secure its perfect straightness. A *sight* is affixed to it near the end. The arrows used in that district are 15 to 18 inches long, made of the spines of another palm, sharply pointed, notched so as to break off in the wound, and their points covered with *curari* poison. A little soft down of the silk-cotton tree is twisted round each arrow, so as exactly to fit the tube. In Peru arrows of only 1½ to 2 inches long are used, and a different kind of poison seems to be employed. An accidental wound from one of these poisoned arrows not unfrequently proves fatal. In the hand of a practiced Indian the weapon is very deadly, and particularly when directed against birds sitting in the tops of high trees. As his weapon makes no noise, the hunter often empties his quiver before he gathers up the game, and does more execution than an American sportsman could with his double-barreled fowling-piece.

BLUDGEON.—A short stick, with one end loaded or thicker and heavier than the other, used as an offensive weapon.

BLUE-LIGHT.—An ornamental composition in pyrotechny. For one hundred lights the following materials are required: *niter*, 9 pounds 10 ounces; *sulphur*, 2 pounds 6¼ ounces; *red orpiment*, 11 ounces; *mealed powder*, 11 ounces. The materials should be pure, well pulverized, and thoroughly incorporated, rubbing them in the hands, and passing them several times through a fine hair-sieve. *Hemispherical cups*, of well-seasoned wood (beech, linden, etc.), with a handle 10 inches long, 1¾-inch diameter; *quick-match; paper; paste.* To prepare a blue-light, fill the cup with composition, and press it firmly in; prime the cup with quick-match, and cover the whole with cartridge-paper pasted to the bottom of the cup. The brilliancy of the light depends on the purity and thorough incorporation of the ingredients. The composition may also be driven in a paper case, and afterwards cut off to suit the required time of burning. Both ends of the case are closed with paper caps and primed with quick-match, in order that one or both ends may be lighted at pleasure. A light in which the composition is 1.5 inch in diameter can be easily distinguished at a distance of 15 miles. See *Compositions* and *Fire-works.*

BLUE PETER.—A blue flag with a white square in the center, used to signify that the ship on which it is raised, or the fleet of which that is the flagship, is about to sail. "Peter" is a barbarism for the French *partir*, a notice of departure.

BLUES.—One of the three mounted regiments of household troops. This regiment was originally raised at Oxford, and was commonly called the Oxford Blues. It is now known as the regiment of Royal Horse-guards.

BLUING.—The art of imparting a blue color to finished iron-work or steel, such as gun-locks, barrels, gun-sights, etc. The object in bluing articles, which is simply coating them with a thin film of oxide, is to prevent further oxidation from exposure to the atmosphere.

BLUNDERBUSS.—A kind of short musket with a very wide bore, sufficient to take in several shot or bullets at once. It has a limited range, but is very destructive at close quarters. As a military weapon it is chiefly of service in defending passages, doorways, staircases, etc. Some of the English and German troopers in the seventeenth century were armed with the blunderbuss; but the carbine has since nearly superseded this weapon.

BLYDE.—A kind of war-machine, which was used in ancient times to throw stones; some authors compare it to the catapult. In the year 1585, at the siege of the Castle of Rucklingen, Albert, Duke of Saxony and Lüneburg, was killed by a stone thrown from a blyde. Also written *Bly* and *Blude.*

BOARD OF ENGINEERS.—A Board consisting of not less than three officers to be designated by the Chief of Engineers, with the sanction of the Secretary of War, whose duty is to plan or revise, as may be directed by the Chief of Engineers from time to time, projects of permanent fortifications required for the defense of the territory of the United States, and works of river and harbor improvement; also to consider and report upon such other matters as may be referred to it by the Chief of Engineers. It is the duty of the Members of the Board, whenever required by the Chief of Engineers, to inspect and report upon any of the works of construction or other of the operations of the Engineer Department.

Whenever the defense or improvement of any particular locality or other work is under consideration, the local Engineer officer may be associated with the Board as a member thereof, if, in the opinion of the Chief of Engineers, this can be done consistently with his other duties. Two Members of the Board constitute a quorum for the transaction of business, but its final decisions in important matters must be sanctioned by a majority of its members. A dissenting member may present his views or project through the Board to the Chief of Engineers, with drawings and estimates. The reports of the Board are made to the

Chief of Engineers. It keeps a journal of its proceedings, and on the first day of each month reports to him the movements of its members, and a brief statement of the occupation of the assembled Board. The Chief of Engineers submits all important reports of the Board, with his views thereon, to the Secretary of War, without whose sanction no important work can be undertaken.

BOARD OF EXAMINATION.—A Board instituted in the Army to determine upon appointments in regiments, and for appointments and promotion in the Medical Staff, Engineer Corps, and Ordnance Department. All members of these Boards are army officers.

BOARD OF OFFICERS.—A number of officers assembled by military authority for the transaction of business.

BOARD OF ORDNANCE.—A Government Department formerly having the management of all affairs relating to the Artillery and Engineering Corps, and to the *matériel* of the British army. Under this precise designation, the Board no longer exists; a change having been made which requires brief explanation. The Board existed from the time of Henry VIII. until 1855, when it was abolished, its functions being vested in the Secretary of State for War as regarded *matériel*, and in the Commander-in-Chief as concerned the military command of the Artillery and Engineers. The Board of Ordnance until 1854 comprised the Master-general of the Ordnance, the Surveyor-general, the Clerk of the Ordnance, and the principal Storekeeper, all of whom were usually Members of Parliament. There was no chairman at the meetings, and the Board often consisted of only one officer. The Master-general had a veto, and was in that respect more powerful than the chief member of the Board of Admiralty; although, not having necessarily a seat in the Cabinet, he had less political power. The Board days were thrice a week; and each of the four members had control over certain Departments—the patronage of which was generally vested in him. Scarcely any improvements were made from 1828 till 1854, and the general arrangements were very defective. Of the four members, the Master-general, besides his veto, had a general authority; the Surveyor-general had control over the Artillery, Engineers, Sappers and Miners, Ordnance Medical Corps, contracts, laboratory, gunpowder, barracks, and navy gunners; the Clerk of the Ordnance managed the estimates, money-arrangements, civil establishment, pensions, superannuations, and ordnance property; while the principal Storekeeper had charge of stores, store-rooms, naval equipments, and naval war-stores. In matters relating to coast-defenses it was often difficult to decide between the Admiralty and the Ordnance, each Board claiming authority. When the Crimean disasters took place in 1854, the defects of the Board of Ordnance became fully apparent: it could not work harmoniously with the other Government Departments. The Board was dissolved, and the office of Master-general abolished. By the War Office Act of 1870 the post of Surveyor-general of the Ordnance was revived as one of the principal officers of the Secretary of State for War. He is responsible for the *matériel* and supplies of the army. See *Ordnance Board* and *Ordnance Corps*.

BOARD OF VISITORS.—A Board appointed by Act of Congress approved August 8, 1846, amended by Acts of March 16, 1868, and February 21, 1870, to attend the Annual Examination and make an annual report on the condition of the United States Military Academy. It consists of seven persons appointed by the President of the United States, two Senators appointed by the President of the Senate, and three Representatives appointed by the Speaker of the House of Representatives. An annual examination of the classes, preparatory to their advancement, shall commence on the first day of June (except when that day comes on Sunday or Monday, in which case it shall commence on the first Tuesday), at which time the Cadets shall be examined by the Academic Board, or its Committees, in all the branches of study and instruction through which they have passed in the previous academic year, in the presence of the Board of Visitors, or such members as may be present.

BOARDS OF SURVEY.—Boards of Survey have no power to *condemn* public property. They are called only for the purpose of establishing facts or opinions by which questions of administrative responsibility may be determined, and the adjustment of accounts facilitated; as, for example, to assess the amount and kind of damage or deficiency which public property may have sustained from any extraordinary cause, not ordinary wear, either in transit or in store, or in actual use, whether from accident, unusual wastage, or otherwise, and to set forth the circumstances and fix the responsibility of such damage, whether on the carrier, or the person accountable for the property or having it immediately in charge: to make inventories of property ordered to be abandoned, when the articles have not been enumerated in the orders; to assess the prices at which damaged clothing may be issued to troops, and the proportion in which supplies shall be issued in consequence of damage that renders them at the usual rate unequal to the allowance which the regulations contemplate; to verify the discrepancy between the invoices and the actual quantity or description of property transferred from one officer to another, and ascertain, as far as possible, where and how the discrepancy has occurred—whether in the hands of the carrier or the officer making the transfer; and to make inventories, and report on the condition of public property in the possession of officers at the time of their death. In no case, however, does the report of the Board supersede the depositions which the law requires with reference to deficiencies and damage.

It is required that Boards of Survey shall *fully investigate* the subject of losses submitted to them; that they shall call for all evidence attainable without limiting their inquiry to that submitted by the party or parties at interest; that they shall scrutinize rigidly the evidence, especially in the matter of property alleged to have been stolen or embezzled by deserters or others; and that they shall recommend no officer or soldier to be relieved from responsibility for property till the proof shall be clear and conclusive that he has given it his watchful attention, and fully performed his duty in regard to it. In order to relieve an officer from liability on account of public property which has become damaged, except by fair wear and tear, or which is believed to be unsuitable for the service, it shall, before being submitted to an Inspector for condemnation, be examined by a Board of Survey. Exceptions will be made in cases of animals or other public property infected with contagious disease, which may be summarily disposed of by order of a Commanding Officer. One copy of the proceedings of the Board will accompany the inventory and inspection report which is transmitted, as a voucher, with the accounts and returns of the officer responsible for the property. Another copy of the proceedings of the Board and of the inventory and inspection report will be filed with his retained papers.

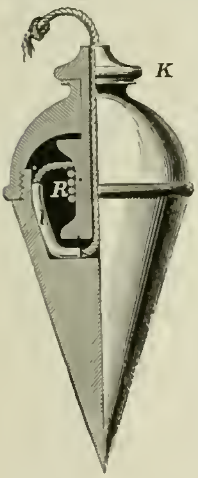
Boards of Survey are not convened by any other than the Commanding Officer present. They are composed of as many officers, not exceeding three, as may be present for duty, exclusive of the Commanding Officer, and the officer responsible in the matter to be reported on. In case the two latter only are present, then the one not responsible will perform the duties. When the responsible officer is the only officer at a post, he will, instead of constituting himself a Board, furnish his own certificate of the facts of the case, accompanied by affidavits of Non-commissioned Officers at the post cognizant thereof. If this should not be satisfactory, the Department Commander, upon notification, may send an Inspector to make the necessary report. Neither the Commander nor any member of the Board should be parties interested in the matter to be investigated. A Board of Survey has no legal power to swear either itself, its members, or witnesses before it.

BOAR'S HEAD ORDER OF BATTLE.—Among the orders of battles among the ancients, that known as the *wedge*, or *boar's head*, is the most celebrated. In this disposition, the *point*, or *head*, is formed of a subdivision of the phalanx of greater or less strength, according to circumstances; this being supported by two, three, and four subdivisions of the same force, one behind another. See *Order of Battle*.

BOAT.—A small open vessel used in military operations for crossing rivers, and for forming pontons, flying-bridges, etc. When the services of a bridge of boats is dispensed with, i.e., no longer required by the army, the boats should be broken up, to prevent their falling into the hands of the enemy.

BOAT-BRIDGE.—A boat-bridge consists of a track laid on a number of boats anchored parallel in the stream, or moored to ropes or chains which pass from bank to bank. The bridge thrown across the Hellespont by Xerxes when he invaded Greece, 480 B.C., had a length of 500 paces, and was supported on ships used as *pontons*. Suspension-cables of flax and biblos united the ships; transverse beams were laid on the cables; the beams supported planks and earth, and the army marched across, bag and baggage. Many years after, there appears to have been a more permanent construction of this nature in the same vicinity. At Abydos is the Zengma, a bridge of boats which could be unfixed at pleasure for the passage of vessels. Cyrus, according to Xenophon, crossed the Meander on a bridge supported by seven boats. Bridges of boats were in general use in the Middle Ages, and are still used on the Continent of Europe. One at Strasburg is 1300 feet long. Boat-bridges, in a military point of view, are classed as ponton-bridges, the pontons or bateaux and the road-bed being transported on wagons with inclined planes, and raised and lowered by means of machinery driven by water-wheels. See *Bridges*.

BOB.—A conoidally shaped piece of metal suspended by a cord attached to its upper end, and used for determining vertical or, in connection with a level or straight edge, horizontal lines. It is indispensable in engineering operations, sighting guns, and placing various surveying and astronomical instruments centrally over stations or points of departure. The drawing shows an adjustable plum-bob, having a concealed reel, *R*, around which the cord, *l*, is wound by turning the milled head, *K*, on top. The friction upon the reel within will hold the bob at any desired point of the line. See *Pendulum* and *Plummet*.



Adjustable Plumb-bob.

BOCCACCI.—A peculiar kind of fire-arm used by the Italians. It is enlarged towards the muzzle in the shape of a trumpet. This gun is principally used, at present, by the Calabrians.

BOCH MAGAZINE-GUN.—This gun belongs to that system in which a fixed chamber is closed by a bolt by direct action, and in which the lock is concealed. The stock is in a single piece, extending nearly to the end of the barrel, and secured to it by bands held in place by springs. The tang-screw and the screw which passes into the receiver secure the latter to the stock. The trigger-guard is fastened by screws. The receiver has two longitudinal holes, one on each side. The opening on the left side is for the ejection of empty shells, and the one on the right side is for the introduction of cartridges, whether used as a magazine-gun or as a single-loader. The latter opening has at its ends two projections, which fit to corresponding surfaces on the magazine when the latter is attached. The receiver is perforated at its rear for the reception of the breech-bolt. The latter consists of three parts, viz., the rear piece through which the firing-pin passes, the projection of the pin fitting into a cut; the locking-tube, including the handle; and the bolt-head or body, through which the firing-pin passes, and which supports the cartridge at the instant of fire.

The firing-pin having been introduced into the rear piece is then passed through the firing-pin spring; the movable shoulder is then, by sufficiently compressing the spring, introduced over the head of the pin, and by giving it a quarter turn is retained on the pin bearing against the shoulders of the latter. The spring is then held compressed between the ends of the rear piece and the movable shoulder. The firing-pin and spring are passed through the locking-tube, and then through the bolt-head, which is screwed to the rear piece. The locking-tube has two projections which, when the handle of the bolt is turned down in the receiver, fit into two recesses in the latter, and the bolt is thereby held in position. When the handle of the bolt is turned up from the locked position, the curved surface of a cut cams back the firing-pin by means of a projection (which slides in the cut), and the latter then rests in a notch and the piece is cocked. When the handle is turned down the cut is brought opposite to the projection which, released from the notch, is held by the nose of the sear; hence the firing-pin cannot reach the cartridge until the bolt-handle is turned down, and accidental explosions are therefore avoided. The bolt-head carries the extractor, which is fastened to it by means of a dovetail-tenon which fits into a recess in the bolt-head. The bolt-head is prevented from turning by a projection fitting into a groove in the receiver. The sear is notched for the nose of the trigger. The sear-spring is attached to the under side of the tang by a screw. The trigger when pulled releases the projection of the firing-pin, and the cartridge is exploded. The extractor hooks on the rim of the cartridge when the bolt is closed, and, when it is withdrawn, throws out the empty shell through the hole in the left side of the receiver by deflecting it from the axis of the chamber. The magazine is attached to the right side of the receiver, and is operated by a wheel which, when a cartridge is to be introduced, is turned so that a cartridge can drop into the receiver, when the bolt pushes it well into the chamber. The magazine holds twenty cartridges.

In another pattern of the Boch gun the stock is in two parts, the butt and the tip; these are joined together and to the barrel by a band which passes around the ends of the two parts, at their junction, and the barrel. Another band fastens the front end of the tip-stock to the barrel. In the right side of the butt-stock is a longitudinal opening coincident with a similar one in the receiver. Through this hole cartridges may be introduced on the carrier. The butt-stock is grooved to fit the barrel and cut through for the receiver, which is fastened to the stock by means of a tang-screw, passing through the stock into the trigger-guard plate. The butt-stock is also perforated by a hole continuous with one in the tip-stock, through which the magazine-tube passes, the latter being fastened to the receiver by a screw-thread. This gun carries nine cartridges in the magazine and one in the chamber. As a magazine-gun, three motions are necessary to operate it, viz., opened, closed, fired; as a single-loader, four motions, viz., opened, loaded, closed, fired. See *Magazine-gun*.

BODKIN.—Anciently a dagger. The bodkin was used by women of antiquity to fasten up their hair behind. It was the method commonly adopted by the priests of Cybele, as well as by the female characters in Greek tragedy, the bodkin being highly ornamented. Silver bodkins are still worn in a similar way by the peasant-girls of Naples. The term bodkin is also applied to a sharp-pointed instrument for piercing holes in cloth, and it was at one time a very common name for a dagger.

BODY.—1. In the nomenclature of modern ordnance, the part of the piece in rear of the trunnions. 2. In the Art of War, a number of forces, horse or foot, united and marching under one commander. 3. That portion of a carriage, including framing and boarding, which forms the receptacle for conveyance of stores. The frame of the body generally consists of two frame sides, a front and hind ear-bed, and two or more summers. 4. That portion of the axletree between the axletree-arms.

BODY-GUARD.—A guard designed to protect or defend the person; a life-guard.

BODY OF THE PLACE.—The enceinte of a fortress, or main line of bastions and curtains, as distinguished from outworks.

BŒOTIAN HELM.—An ancient and favorite head-covering. It was made deep, with neck and cheek-guards, the whole being wrought into a solid mass, which would cover and effectually protect the wearer from the shoulders upwards.

BOGHEAD COAL.—Bituminous coal of Scotland, more valuable for making gas than for fuel. Named from the chief place of deposit, Boghead, Linlithgowshire.

BOG IRON-ORE.—A mineral of very variable composition, but regarded as consisting essentially of peroxide of iron and water; the peroxide of iron often amounts to about 60 per cent, the water to about 20. Phosphoric acid is usually present in quantities varying from 2 to 11 per cent. Silicic acid, alumina, oxide of manganese, and other substances, which seem accidentally present, make up the rest. Bog iron-ore occurs chiefly in alluvial soils, in bogs, meadows, lakes, etc. It is of a brown, yellowish-brown, or blackish-brown color. Some of its varieties are earthy and friable, formed of dull dusty particles; some are in masses of an earthy fracture, often vesicular; and some more compact, with conchoidal fracture. It is abundant in some of the northern and western islands of Scotland, and in the northern countries of Europe generally; also in North America. When smelted it yields good iron. From what source the iron in bog iron-ore is derived has often been a subject of discussion; but Ehrenberg appears to have determined that it proceeds from the shields of animalcules, and he regards the mineral itself as composed of incalculable multitudes of these shields. He found in the marshes about Berlin a substance of a deep ochre-yellow passing into red, which covered the bottom of the ditches, and which, when it had become dry after the evaporation of the water, appeared exactly like oxide of iron; but which under the microscope was found to consist of slender articulated threads, formed of the partly silicious and partly ferruginous shields of *Gaillonella ferruginea*.

BOG-SPAVIN.—This singular name has been applied to a lesion of the hock-joint of the horse, consisting in distension of the capsule inclosing the joint. It usually arises suddenly from a sprain in action. It most commonly affects young horses with defective hocks, and is associated with other indications of weakness of the injured joint.

Symptoms.—As the immediate result of a violent sprain, the hock becomes swollen, hot, and tender, and there is considerable lameness. The acute symptoms subside readily, but a circumscribed swelling remains towards the front, inner, and lower part of the joint. The swelling is soft, partly disappears on pressure if the joint is moved; but on the horse standing firmly on its limbs, the projection is distinctly visible. At every recurring strain lameness supervenes, but commonly passes off within a short time. If the bog-spavin has accidentally occurred in a young horse with good hocks, it may never be attended with inconvenience, and the acute symptoms mentioned do not relapse.

Treatment.—The treatment of bog-spavin consists in the application of stimulating embrocations, or mild blisters, in the early stage; in severe cases the golden ointment of iodine is the best application; but we can only obtain a reduction in the inflammatory symptoms, and disappearance of the lameness. The capsular ligament which is injured is never again completely restored, and the horse is more or less blemished for life. See *Veterinary Art*.

BOILER.—The name given to a vessel in which steam, usually for a steam-engine, is generated. In its simplest form it consists of a close vessel made of metal plate, having apertures for the admission of water and egress of steam, fitted with apparatus for showing the level of the water and the pressure of the steam, and in connection with a furnace, either internal or external. When water is boiled in an open pan, the temperature of the water and of the steam rising from it remains at or very near 212 F., and the tension or pressure of the steam is no more than sufficient to make its way into the atmosphere, being exactly equal to that exerted in all directions by the atmosphere itself—namely, 14.7 lbs. per square inch. In a close vessel, on the other hand, the temperature and pressure to which we can raise the steam are only limited by the strength of the vessel or boiler against bursting. The form of a boiler is determined by two considerations—namely, strength to withstand internal pressure, and efficiency in producing steam; and the object of the designer is to combine in one apparatus sufficient strength to work safely at the proposed pressure, with such a form and arrangement as shall abstract the maximum of heat from the gases of combustion, and at the same time be in all respects suitable to the special circumstances of the case. The globular form is that best adapted for strength, and was the earliest to be used. It presents to the fire, however, the minimum area in proportion to its contents, and therefore has a minimum efficiency. After spherical boilders, cylindrical ones came into use, at first set on end, and afterwards laid on their sides, and later on these were furnished with internal cylindrical tubes for furnaces. Watt's "wagon-boiler" (so called from its shape) was used for many years, but, being quite unfit for any but the lowest pressures, it has long been discarded; and the "egg-end" boiler, or plain cylinder with hemispherical ends, also much used at one time, has now almost disappeared on account of its small evaporative efficiency. At present it is quite common to use a working steam-pressure of 50 lbs. per square inch in ordinary factory boilers, and in some cases this is already greatly exceeded, while the tendency to use higher pressures seems to grow yearly. Under these pressures, the only forms of boiler which can be used without heavy and expensive internal stays to prevent the danger of bursting are the globular and the cylindrical. The former shape is rejected for the reason already given, and the latter form is used almost invariably in the construction of modern boilers, as will be seen from the examples given below. The ends of the cylinders, when it is necessary to make them flat, must, of course, be strengthened by stays. Boilers may be classified in several ways—as (1) horizontal and vertical; (2) internally and externally fired; and (3) plain multitubular, and tubulous. Large boilers are almost invariably horizontal, but small vertical boilers are often used. They are employed in steam-cranes and other situations where great length would be an inconvenience, and often in traction-engines, where steep inclines have to be traversed, and where, if a locomotive-boiler were used, one or the other end of its tubes might become uncovered and so get burned. In Great Britain, when moderately good fuel is used, boilers with an internal furnace are generally preferred; but in America the common brown coal is much inferior to English fuel, and a correspondingly larger quantity of it must be used to generate a given volume of steam. As the size of a furnace limits the fuel which it can burn, this fre-

quently involves having a much larger grate than could be conveniently arranged inside the boiler, and on this and other accounts boilers are more frequently externally fired. See *Furnace*.

BOILING-POINT.—When heat is applied to a vessel containing water, the temperature gradually rises, and vapor comes silently off the surface; but at a certain degree of heat steam begins to be formed in small explosive bursts at the bottom, and rising through the liquid in considerable bubbles, throws it into commotion. If, after this, the steam is allowed freely to escape, the temperature of the water rises no higher, however great the heat of the fire. The water is then said to *boil*, and the temperature at which it remains permanent is its *boiling-point*. The boiling-point of water is ordinarily 212°; but every liquid has a point of its own. Thus, sulphuric ether boils at 96°; alcohol, at 176°; oil of turpentine, at 316°; sulphuric acid, at 620°; and mercury, at 662°. The boiling-point of liquids is constant under the same conditions, but is liable to be altered by various circumstances. For example, water with common salt in it requires greater heat to make it boil than pure water. The nature of the vessel, too, exerts an influence; in a glass vessel the boiling-point of water is a degree or two higher than in one of metal, owing to the greater attraction between water and glass than between water and a metal. But what most affects the boiling-point is variation of pressure. It is only when the barometer stands at 30 inches, showing an atmospheric pressure of 15 lbs. on the square inch, that the boiling-point of water is 212°. When the barometer falls, or when part of the pressure is in any other way removed, it boils before coming to 212°, and when the pressure is increased the boiling-point rises. Thus, in elevated positions, where there is less air above the liquid to press on its surface, the boiling-point is lower than at the level of the sea. An elevation of 510 feet above the sea-level makes a diminution of a degree; at higher levels, the difference of elevation corresponding to a degree of temperature in the boiling-point increases; but the rate of variation once ascertained, a method is thus furnished of measuring the heights of mountains. At the city of Mexico, 7000 feet above the sea, water boils at 200°; at Quito, 9000 feet, at 194°; and on Donkia Mountain, in the Himalayas, at the height of 18,000 feet, Dr. Hooker found it to boil at 180°. Boiling water is thus not always equally hot, and in elevated places many substances cannot be cooked by boiling. Under the receiver of an air-pump the same effect is still more strikingly seen; water may be made to boil at the temperature of summer, and ether when colder than ice. In complete vacuo, liquids, in general, boil at a temperature 140° lower than in the open air. The knowledge of this effect of diminished pressure is now largely turned to account in sugar-boiling, in distilling vegetable essences, and in other processes where the substances are apt to be injured by a high temperature.

BOLA.—A long strong cord, or small rope, having a stone or a ball of metal fixed at one end; or, sometimes, it consists of two such cords, each provided with a stone or ball. The cords being secured by their other ends to the person, he whirls the two balls rapidly, and with great adroitness, about his head, and then discharging them at the object, strikes it as with a blow from a flexible club. Such a blow takes effect with great violence. The management of the bola requires long practice and no ordinary skill.

BOLADE.—An ancient weapon of the shape of a mace. Now little used.

BOLAND KNAPSACK.—This knapsack is made up as follows: The body is made of water-proof material, 14½ inches square by 4 inches deep for the largest-sized men. The sides are made of sole-leather and have the necessary stiffness. Stay-straps pass entirely around the knapsack-box proper, and side-straps are provided to secure the blanket when rolled. The shoulder-straps are secured by buckle on one, and hook and loops on the other. The blanket is carried rolled, and secured to three sides of the knapsack; overcoat on top.

The advantages claimed for this knapsack are that the weight carried is more equally distributed; that it is kept close to and inside the line of gravity of the carrier, and is well up and retained close to the shoulders. The knapsacks are made of four sizes for different-sized clothing.

BOLAS.—A form of missile used by the Paraguay Indians, the Patagonians, and the Esquimaux. The Patagonians have several varieties. That used in war consists of a single ball of hardened clay or rounded stone, weighing about a pound, and fastened to a stout rope of sinew or skin. This they sometimes throw at their adversary, rope and all, but generally they prefer to strike his head with it, like a slung-shot. That used by the hunters in capturing wild cattle consists of two leather balls, covered and united by a narrow but stout thong. The cattle-hunter holding one ball swings the other around his head until proper momentum is gained, and then launches the bolas at the legs of the animal, which it instantly ties together, rendering him helpless. It is said that the natives can use the bolas effectually at 80 yards. The bolas of the Esquimaux consists of a number of walrus-teeth attached to the ends of strings whose other ends are united into a knot.

BOLLARS.—Large posts driven into the ground to which hawsers or cables of any sort can be made fast. They are recommended to be provided at the tops of ramps, or in narrow passages, and in masonry-works.

BOLSTERS.—Strong stout bars or beams fastened across the under portion of the frame of a wagon-body, or across the futchells of the fore-carriage. Their functions are various; sometimes they are added to give strength and rigidity to the structure, sometimes to raise its height above the axletree, and sometimes to form a convenient attachment for springs or other necessary iron-work. The term *bolster* is also applied as follows: The lower part of the cheek of a gun-carriage. The iron collar in which a gun turns in the boring-bench. The quoin or wooden bolster by which a mortar is raised in its bed.

BOLT.—1. A pointed shaft or missile intended to be shot from a cross-bow or catapult. 2. An elongated solid projectile for rifled cannon, as the Whitworth and Armstrong guns. See *Bolts*.

BOLT-CUTTERS.—In these most valuable machines for the arsenal, the bolts are generally cut as with solid dies, at one operation, the dies opening under cut when the work is done, and in releasing the bolt remove all trace of the chip made by the cutting-tools. On the back of the large driving-wheel (Fig. 1), is an index or pointer, which must be set to numbers given on a card furnished with each machine. When so set, the bolt will fit a nut of corresponding size cut with the tap sent with machine. An adjustment of the index, one way or the other, will cause the bolt cut to be larger or smaller, thus permitting the thread to be adapted to the use required of it, and also permitting an adjustment of dies to compensate for wear. Some important improvements have recently been made in this machine, viz.: A change in the mode of driving renders it possible to run them at a higher speed, and a novel oil-feeding device supplies the oil to the back of the dies, whence flowing out it thoroughly lubricates the cutters and the bolt-end, and washes out the chips as they are cut from the bolt. A regulating cock in the feed-pipe directs the oil either to the dies as above stated, or to the tap when the machine is used as a nut-tapper. The machines are constructed with four dies in the die-box. These dies are equally spaced, and each pair has one die diametrically opposite to the other one of the pair. This arrangement insures accurate work, inasmuch as the opposite dies calliper the bolt while being cut, thus making the bolt round and to gauge. Added to this a convenient adjustable stop-motion is provided whereby the dies are opened automatically when a given length of thread has been cut. These improvements have added greatly to the value of this important tool, which is made and used extensively in England and on the Continent, and is believed to have no equal in durability and

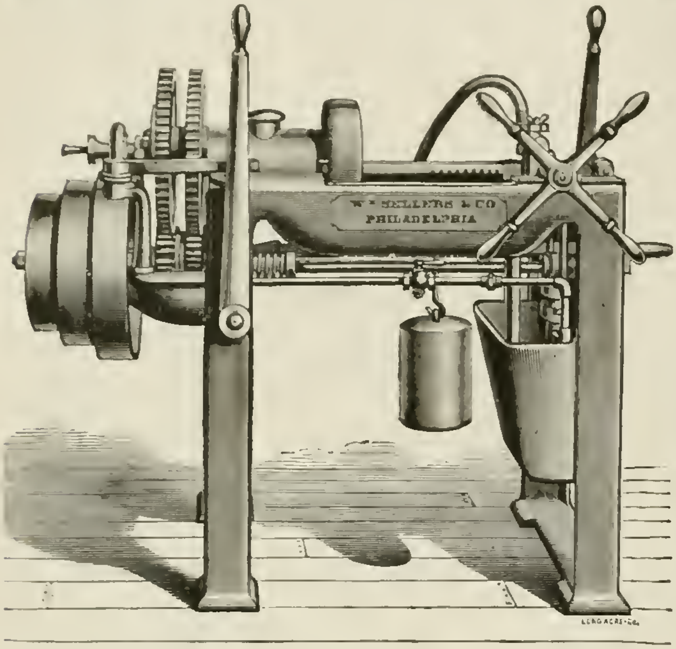

Fig. 1.

efficiency. The counter-shafts are made with two loose pulleys, one on each side of a fast one, so that open and cross belts can be used to run the machine backwards as well as forwards. This running backwards is only of use in recutting dies or cutting left-handed screws. To sharpen the dies, they must be softened, and then recut with hobs which are specially made for this purpose. The hobs are guided in recutting dies by collars fitting in a hollow sleeve, which guide a prolongation of one end of the hob, while the other end is steadied in the clamp for holding the bolts to be cut. This insures perfect concentricity to the dies. It must be borne in mind that in the use of bolt-cutters oil should be freely used upon the work. This on the new-style machine is accomplished by the automatic feed; and the oil used should be *animal*, not from *coal*. The commonest lard or fish oil will answer a good purpose. Fig. 1 represents the Sellers ¾-inch size of machine intended to cut from ¼ to ¾ inch. This size is admirably adapted to cut set-screws and small bolts. In using it with set-screws it is well to arrange a socket-wrench to be clamped in the bolt-holder, the head of the set-screw fitting the socket loosely. By the use of such a device the bolts can be set and removed more rapidly than when each one has to be clamped in the bolt-holder. This machine has been run at the rate of 2800 bolts in ten hours on ⅜-inch bolts threaded two inches in length, but this rate is not economical, inasmuch as the excessive speed is too hard on the dies. The counter-shaft should be speeded to 200 revolutions per minute; the speed on the dies of the fastest and the slowest speeds will then be at the rate of 12 feet circumferential motion per minute on ¾-inch and on ⅜-inch bolts. The ¾-inch bolt, having ten threads per inch, will be threaded at the rate of six inches in length of bolt per minute, and if the thread be 1½ inches long, at the rate of four per minute, exclusive of the time consumed in putting in and taking out the bolts; one man can at this rate very well run two machines cutting from 1500 to 1800 ¾-inch bolts on each machine.

The Babbitt bolt-cutter will cut screw-threads in nuts and on bolts by once passing over them, cutting the standard number of threads to the inch on all the sizes, and making as great uniformity in the fits between the nuts and bolts as can be desired. The great advantage of this machine consists in the facility and ease in changing dies. No backing off is required. This saves nearly one half the time required to do the work over the solid die. There is no danger of tearing off the thread or injuring the die in breaking off. A solid die soon wears a little, and the tap the same. The result is that the bolt will not enter the nut without a wrench, if at all, and a new tap or die has to be made. This machine, if properly adjusted, will cut a complete thread, and reduce the bolt to suit the tap, however much it may be worn. It is much praised for its practical efficiency and economy in running, as well as adaptation to all kinds of work in the armory. The counter-shaft has pulleys fourteen inches diameter and four inches face. Should run one hundred and fifty revolutions.

The open-die machine made by the Pratt and Whitney Company is a very superior one. Instant release of the bolt when threaded, without running back through the dies, is a peculiarity of this machine. The die-head is constructed to receive finished blocks or cases, with inserted chasers, forming the dies, thus doing away with the labor of fitting each die or chaser to the head. The chasers, four in number, in simpler form, are planed or fitted to cases with a file, from pieces of flat steel, averaging 1¼ inches in length and $\frac{5}{16}$ inch in thickness, threaded in the machine by hobs or master-taps and set forward by a screw in the end of each case for dressing when the thread is worn out. Broken or damaged chasers can be replaced by duplicates at little expense. The adjustment of dies to the proper diameter is accomplished by

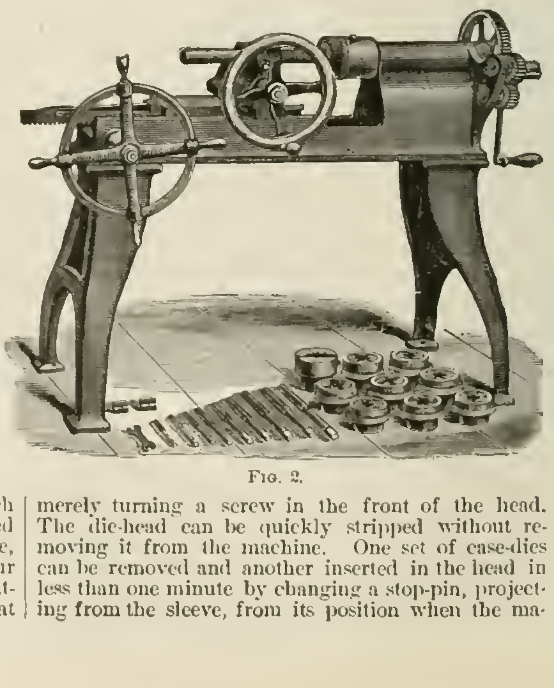

Fig. 2.

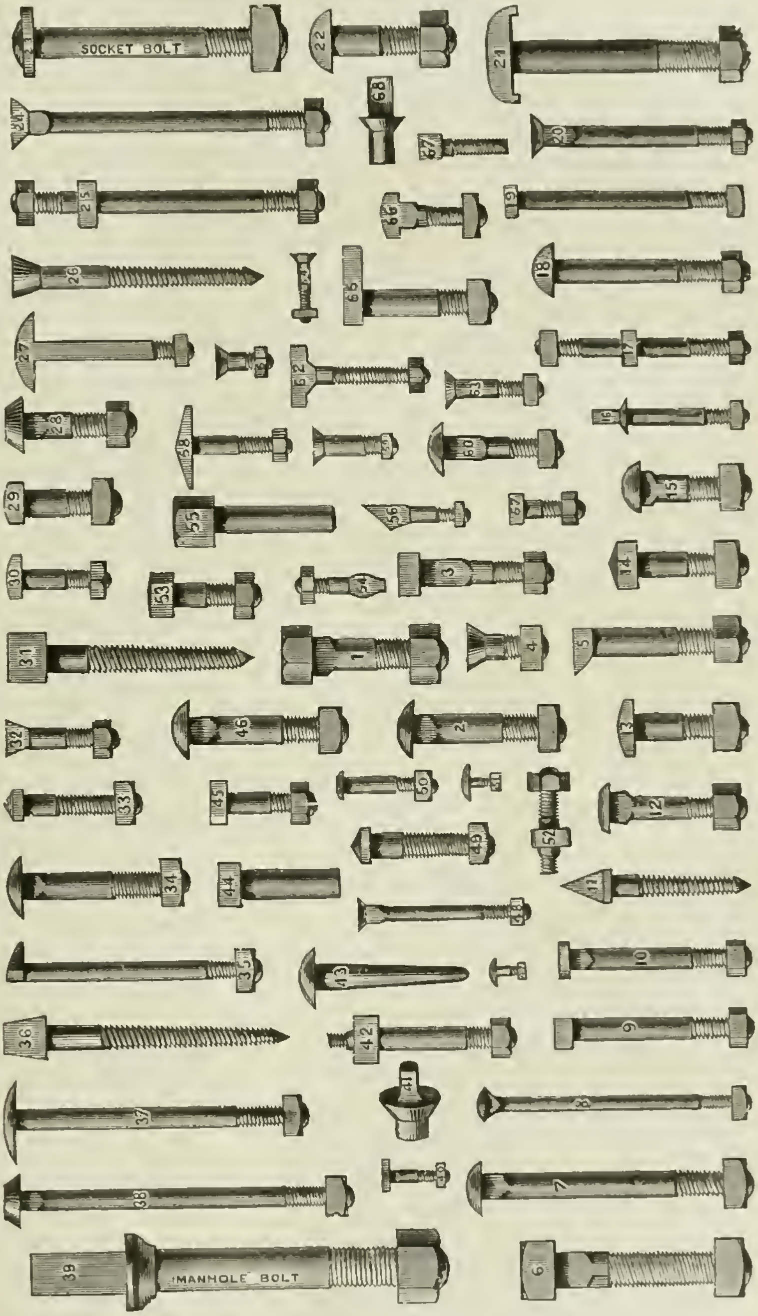
merely turning a screw in the front of the head. The die-head can be quickly stripped without removing it from the machine. One set of case-dies can be removed and another inserted in the head in less than one minute by changing a stop-pin, projecting from the sleeve, from its position when the machine is working, to a point opposite a hole in the flange at the rear of the head, then, by means of the lever, pushing the sleeve back to the flange, uncovering the cases, and permitting their removal and replacement by hand. The machine can be quickly converted into a nut-tapper, by removing the case-dies and putting in their place a steel block to which is secured a universal chuck for holding taps that is furnished with each single-head machine only. The locking device is positive and requires but one movement of the lever, by hand or automatically, for unlocking and opening the dies, when the desired length of thread has been cut, or closing and locking. The hollow spindle allows a piece to be threaded any length desired. The machines work rapidly, the bolt being cut to a full thread at one operation. The die-blocks are held rigidly by the inclosing sleeve when locked, and consequently cut bolts of more uniform diameter than is the case when the chasers or cutters can spring away from the bolt when cutting. The arrangement and operation of the stop-pin is such that a longer thread cannot be cut on a bolt than is permitted by the adjustment of the automatic opening apparatus when the latter is employed.

Fig. 2 shows a small hand bolt-cutter adapted for light work on gun-carriages, etc. It is mounted on legs, and is suitable for cutting ½-inch to 1½-inch bolts and ¼- to 2-inch pipe. The crank and socket are used on the stud of a small gear to cut ⅞ and larger bolts, and upon the spindle of the machine to cut ¾-inch and smaller bolts, and to back the die quickly off from large bolts after cutting, the spindle and the die revolving in the direction that the crank is turned. Threads may be cut a length of eighteen inches as the machine is usually constructed. Nine taps and dies are furnished with the machine to cut threads of the following sizes: ½, 13; ⅝, 11; ¾, 10; ⅞, 9; 1, 8; 1⅛, 7; 1¼, 7; 1⅜, 6; 1½, 6. Weight of machine, with tap-chuck, nine dies and taps, about 350 pounds.

BOLTS.—Stout metal pins, variously employed in ordnance and artillery constructions for holding objects or parts together, and frequently screw-threaded at one end to receive a nut. Bolts for permanently fastening objects may be distinguished, first, by their construction; secondly, by their application. As to construction, the difference may regard the head; as, round, square, hexagon, octagon, saucered, countersunk-headed, clinch, collared, chamfered, diamond, convex, etc.: some structural peculiarity of the head; as, eye, doubled-headed, hook, ring, T-headed, etc.: the mode of securing; as, screw, fox, forelock, clinch, rivet, rag, bay, barb, jag, key. As to the nature and purpose of their application they may be,—assembling, fish, foundation, bringing-to, carriage, drive, fender, lewis, set, shackle, wagon-skein, tire, king, scarf, through, etc. The following list of bolts, manufactured by Messrs. Hoopes & Townsend of Philadelphia, and exhibited at the Centennial in 1876, is approximately complete:



Bolts used in Arsenals and Armories.

Assembling-bolt,
Barbed bolt,
Bay-bolt,
Bringing-to bolt,
Carriage-bolt,
Clinch-bolt,
Countersunk-headed bolt,
Diamond-headed bolt,
Door-bolt,
Drive-bolt,
Eye-bolt,
Fender-bolt,
Fish-bolt,
Flour-bolt,

Flush-bolt,
Forelock-bolt,
Foundation-bolt,
Fox-bolt,
Half-turning bolt,
Holding-down bolt,
Hook-bolt,
Jagged bolt,
Key-bolt,
Lewis-bolt,
Manhole-bolt,
Pointed bolt,
Rag-bolt,
Ring-bolt,
Riveted bolt,
Rose-headed bolt,
Round-headed bolt,
Scarf-bolt,
Screw-bolt,
Set-bolt,
Shackle-bolt,
Shingle-bolt,
Socket-bolt,
Square-headed bolt,
Tire-bolt,
Wagon-skein bolt.

The important bolts fabricated and used in arsenals and armories are shown in the drawing on the preceding page. The following table gives the weight of bolts, of given diameter and length, per hundred:

Diam	1/4	5/16	3/8	7/16	1/2	9/16	5/8	3/4	7/8	1
Lgth.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.
1½	4	7	10.50	15.20	22.50	30	39.50			
1¾	4.35	7.50	11.25	16.30	23.82	31.75	41.62			
2	4.75	8	12	17.40	25.15	33.50	43.75	69	108	
2¼	5.15	8.50	12.75	18.50	26.47	35.25	45.88	72	112.25	
2½	5.50	9	13.50	19.60	27.80	37	48	75	116.50	175
2¾	5.75	9.50	14.25	20.70	29.12	38.75	50.12	78	121.75	180

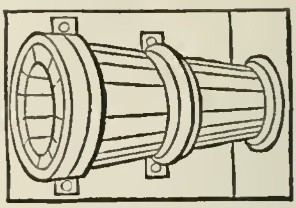
19					117.90	152.50	188	274.70	398.25	536
20					123.20	159.50	196.50	286.80	415.30	558

The following general rule is given for the computation of the weight of wrought-iron bolts: Square the radius of the bolt, and multiply it by ten; the product will give the weight in pounds per foot. For cast-iron bolts, multiply the above result by .074.

BOMB.—A missile which also receives the names of *bomb-shell* and *shell*. It is a hollow ball, usually of cast-iron, fired from a mortar or other large piece of ordnance, and filled with combustibles which work great havoc when the ball bursts by the firing. All such projectiles were formerly fired from mortars only, and there was thus a definite relation between the bomb and the mortar; but since the invention of shell-guns and other modern pieces of artillery, the name *shell* has been generally substituted for that of *bomb*. The 13-inch bomb, which is the largest size used in ordinary warfare, weighs about 195 lbs., with a thickness of metal varying from 1½ to 2 inches at different parts; it bursts with about 8 lbs. of powder. The vent through which it is filled with powder is, after the filling, closed with a plug called a *fuse*, which sets fire to the powder, and at the proper moment bursts the bomb into fragments. The 10-inch bomb, weighing about 90 lbs., is proportionably less in all dimensions than that just described; and so on for those of smaller diameters. It should be understood, however, that the above are conventional quantities prescribed and adopted more than half a century ago. Modern artillerists try experiments on bombs of various degrees of thickness with various charges and fuses. See *Shell*.

BOMBARD.—An ancient piece of ordnance, which was very short, thick, and wide in the bore. It differed from the balista in being worked with gunpowder instead of by mechanical force, and from the mortar in shooting forth stones instead of iron shells. Some of the bombards used in the fifteenth century propelled stones weighing from 200 to 500 lbs. each. The shape of the first cannon used after the invention of gunpowder was conical, internally and externally resembling an apothecary's mortar. They were called *mortars*, *bombards*, and *vases;* were tired at high angles; and, in consequence of the slow burning of the powder of that day and the conical shape of the bore, the stone balls projected by them proceeded with very little velocity and accuracy. Bombards were made first of wood banded with wrought-iron, then of sheet-iron strengthened by hoops and brazing, and later of longitudinal iron bars, connected and hooped like the staves of a cask. As none of these constructions gave the requisite strength, cannon were subsequently made of wrought-iron, then of cast-iron, and finally of bronze.



BOMBARDELLE.—A small bombard which was used in ancient times. In 1830 one was disinterred near Laon, France; it is the opinion of some that this bombardelle was manufactured during the reign of Charles VII., from 1436 to 1440.

BOMBARDIER.—An artilleryman versed in that department of arms which relates especially to bombs and shells, mortars and howitzers, grenades and fuses. He has learned to load shells and grenades, fix fuses, prepare composition for fuses and tubes, etc.; and on the field or at sieges he fires the mortars. In some foreign armies the bombardiers form a separate corps; but usually there are some attached to every battery.

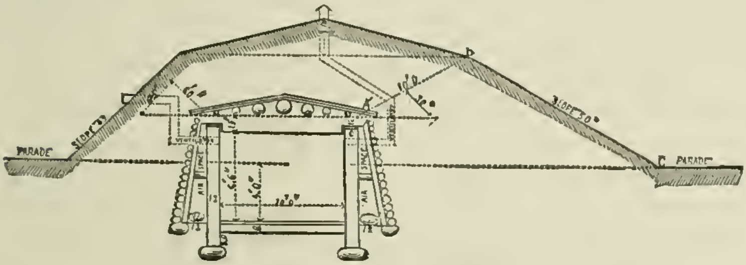
BOMBARDMENT.—An attack upon a fortress or fortified town by means of shells, red-hot shot, carcasses, rockets, etc., to burn and destroy the buildings and kill the people. A bombardment is most likely to be successful when the place is destitute of bomb-proof cover; or when the Governor is too humane to expose the unoffending inhabitants to this dreadful ordeal; or when the population is strong enough to compel him to yield. A bombardment requires little engineering science; whereas to reduce a place by regular siege requires the aid of engineers to direct the attack against fortifications, guns, and soldiery, leaving the inhabitants and buildings untouched. Military engineers generally regard a bombardment as a cruel operation; it is especially directed against the civilians and their buildings, as a means of inducing or compelling the Governor to surrender the place and terminate their miseries. In a well-defended place, the soldiers, the ammunition, and the defense-works suffer comparatively little, seeing that the bombardiers aim at pitching their terrible missiles into the heart of the place. In modern times a bombardment is mostly adopted as an adjunct to a siege, distracting the Governor by an incessant fire of mortars day and night. At Sebastopol, for instance, the mortars fired shells into the center of the city, to weaken the defense of the forts which were cannonaded by the siege-guns. Bombardment is more frequently a naval than a military operation. The stores required for a vigorous bombardment are immense. Thus, in 1759 Rodney threw 20,000 shells and carcasses into Havre; in 1792 the Duke of Saxe-Teschen threw 36,000 shot and shell into Lille in 140 hours; in 1795 Pichegru threw 8000 shells into Mannheim in 16 hours; and in 1807 the English threw 11,000 shot and shell into Copenhagen in three days.

BOMB-CHEST.—A chest filled with bombs, or only with gunpowder, placed underground, to cause destruction by its explosion.

BOMB-LANCE.—A sharp-pointed projectile, used principally in whale-fishing, charged like a grenade, and shot from a musket, the slow fuse that explodes it being first lighted. Its power is sufficient to stun the whale.

BOMB-PROOF.—A term applied to military structures of such immense thickness and strength that bombs cannot penetrate them. Military buildings, generally within permanent fortifications, and which are formed so as to withstand the shock of heavy shot or shell falling on them. Magazines for holding gunpowder should be placed in the most sheltered position within a fortress, and strongly constructed to resist direct and vertical fire from heavy ordnance. In the forts recently built for coast-defense in England, 17 feet of masonry has been considered necessary against direct fire, and an arch 3 feet thick, with 3 feet of concrete over the roof, against vertical fire.

BOMB-PROOF MAGAZINES.—For field-works of a semi-permanent character which are to be indefinitely occupied, have an armament of heavy guns, and are expected to stand a siege,—like the defenses around Washington, for example,—the magazines, bomb- and splinter-proof shelters should be constructed of the heaviest timber, and be covered securely with earth from the assailant's curvated and direct fire. The ventilation of the magazines and precautions for their drainage are of the utmost importance. The drawing shows a cross-section of a magazine con-

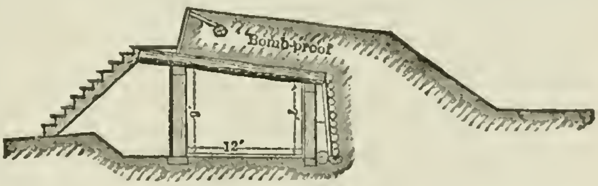


Cross-section of Bomb-proof Magazine.

structed in a work of this character. The sides of the interior of the magazine are formed of twelve-inch logs placed vertically in juxtaposition and resting upon a ground-sill. These are capped on top by a two-inch board, a strip of a like kind being spiked on within the cap. The top is formed of fifteen-inch logs, also in juxtaposition, each having a shoulder of three inches to fit it to the cap and inside strip. Longitudinal logs are laid on these with varying diameters, so as to give a proper pitch for the roof. Earth is solidly packed upon the top and between the roof-logs, receiving the proper slope for the roofing-boards. These boards, carefully jointed, are laid on in two thicknesses, each being covered with a coating of asphalt. The flooring of the magazine is of joists and boards. The sides of the magazine are surrounded with an air-chamber formed by inclined logs supported on a ground-sill and resting against the top logs; these are placed at three or four feet apart, each one being braced at the middle point to resist flexure from the pressure of earth. The chamber is covered in by saplings laid in juxtaposition. There are ventilators between the magazine and the air-chamber near the top, and also between the latter and the external air; the two not being opposite, and the usual precautions to guard against accidents from sparks being taken. The earth-cover is ten feet on the exposed side, and six feet on the other sides and on top. The entrance to the magazine is well secured by a bomb-proof covering. A slope is given from the interior to the foot of the steps leading to the level of the floor for the purposes of draining.

BOMB-PROOF QUARTERS.—Casemated bomb-proof quarters are indispensable to the safety and comfort of the garrison during siege, or any prolonged attack for the annoyance or reduction of the work by a bombardment. In small works like most of our forts, which are chiefly designed for sea-coast defense, casemated quarters have been generally arranged in the rear of the batteries, a portion of each casemate towards the parade being partitioned off and suitably disposed for the object in view. In some cases advantage is taken of a scarp-wall, on a land-front, which is well covered by a glacis or other face-cover, to form in its rear quarters of this character. In all cases care should be taken to place such quarters on those fronts which are best covered from a direct fire, and the parade-walls of which are not exposed to reverse-fire. Whenever the plan of the work admits of it, quarters of this kind should be arranged for defense, by being pierced with loop-holes and even with embrasures for cannon. Defensive casemated quarters form a prominent and distinctive feature in what is now known as the German School of Permanent Fortification.

BOMB-PROOF SHELTERS.—These structures are for the protection of the troops when not on duty. They should be located on the parade, convenient to the pieces to be served, yet not so near as to interfere with the defense. They are usually constructed in half-excavation of logs built up like a log-house, or of a framework in the manner shown in the drawing, the exterior side being of heavy logs placed vertically in juxtaposition, resting on a ground-sill and capped at top. Parallel to this is another row, forming the other side, which may also be placed side by side or at short intervals apart, and capped like the outside row. The roof, consisting of heavy logs laid in juxtaposition and covered with thick boards joined, rests on the capping, the whole covered over on the side of the enemy with earth to a depth of at least 14 feet from the wood-work. To prevent this mass of earth from pushing the structure over to the rear, one in every two or three of the roof-logs is cut of sufficient length to extend about 8 feet beyond the front of the wall, and dovetailed to a longitudinal log held in position by vertical posts, the anchor-log being sufficiently covered with earth to protect it from injury by shot from the enemy. These bomb-proofs are made to serve the purpose of traverses, and are frequently arranged with a staging or gallery along the rear side for the accommodation of infantry, who deliver their fire over the top, arranged for this as a parapet. In all interior arrangements, system and regularity should be observed from the first; otherwise the work will grow into a labyrinth of con-



Bomb-proof Shelter.

fusion greatly opposed to efficiency and comfort. See *Shelters* and *Splinter-proof Shelters*.

BOMB-SHELL.—A hollow globe of iron, filled with powder, and thrown from a mortar. See *Bomb*.

BOND.—A bond, in law, is simple or conditional, the latter being generally used. It must be in writing, and signed, and should be sealed. The condition is the vital part, limiting and determining the amount to be paid or the thing to be done, and no person can take the benefit of a bond except the parties named therein, save in the case of a bond given by an officer for the performance of duty. If a bond runs to several persons jointly, all must join in suit for breach, although the conditions may not at all affect some of them. Recovery against a surety on a bond is not limited to the penalty, but may go beyond as far as necessary to include interest from the time of default. A bond dormant for twenty years cannot afterwards be recovered, the presumption being that it has been satisfied. If the maker of a bond binds himself without adding "heirs," the heirs cannot be held, but the executors and administrators are liable. All Disbursing Officers of the army are required to give bond.

BONE-SPAVIN.—A bony tumor in horses where the head of the splint-bone joins the shank. Inflammation of the ligaments of any of the small bones of the hock proceeding to bony tumor classes as spavin.

BONFIRE.—A fire kindled for some purpose of public rejoicing, usually in an open conspicuous place, as the top of a hill or the center of a village-green. The burning materials consist of tar-barrels, coal, and other combustibles. The practice of kindling fires of this kind is of so great antiquity in England, Ireland, and Scotland as to be traced to pagan rites. The origin of the word *bonfire* has been very puzzling to etymologists. In Scotland the popular term is *banefire* or *bainfire*, which Jamieson says is apparently a corruption of *bailfire*, which may be doubted. The most probable etymology is the Welsh *ban*, high, whence *ban-ffagl*, a lofty blaze, a bonfire. The same hills that in English are called *beacons* are in Welsh called *bans* or *vans*. In Danish, also, *baun* is a beacon, and may be traced in such names as *Banbury*.

BONING-STAFF.—A T-headed staff, used in conjunction with a plummet and line for taking short levels.

BONNET.—1. In fortification, a small defense-work constructed at the salient angles of the glacis or larger works. It consists of two faces only, with a parapet three feet high by ten or twelve broad. There is no ditch. A larger kind, with three salient angles, is called a *priest's bonnet*, or *bonnet à prêtre*. The use of the bonnet is to check the besiegers when they are attempting to make a lodgment. See *Bonnettes*.

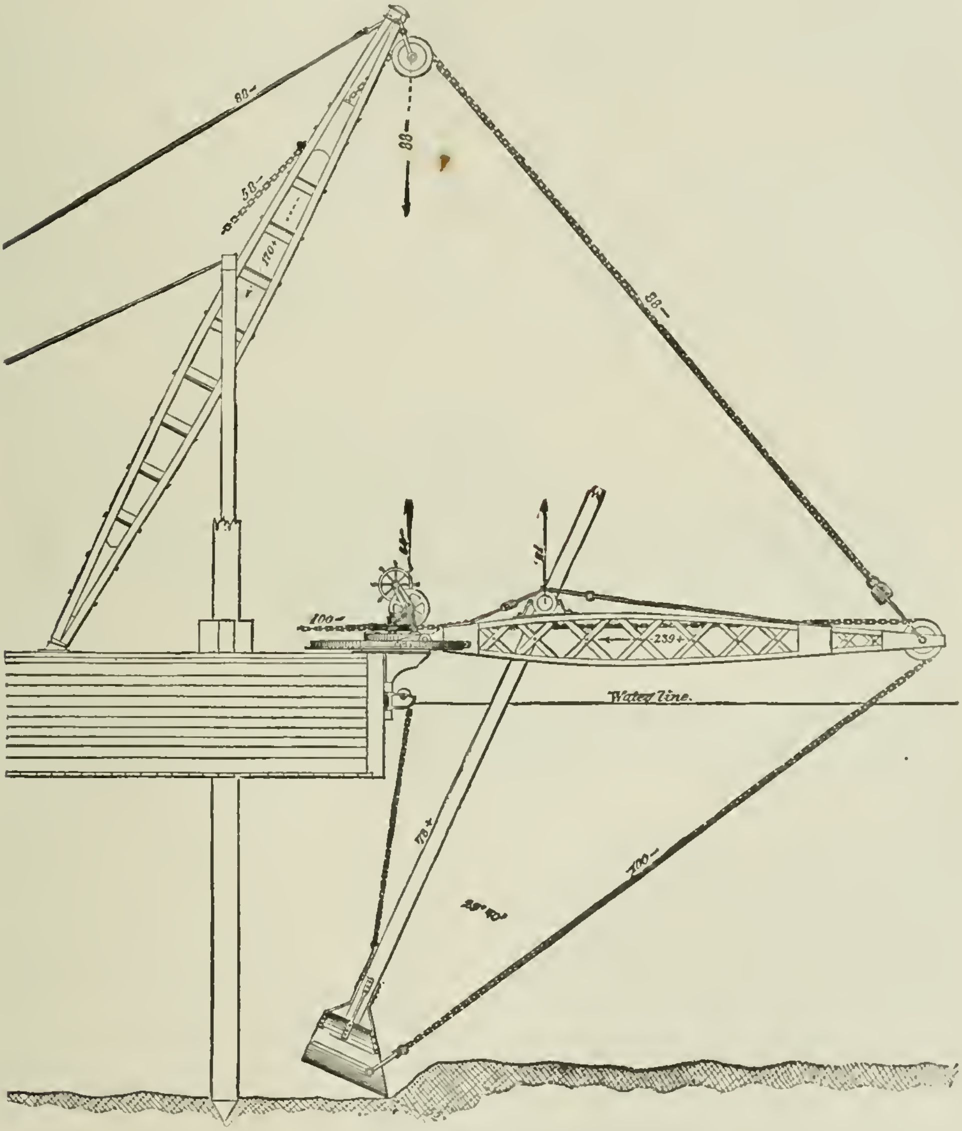
2. A covering for the head, of which there are many varieties. The French, from whom we have the word, apply it as we do to male as well as female head-dress. From the frequent notice of the blue bonnet in historical records and in song, it would seem that the Scotch were long identified with this kind of head-covering. The genuine old bonnet of the Lowland Scottish peasantry was of a broad, round, and flat shape, overshadowing the face and neck, and of a dark blue color, excepting a red tuft like a cherry on the top. The fabric was of thick milled woolen, without seam or lining, and so exceedingly durable that, with reasonable care, a single bonnet worth about 2*s*. would have served a man his whole life. No head-dress ever invented could stand so much rough usage. It might be folded up and put in the pocket, or laid flat and sat upon, with equal impunity; it might be exposed to a heavy drenching rain without the head being wetted, and when dried it was as good as ever. Besides it could be worn on the top of the head, or slouched in front, behind, or sidewise, as a protective against a cold blast; and from its softness and elasticity it very fairly saved the head from the effects of a blow. In short, there was no end to the adaptability of the old "braid bannet," as the Scotch termed it; and one almost feels a degree of regret that, in the progress of fashion, it should have gone so much out of use. The Highlanders have long worn bonnets of the same fabric, but these rise to a point in front and are without any rim. Such is the cap now known as the *Glengarry bonnet*. From time immemorial, these various kinds of Scots bonnets have been manufactured at Stewarton, a small town in Ayrshire. Formerly the Stewarton bonnet-makers formed a corporation, which, like other old guilds, was governed by regulations conceived in a narrow and often amusingly absurd spirit; one of the rules of the fraternity, however, can be spoken of only with commendation, for it enforced a certain weight of material in each bonnet, as well as durability in the color. The bonnets used in the Highland regiments are made at Stewarton and Kilmarnock; they are usually distinguished by a checkered fillet, being the *fess-cheque* of the House of Stuart. Latterly, although hats and caps have, to a great extent, superseded bonnets of the old varieties, the bonnet-manufactories of Stewarton have much increased, and are still increasing.

BONNETTES.—It is frequently desirable that the height of the parapet, at certain points, should be increased for a short distance. This increase is generally obtained by making use of the constructions known as bonnettes. A bonnette extends but a short distance along the parapet, is made of earth, and is used generally to give greater protection to the men standing on the banquette against a slant or an enfilading fire of the enemy. Bonnettes are placed usually on the salients; they are sometimes placed on the parapet between guns *en barbette*. They may be constructed during the progress of the work, or after the work has been finished. In the former case their construction is, to all intents and purposes, similar to that of the parapet. In the latter case they are constructed generally in haste, and sand-bags or gabions filled with earth are used to build them.

BONTCHOUK.—A lance ornamented with a horse's tail. When the kings of Poland led their armies, bontchouks were carried before them.

BOOM.—A strong chain of timber logs or iron employed in barring the passage of the mouth of a harbor or river, or to cut off the retreat of an enemy if he has actually entered. Such a boom should be protected by a battery or batteries. There should be two such chains, one to afford resistance if the enemy has penetrated the other; they need not extend all across the passage, seeing that shallow spots are self-defended. A modern war-steamer would cut through a chain-boom, unless made of very thick and strong iron. Sometimes hempen cable-booms are used to resist small-craft. The Russians effectually boomed the harbor of Sebastopol in September, 1854, thereby preventing the entrance of English and French ships; this was done partly by sinking some of their own ships, and partly by the laying of booms.

BOOM-DREDGE.—This machine, recently given to the public by its inventor, Mr. Ralph R. Osgood, of Troy, N. Y., and built by the Osgood Dredge Company, is destined to effect a revolution in dredging methods and operations. Its general outline is shown in the drawing, as also the essential working elements, and the strains to which the various parts are subjected. In this machine we have the dipper and handle essentially the same as in the crane-dredge. The dipper-handle is held in position by a friction-clutch, of Mr. Osgood's design and patent, placed on top of the boom near to the boat. The excavating power is applied to the dipper by means of a chain running over a sheave at the outer extremity of the boom, and thence along the boom to the hoisting-drum on deck. The boom is pivoted or hinged to a turn-table at the boat end and supported at its outer end by a chain passing to an overhead-pulley, pendant from the combination of timber A-braces and iron ties. This chain is worked by a drum, and therefore allows the boom to take any position required by the caprice of the operator. The strains are based upon the tension occurring in the hoisting-chain, taken at 100. Compressive strains are denoted by a +, while those of a tensile nature are indicated by a −. Each degree is assumed to be working in 25 feet of water. In the boom-chain a 15-ton steel spring is placed, through which all shocks and jars must pass before reaching the machinery. This adds greatly to the life of the machine. The boom can swing and operate through a complete semicircle. The hoisting-chain can be changed from the intermediate sheave to the sheave at the outer end of the boom, for delivering on banks. The boom can be raised or lowered by means of the chain connecting it with the A-frame. The turn-table is made of iron, and is mounted on friction-rollers which greatly reduce the strain of swinging. All the different levers for working the throttle, spud and hoisting-drum frictions, for swinging the turn-table, etc., are placed near together and are operated by one man. The peculiar advantages of this machine will be readily comprehended from the brief description which has been given. They lie in the fact that material can be dredged at greater depths, raised higher, and dumped further from the center of the dredge-boat than is practicable with any of the old-style crane-dredges. The advantages may be briefly stated as follows: 1. Greater pulling force or excavating power in the direction of the bank. 2. Less strain in the dipper-handle and hull of boat. 3. Less loss of power by frictional resistances. 4. Greater rapidity in delivering the dipper-contents, thus making, other things being equal, greater capacity. 5. Dredges on the half-circle. 6. With the same length of dipper-handle as the crane-dredge has, can dredge in deeper water. 7. With a slight additional expense, may be made to work as a "clam-shell" dredge. See *Crane-dredge, Dredging-machine,* and *Excavator.*



Osgood Boom-dredge.

BOOMERANG.—A missile instrument for war, sport, or the chase, much used by the aborigines of Australia. It is of hard wood, of a bent form; the shape is parabolic. It is about two and a half inches broad, a third of an inch thick, and two feet long, the extremities being rounded. One side is flat, the other rounded; and it is brought to a bluntish edge. The method of using this remarkable weapon consists in throwing it in a particular manner. It is taken by one end, with the bulged side downward and the convex edge forward, and thrown directly onward, as if to hit some object thirty yards ahead. Instead of going directly forward, as might be expected, and there falling to the ground, it slowly ascends in the air, whirling round and round, and describing a curved line of progress till it reaches a considerable height, when it begins to retrograde, and finally it sweeps over the head of the projector, and falls behind him. This surprising motion is produced by the bulged side of the missile. The air impinging thereon lifts the instrument in the air, exactly as by hitting the oblique bars in a windmill it forces it to go round. The ingenuity of the contrivance, which is worthy of the highest scientific calculation, is very extraordinary as coming from almost the lowest race of mankind. The boomerang is one of the ancient instruments of war of the natives of Australia. They are said to be very dexterous in hitting birds with it, the animals being of course behind them, and perhaps not aware that they are objects of attack. This curiosity, as it must be called, was first made known by being brought before the Royal Irish Academy by Prof. M'Cullagh in May, 1837.

BOOMING OUT.—A method of constructing a ponton-bridge. A frame of two saddles, connected by their balks, is prepared on shore: a ponton being launched, the frame is lifted up, and the ponton is brought under the first saddle, and fastened to it; in the mean while the balks of another frame are bolted to a third saddle, the bridge is *boomed out*, and a second ponton is fixed under the second saddle, and so on. The bridge is kept in its proper position by means of ropes secured to anchors.

BOOTS AND SADDLES.—A sound on the trumpet which is the first signal for mounted drill, and for all other formations mounted; it is also the signal for the trumpeters to assemble. In the English service, it is a parade-call in the cavalry and artillery, sounded half an hour before the turn-out.

BOOTY.—Despoiling a people or city is barbarous and not tolerated in civilized warfare, but legitimate subjects of booty are well described in an Act of the British Parliament; as, arms, ammunition, stores of war, goods, merchandise, and treasure belonging to the *State* or any *public trading company of the enemy*, and found in any of the fortresses or possessions, and all ships and vessels in any road, river, haven, or creek belonging to any such fortress or possession. It should be the duty of Commanding Generals to cause an exact account of such captures to be kept, in order that the captors may be remunerated by the Government for such stores as are reserved for the public service, and in order that *all* such prizes of war may be legally and equitably divided amongst the captors. Such is the practice in England. There land-prizes are divided according to an established rule of division. In the Piedmontese army the administration of booty is intrusted to a special Staff Corps; the French laws (says Bardin, *Dictionnaire de l'Armée de Terre*) are silent on this subject, or else those which are in force announce nothing positive; and in their silence there is inhumanity, hypocrisy, and mental reserve. In a memorial presented by the Duke of Wellington, he claimed of his Government for the English army more than a million sterling which had been used in the king's service from captures made by the British army in Spain and France, and the English budget of 1823 shows that the amount so claimed was given to the army. An Article for the government of the armies of the United States provides that "All public stores taken in the enemy's camp, towns, forts, or magazines, whether of artillery, ammunition, clothing, forage, or provisions, shall be secured for the service of the United States; for the neglect of which the Commanding Officer is to be answerable." This Article of War is borrowed from a corresponding British Article, which directs that the same stores shall be secured for the king's service. But by proclamation in Great Britain the money-value of all captures is invariably divided amongst the captors. No practice can be more wise and just; for although it is necessary to proscribe *marauding* or *pillage*, it is impossible to extirpate the desire of gain from the human heart, and it is therefore necessary that the law should frankly provide for an equitable distribution of captures amongst the army. The absence of a law of division tends to introduce into an army the greatest evils: soldiers disband themselves in search of pillage, and their cupidity leads to the greatest horrors. These great evils are avoided by a legal division of booty, when all soldiers, animated by the hope of sharing the fruits of victory, are careful not to abandon to the greedy, the cowardly, and the wicked amongst themselves advantages properly belonging to the gallant victors. See *Prize*.

BORDURE.—In Heraldry, coats of arms are frequently surrounded with a bordure, the object of which is generally to show that the bearer is a cadet of the house whose arms he carries. The character of the bordure often has reference to the profession of the bearer: thus, a bordure *embattled* is granted to a soldier; and a bordure *ermine*. to a lawyer. Also written *Border*.

BORE.—The internal cavity of a cannon, mortar, howitzer, rifle, musket, fowling-piece, pistol, or other kind of fire-arm. It is in most cases cylindrical; but in the Lancaster gun the bore is oval; in the Whitworth gun it is hexagonal; while in the Armstrong and many other kinds of gun it is furrowed by spiral grooves. Technically, the bore of a gun often means simply the diameter of the cavity, as when we speak of a gun "of 8-inch bore;" and in that case its meaning is equivalent to "caliber."

The Boring of a cannon is a process which may best be described in connection with Cannon-founding and Boring-machine. It is desirable to mention in the present place, however, that there is an operation called "boring-up" conducted at Woolwich Arsenal, for enlarging the bore of a gun. It has been found in recent years that many of the old cannon are thicker and heavier than needful for the size of shot propelled, and that they could be fitted for the discharge of larger shot without danger. A change was begun in the armament of the British fleet in 1839 by substituting heavier broadsides; and as one part of the process, many of the old 24-pounders were "bored-up" to 32's; even some of the 18-pounders were found to be thick and strong enough to undergo this process. More than 2000 iron naval guns were thus treated at Woolwich preparatory to the change in 1839; and many others have since been similarly bored-up. About 1860, important experiments were carried on at Woolwich, to determine whether the old smooth-bore iron guns could not only be bored-up, but *rifled* at the same time. There were 15,000 of such guns belonging to the British Government, and it was suggested that they ought to be improved, instead of being cast aside as useless in the event of the success of the Armstrong and Whitworth guns. The process has not proved altogether satisfactory.

BORERS FOR FUSES.—Instruments for boring out fuses. There are two kinds, termed *hook* and *hand* borers; the former consists of a hook into which the fuse is placed, and a shank which contains a female screw. The bit passes through the center of the handle and male screw, and it is secured by a small screw which presses upon the bit. The hand-borer is a simple instrument, somewhat like a hand-gimlet, but the blade is fluted and not spiral. This instrument is supplied to each gun.

BORI.—A Turkish term for military trumpets and other similar instruments.

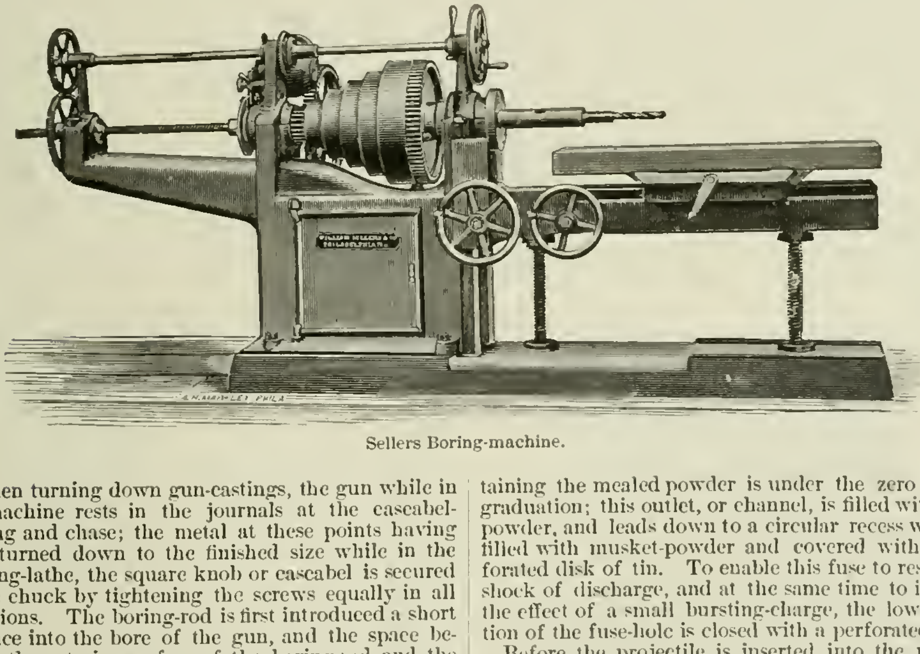
BORING-MACHINE.—This machine, designed to bore and drill horizontally work resting on a table or platform, has been considered by Engineers and Ordnance Officers as coming next to the lathe in usefulness in the armory. It should drill work that cannot be operated on in an ordinary vertical drill-press, and have all the advantages of a facing-lathe for some kinds of work.

Marked advantages which the Sellers machine (see cut) has over similar tools lie in the nature of the feed-motion, which, by use of the friction feed-disks, admits of an infinite variety of feeds between its finest and its coarsest; in the ready application of the feed, and its quick hand-motion; also in the manner of operating the compound table upon which the work rests, the handles to govern the motion of table being all on one side and within easy reach of the workman. The screws which raise the table require holes in the foundation below the bed; as when the table is lowered they project below the base of the machine. If placed in damp places, the boxes or recesses in foundation for these screws should be made water-tight. The machine is provided with an out-board bearing when that style of machine is required. This bearing is carried from the bed-plate, arching over the knee which carries the table; it bolts to the bed-plate, and to the knee also. It can be placed 29 inches from the face-plate, or it can be moved off to 53 inches from the face-plate; it does not interfere with the ready adjustment of the table vertically. The feed-motion now applied is arranged in two series, a fine and a coarse, both of these series being applicable to any speed or any size of drill. The value of the coarse feed will be felt in all kinds of boring with bars and cutters, inasmuch as it is possible to rough out with a fine feed, and to finish with a light cut and a very coarse feed. In this way the finishing cutter is hurried through the work, is less liable to wear in the length of the hole to be bored, and much time is saved.

ping and filing. To insure a smooth surface in the bore, all the work on the exterior surface of the gun is suspended while the reamer, or finishing-tool, is being used. The boring being completed, the *cylinder-gauge* is inserted before removing the gun from the lathe, to ascertain if it passes freely to the bottom of the bore; the chamber-reamer should also be measured after use in each gun, and if found correct the gun is moved from the lathe.

A general difference in the style of the tools between those employed for wood and those for metal gives opportunity for distinguishing between the two classes of machines, although the modes of propulsion in some machines of the respective classes are very similar, and the boring *bits* for hard wood are much like the *drills* for metal. See *Drilling-machine* and *Heading-lathe*.

BORMANN FUSE.—This fuse is the invention of an officer of the Belgian service. The case is made of an alloy of tin and lead, cast in iron molds. Its shape is that of a thick circular disk; and a screw-thread is cut upon its edge, by which it is fastened into the fuse-hole of the projectile. The upper surface is marked with two recesses and a graduated arc. The former are made to receive the prongs of a screw-driver; and the latter overlies a circular groove, filled with mealed powder, tightly pressed in and covered with a metal cap. The only outlet to the groove con



Sellers Boring-machine.

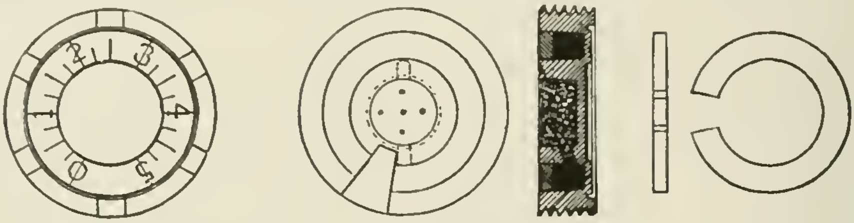
When turning down gun-castings, the gun while in the machine rests in the journals at the cascabel-bearing and chase; the metal at these points having been turned down to the finished size while in the heading-lathe, the square knob or cascabel is secured in the chuck by tightening the screws equally in all directions. The boring-rod is first introduced a short distance into the bore of the gun, and the space between the exterior surface of the boring-rod and the exterior surface of the gun at the muzzle observed. For this purpose a thin wooden gauge is used, pointed at one end and having a notch at the other, which takes the outer surface of the gun at the muzzle, the gauge being laid on the face of the muzzle, and, of course, perpendicular to the axis of the bore. As the gun revolves, the distance above, below, and on either side is observed, thus verifying the perfect concentricity of the axis of the gun at the muzzle. The adjustment is completed at the breech, by slackening the bolts at the cascabel-bearing, leaving it free to move on the rest; and should any lateral motion be perceptible, it is corrected by adjusting the screws in the chuck, after which the concentricity is complete from breech to muzzle. During the process of boring, the turning continues, and the exterior is finished, except between the trunnions and about the lock and sight-masses; the former being planed off by a machine for the purpose, and the latter reduced by chip-

taining the mealed powder is under the zero of the graduation; this outlet, or channel, is filled with rifle-powder, and leads down to a circular recess which is filled with musket-powder and covered with a perforated disk of tin. To enable this fuse to resist the shock of discharge, and at the same time to increase the effect of a small bursting-charge, the lower portion of the fuse-hole is closed with a perforated disk.

Before the projectile is inserted into the piece, a cut is made across the graduated portion, laying bare a small proportion of the mealed powder, which, being ignited by the flame of the charge, burns in both directions until the outlet is reached and the grain-powder ignited. The graduations are seconds and quarter-seconds, and the time of burning of the fuse depends on the length of the column of mealed powder included between the incision and outlet. If the metal covering be not cut, the projectile may be fired as a solid shot. The Bormann fuse is used for the field and siege services, and is found to be accurate and reliable, especially for spherical-case shot. The time of burning not being long enough for the general service of rifle-projectiles, the paper time-fuse is used instead of it for all of those projectiles which require the time-fuse. It is inserted into a zinc plug, which is screwed into the fuse-hole of the projectile.

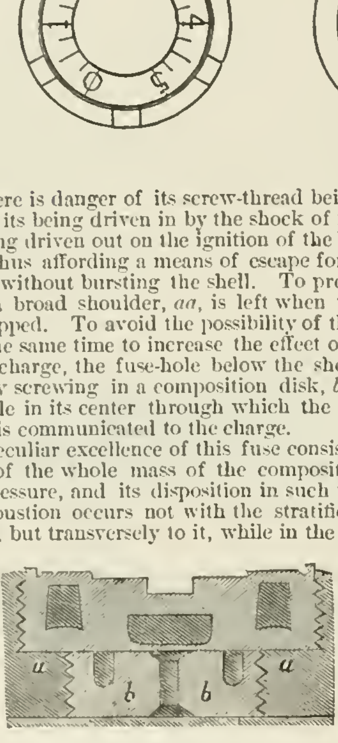
The action of the Bormann fuse is as follows: The thin covering of metal above the composition is cut so as to lay bare the upper surface of the composition, and to afford the flame access to it at the part desired. The cut should be made with the fuse-cutter close to the right of the mark in the index-plate; and it is best made in two or three efforts instead of trying to effect the cut at once. The combustion occupies the assigned time in passing from the incision towards the origin of the graduation, when it traverses the orifice leading into the magazine, the contents of which explode smartly towards the interior, and then encounter instantly the charge in the shell.

The metal of this fuse being soft and its diameter great, there is danger of its screw-thread being stripped, and its being driven in by the shock of firing, or of its being driven out on the ignition of the bursting-charge, thus affording a means of escape for the gas evolved, without bursting the shell. To prevent the former, a broad shoulder, *aa*, is left when the fuse-hole is tapped. To avoid the possibility of the latter, and at the same time to increase the effect of a small bursting-charge, the fuse-hole below the shoulder is closed by screwing in a composition disk, *b*, with a small hole in its center through which the fire from the fuse is communicated to the charge.



Bormann Fuse.

The peculiar excellence of this fuse consists in the driving of the whole mass of the composition by a single pressure, and its disposition in such wise that the combustion occurs not with the stratification of the mass, but transversely to it, while in the ordinary fuses the solidification and the process of combustion are just the reverse; that is, the column is composed of a number of layers solidified successively by an equal pressure; but as the inferior layers have, besides the pressure applied to them, to bear that of the superincumbent layers, it follows that the mass is not homogeneous, but increases in density with the inferior position of the layers. See *Fuse* and *Time-fuse*.



Shoulder and Disk.

BOSHES.—The sloping sides of the lower part of a blast-furnace, which gradually contract from widest part of the furnace to the hearth. In a furnace 55 feet high and 38 feet wide at the base of the structure, the boshes will be about 8 feet in perpendicular height, 12 feet wide at the top, and 2¼ feet at the bottom where they join the hearth. The boshes are built of a coarse-gritted freestone, abounding in small nodules of quartz. A number of newly invented puddling and boiling furnaces have iron floors and boshes. A current of water is caused to circulate in them to prevent destruction of the iron under the extreme heat. The material which is banked up against the boshes to protect them from the heat is called *fixing*. It consists of scrap and ore, and receives a preliminary melting. One *composition for fixing* furnaces consists of finely pulverized ore and German clay made into a paste; and another for the same purpose is a paste made by grinding the ore and rendering it plastic by moistening and working. *Bull-dog* is a decomposed protosilicate of iron used in England and France for this purpose.

BOSNIAKEN.—Formerly light cavalry of the Prussians, resembling the present Uhlans. Frederick I. formed this cavalry in 1745.

BOSS.—1. A stud or ornament raised above the leather-work of a cavalryman's horse-trappings. 2. A protuberance raised as an ornament on any work; the part rising in the center of a shield. 3. A plate of cast-iron secured to the back of the hearth of a traveling-forge. 4. In architecture, a raised ornament covering the intersections of the ribs of ceilings. They are more frequently seen in vaulted roofs, as in the aisles of a church, but occur also where the ceiling is flat. In early Norman work there are generally no bosses, and they become richer and more frequent as we advance towards the decorated and perpendicular styles. In the decorated style the boss usually consists of foliage, sometimes combined with animals, heads, and the like. Coats-of-arms, charged with armorial bearings, came then also to be used for this purpose, though they were more frequent in the perpendicular.—The boss was borne in the arms of the Corporation of Lorimers. See *Lorimer*.

BOSSE—BOSSE A FEU.—A term used in the French Artillery to express a glass bottle which is very thin, containing four or five pounds of powder, and round the neck of which four or five matches are hung after it has been well corked. A cord two or three feet in length is tied to the bottle, which serves to throw it. The instant the bottle breaks, the powder catches fire and everything within the immediate effects of the explosion is destroyed.

BOSSETTES.—In horse-armor, the ornaments on the side of the bit. The term is also applied to the pieces of leather, or blinkers, which cover the eyes of the mule.

BOSTANJI.—A class of men in Turkey who, originally the Sultan's Gardeners (the name being derived from *bostan*, a garden), now perform, in addition to their garden-labor, a variety of duties, such as mounting guard at the Seraglio, rowing the Sultan's barge, and attending on the Officers of the Imperial Household. They are under a Chief called Bostanji Bashi, who holds the rank of a Pasha, and is Governor of the Sultan's residences, and Steersman of his barge. He also holds the Inspector-generalship of the woods and forests in the vicinity of the capital, has the jurisdiction of the shores of the Bosporus and Sea of Marmora, and is, altogether, so important a functionary that only personal favorites of the Sultan can hope to fill the office. The financial reforms of Sultan Mahmoud, however, have greatly lessened the emoluments of the post. The Bostanji at one time amounted to 5000, and were divided into companies like the Janissaries, with whom they were united in military duty. In war-time their strength was 12,000. A scarlet bonnet, of excessive dimensions, formed the distinctive part of their costume. Their number now does not amount to more than 600.

BOTHWAY BLOCKS.—Two natures of these blocks have been introduced into the English service, the 18- and 15-inch. They are each *single*, *double*, and *treble* blocks. These blocks in the land-service have superseded the ordinary common blocks of 18 inches and upwards, but the existing store of iron gyn blocks will be used up. Bothway's blocks are made of the best English elm; the swivel, hooks, and shackles, of the best manufactured scrap-iron; the straps and pins for sheaves, also connecting-pins, of the best iron; and the sheaves, of phosphor-bronze. See *Blocks*.

BOTONE.—In Heraldry, a cross botoné is a cross of which the ends are in the form of buds or buttons. Also written *Botonny*.

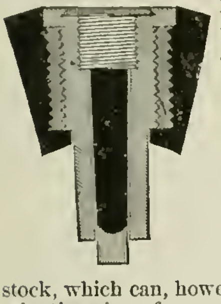
BOTTLE-NECKED CARTRIDGE.—The name given to the Martini-Henry cartridge, from its bottle-necked shape. The neck or smaller diameter of the cartridge-case is formed by means of a die so arranged as to form flutes or folds in that part of the case, and consequently reduce the diameter: the paper covering is dispensed with, a paper lining being substituted.

BOTTOM.—1. A circular disk with holes to hold the rods in the formation of a gabion. 2. One of the plates by which grape or canister is built up into a cylinder suitable for loading into the gun: cast-iron tops and bottoms for grape, wrought-iron for canister.

BOUCANIER.—A long, heavy musket used by the American Buccaneers, and with such skill as to give the weapon a high degree of celebrity.

BOUCHE.—1. The aperture or mouth of a piece of ordnance,—that of a mortar, of the barrel of a musket, and of every species of fire-arms from which a ball or bullet is discharged. 2. A cylinder of copper in which the vent of a piece of ordnance is drilled. It has an exterior screw-thread cut on it, so that it may be removed when the vent becomes worn, or a new bouche substituted. Also written *Bouch* and *Bush*.

BOUCHING.—The fuse-holes of shells are frequently bouched with gun-metal to receive the fuse-stock. In fitting the shell to receive the bouching, the bore should be tapped with a full thread, and the proper shoulder left at the bottom to prevent the bouching from being driven in by the shock of firing and causing premature explosion. The object of the bouching is to prevent rust, and to have the same kind of metal in contact with the fuse-stock, so that there will be less danger in extracting or exchanging a fuse. The fuse-holes of heavy rifle-shell are necessarily cast larger than the diameter of the regular fuse-stock, which can, however, be used with the aid of an *adapting-ring* of gun-metal, which is screwed in to reduce the diameter of the hole to the proper dimensions. The 15-inch spherical shell are cast with three fuse-holes equally distant from each other, and situated in the angles of a triangle 4 inches apart. See *Fuse-hole* and *Shells*.



BOUCHING-BITS.—Instruments used for boring a hole in the vent field of guns, to receive the copper plug, or bouch, through which the vent is afterwards drilled.

BOUGE.—An ancient war-club, the head of which was loaded with lead; also called *plombée*, and frequently written *Boulge*.

BOULAF.—A kind of baton or very short mace, formerly used by the Polish Generals.

BOULENGE TELEMETER.—The Boulengé telemeter is an instrument devised for ascertaining the distance to a point by means of sound proceeding from the point to the place of observation. The one used for artillery purposes consists of a glass tube about six inches in length, filled with a transparent liquid that does not freeze except with intense cold. In the liquid is a metallic disk, which moves freely from one end of the tube to the other. It is so adjusted that the motion will be uniform and comparatively slow. The tube is inclosed in a brass case, to which is attached a scale, after the fashion of a thermometer. This scale is marked for each hundred yards up to 4000. The divisions on the scale show the distance, in yards, through which sound will travel in air, during the time required for the disk to descend over the space on the scale marked by the corresponding number of yards. If, for instance, the disk passes from zero to the 500 mark, it indicates that sound would have traveled 500 yards through the air during that time. The instrument must be held vertically, or as nearly so as possible. To arrest the motion of the disk at any point, the instrument is quickly turned to a horizontal position.

To use it for determining the time of flight of shells, it is held in the right hand, back of the hand up, with the zero of the instrument to the left; a turn of the wrist to the right brings the instrument vertical, with the zero end uppermost; the disk then descends, and a turn of the wrist to the left arrests its motion. The observer, holding the instrument as described, watches for the flash of the shell, and upon seeing it, instantly brings the instrument to a vertical position; upon hearing the report from the shell, he instantly turns it back again. The position of the disk indicates the number of yards from the observer to where the shell exploded. To ascertain the distance to an enemy's battery, the instrument is held and turned in the same manner. The observer watches for the flash of a gun; observing which, he turns the instrument, and, when he hears the report, turns it back and reads off the distance. Each hundred yards on the scale is subdivided into quarters. See *Le Boulengé Chronograph* and *Telemeter*.

BOULEVARD—BOULEVART.—The name given in France to the old fortifications, ramparts, etc., with which towns, or portions of them, were, or still are, surrounded. In France and Germany these ancient works have generally been leveled, the ditches filled up, and the space thus obtained employed for the formation of parks, promenades, and streets lined with trees. These, however, in France still bear the name of *boulevard*. The boulevards of Paris are celebrated, and are of great service as open spaces promoting the circulation of air amidst the dense mass of habitations. Some parts of them present a very dazzling spectacle, and as a whole they afford a striking exhibition of the life and character of the French Capital in all the different classes of society. The *Boulevard des Italiens* is particularly known as the rendezvous of the fashionable, and the *Boulevard du Temple* as the place where the small theaters are to be found which are frequented by the common people and the inhabitants of the suburbs, for which reason the expression *Théâter de Boulevard* is often employed to denote a theater for the common people, or one of an inferior kind. The Thames Embankment is essentially a boulevard.

BOUND.—In gunnery, the path of a shot comprised between two *grazes*.

BOUNTY.—A sum of money given to encourage men to enter the army or navy. In time of peace, when there is little or no need to augment the forces, the bounty sinks to a minimum; but in cases of exigency, it is raised according to the difficulty and urgency of the circumstances. In the British army no bounty was paid to recruits until about half a century ago; the temptations offered to them, if any, were of some other character. The highest bounty ever paid during the great wars against Napoleon was in 1812, when it amounted to £18 12*s*. 6*d*. for limited service, and £23 17*s*. 6*d*. for life; but these sums were in great part nominal, being subject to many unfair and absurd deductions. Even so late as 1849, when the bounty to an infantry recruit was nominally £4, he received little more than one eighth of this amount, all the rest being swallowed up in fees and drawbacks of various kinds. The only bounty which now exists is a free kit—no other being allowed. The young men who used to enter the British army were supposed, for the most part, to have been tempted by immediate bounty rather than by prospective pay and pensions; and thus it arose that the rate of bounty varied frequently, while those of pay and pensions underwent very little change. In 1855 it was £7 per head (for line infantry); in 1856, only £2; in 1858, £3; and it afterwards underwent further changes. It was always higher to the cavalry and artillery than to the infantry; and in the latter it was higher to the Highland than to the other regiments, on account of matters connected with dress and personal ornaments. The term *bounty* is also used in the navy to signify the payment and distribution of money to which the officers and crew of Her Majesty's ships and vessels of war may, on particular occasions of active service, be entitled. See *Prize*.

BOURBON FUSE.—This fuse consists of a bronze fuse-plug screwed into the eye of the shell, with a head larger in diameter than the other part and threaded on the exterior, by means of which a cap is screwed on, covering the fuse until just before it is used. A cap of copper is fixed to the head of the fuse by means of several circular grooves in the fuse-plug; slots and projections being formed on the edge of the cap, and the rabbets of the circular grooves, which allow the cap to be inserted in its place. A threaded hole is placed at the highest point of this cap, in which the fulminating-cap is screwed just before the fuse is used. A steel nipple is screwed into the body of the fuse just under the cap, which, when the cap is exploded, conveys fire to the charge, communicating it first to the powder contained in the channel of the fuse. The bottom of this channel is closed with a cork stopper, which is blown out when the powder in the fuse takes fire. The projectile being supposed to strike with the point first, the shock, in order to explode the cap, must be of sufficient force to flatten the cap; and this cap has been made of such a thickness that nothing less than striking against a fortification or other equally resisting body is sufficient to cause explosion. Ricochets could seldom cause the shell to burst. Such a fuse is evidently good for all projectiles with arrangements to keep particular parts always to the front. See *Fuse*.

BOURDONNANTE.—A name formerly given to a kind of bombard of a heavy caliber.

BOURGUIGNOTE.—A helmet worn by the Burgundians, and from whom it was named. It was of polished iron, with a visor. Under Louis XIV. their head-dress was changed to a kind of bonnet. Also written *Bourgenot* and *Bourgignotte*.

BOURLETTE.—In antiquity, a mace which was garnished with iron points.

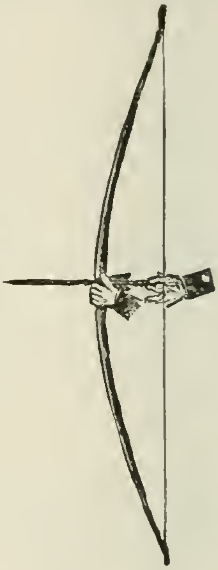
BOURNOUSE.—The Arabic name of a garment worn in Algeria, Morocco, and other parts of northern Africa, and which constitutes a part of the military clothing of some corps of the French army. It is a large woolen mantle, worn above the other attire of the natives, and having a hood, which is thrown over the head in rainy weather. The bournouse is generally white, though distinguished individuals wear it of various colors—blue, green, red, etc. It has been long in use among the Spaniards under the name of *albornoz*. Through the conquest of Algeria by the French, the bournouse was imported into France and England, although its original form has been considerably altered. Also written *Bournous, Burnoose*, and *Burnos*.

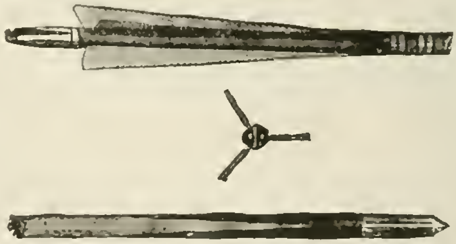
BOUSMARD BASTION SYSTEM.—This system of fortification possesses remarkable features. Taking the enceinte of Vauban's first system, both the crest of the flank and the original face are divided into eight equal parts, being respectively 6, 8, 10, 12, 14, 16, 18, and nearly 20 yards in length. The new faces are composed of eight broken lines. The tenaille has flanks without either terre-plein or banquette. The casemates are skillfully disposed, and their rear is protected by the shoulder-angle of the bastions. The main ditch is reduced to 20 yards, in order that the defenders may throw hand-grenades into the lodgment of the enemy on the covered-way. The covered-way is traced in cremaillère, and extends along the counter-scarp of the main ditch. The traverses have the form of sedans, and the ravelin is detached beyond the glacis of the enceinte. The great defect of this system is that the ravelin and its reduit are liable to be taken by the gorge.

BOUTEROLLES.—The richly decorated termination of ancient sword-scabbards. The figures of lions or other animals, having their bodies stretched out in the direction of the sword-blade, impart a bold and effective finish to the bouterolle.

BOUTON.—A kind of war-club, formerly used by the Caribs of the Antilles. Also written *Boutoou*.

BOW AND ARROW.—In the article Archers will be found a brief account of the military arrangements under which bowmen formed a component element in the armies of the Middle Ages; and under Arbalest is a description of the cross-bow, which was once so favorite a weapon. We here describe the more effective though simpler implement. The long-bow first gained ascendency in England in the fourteenth century. It was found that a dozen arrows could be discharged from this weapon while the Arbalester was winding up his cumbrous cross-bow and discharging one arrow or quarrel from it. Moreover, the long-bow being held vertically, the bowmen were able to stand in closer array than the Arbalesters; they were enabled also to take a greater supply of the munitions of war into the field, seeing that the bow and arrows were much lighter in weight. In the time of Edward III. a bow was priced 1*s*. to 1*s*. 6*d*., and a sheaf of arrows, 1*s*. to 1*s*. 2*d*. In the time of Henry VII. the price (fixed by law) of the bow varied from 6*d*. to 3*s*. 4*d*. The last-named monarch adopted extraordinary means for encouraging the use of the long-bow. Many ordinances were issued for insuring a good supply of bow-staves. The bowyers, string-makers, fletchers, and arrow-head makers were all placed under stringent regulations. Merchants were compelled to import good bow-staves with cargo, in certain proportions. Very long bow-staves were admitted duty free. Yew was considered the best





wood; but in order that the supply should not be too speedily used up, bowyers were ordered to use elm, ash, and witch-hazel in certain proportions to yew. The heads of families were bidden to provide bows for their sons and servants; and town-councils or officers were required to provide shooting-butts just

outside each town. Some of the bows had two arches, connected by a middle straight piece. The best length was regarded as about 5 feet 8 inches from nock to nock; but in earlier times some of the bows were much longer. The first arrows were made of reeds; these materials were afterwards superseded by cornel-wood; but the wood finally adopted as the best was ash. The arrows had heads pointed with steel, sometimes barbed to render their action more terrible. They were feathered with portions of goose-wing. The best length for a bow of the above-named size was set down at 2 feet 3 inches. Sometimes the arrows were tipped with combustibles. The best makers of arrow-heads, as well as of bows, were compelled by law to go from town to town, to exercise their craft wherever it was most needed. The bowman usually carried 24 arrows, called a sheaf, or a quiver, at his right side or at his back; besides others in his girdle. He kept his bow in a case; hence Falstaff's comparison of Prince Hal to a bow-case, in allusion to his slenderness. Bowmen, in their hours of sport, used arrow-heads called *rigged*, *creased*, *shouldered*, and *spoon-headed*, according to the shape.

BOWIE-KNIFE.—A common hunting-knife used by Southwestern pioneers, and improved by Colonel James Bowie, who has been wrongly represented as a bully and a duelist. The bowie-knife is seldom concealed, and it is by no means the commonly used weapon which it is represented to be by foreigners; indeed, of late years it is seldom seen at all unless among hunters or settlers in the extreme frontiers.

BOWLINE.—A very useful knot, known as the single, running, and double bowline knot. The single bowline serves to throw over a post to haul on, also to sling a barrel; the running bowline, for securing paulins on ammunition-wagons; and the double bowline, for slinging a cask.

BOW-SHOT.—A term sometimes employed to denote the space which an arrow may pass over when shot from a bow.

BOWSING ROPE.—A rope used in the artillery service for moving a weight by simply hauling upon it.

BOW-STRING.—1. Great improvements have been made of late years in the strength of field-axletrees, rendered necessary by the increased strains. The

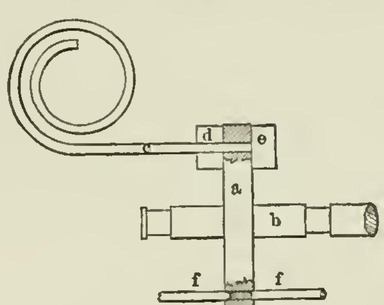
Bow-string.

wooden bed having been given up, the box-girder took its place, and the *bow-string* of steel is a further improvement. In this the bed is the top of a strong girder of deep section, the bottom of which is formed by the axletree; the latter is only pierced with holes for attachment to the bed at its thick ends. This arrangement prevents the thinner parts of the metal from being nipped or pierced when strained—an important matter, especially in dealing with steel. It is also easily taken off the bed when required.—2. On the quality of the bow-string depend in a great measure the shooting qualities of the bow. It should not be too thin, or it will not last long; in the selection of it, it is best to be guided by the size of the notch of the arrows. At one end of it a strong loop should be worked to go over the upper horn; the other end should be left free in order to be fixed on to the lower horn: this is done with a peculiar loop, shown in the drawing. When the lower end is fastened, the distance between it and the loop at the other end should be such, that when the loop is in its place (i.e., the bow strung) the string is, in a gentleman's bow, six inches, in a lady's, five inches, from the center of the bow. The string should be lapped for an inch above the nocking-point, and five inches below it, with waxed thread, and this again with floss-silk—to such a thickness that it completely fills the notch of the arrow, but without being too tight, or it may split it. Never trust a worn string; take it off and put on a new one—should it break, it will most probably snap the bow.—3. A string used by the Turks for strangling offenders.

BOWYER.—The military term for the man who makes or repairs the military bows. Not much used at present.

BOXER CARTRIDGE.—The Boxer cartridges for the Snider and Martini-Henry rifles are made on a large scale at the Woolwich Arsenal in what is known as the Small-arm Cartridge Department. Although the number of pieces constituting a Boxer cartridge is much greater than those on the American plan of drawing the shell out of a single disk of metal, the cost of manufacture is low, inasmuch as the parts are made very rapidly in presses tended by boys. The cost of a single small-arm cartridge at Woolwich is about one penny.

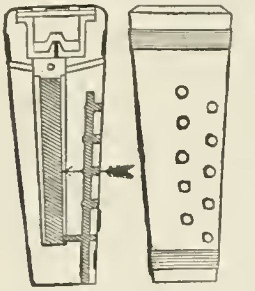
The bullets are made in presses of very strong and solid construction, the principles of which are shown in the accompanying drawing. The lead, hardened



by alloying it with one thirteenth of its weight of tin, is drawn out into wire which is wound on a reel, and from this reel it is fed into a revolving disk of hardened steel, *a*, which is pierced with round holes of the precise diameter of the finished bullet. This disk revolves vertically, and as it passes the sharp edge of a piece of steel, *d*, pressing against its side, the lead wire is shaved off, leaving in the die a quantity just sufficient to form the bullet. Revolving a little further, two punches, *f f*, press on the lead in the die from opposite directions, and give it proper shape at the point and base. In one of the punches there is a small hole for the escape of any surplus lead, if there chance to be any. There is a slight cannelure in the surface of the Martini-Henry bullet into which the mouth of the case is crimped to secure the bullet in its place in the cartridge. The bullets are rolled between a horizontally-revolving disk and a confining rim. The edge of the disk and inner surface of the rim have a raised rib, which make the required indentation or cannelure in the bullet.

The bullet for the altered Enfield rifle differs from the Martini-Henry bullet, inasmuch as it has two cavities and three cannelures. The cannelures are for holding the lubricants. The rear cavity has a clay plug in it for the purpose of expanding the lead, and the forward cavity is formed by a punch, and afterward closed over in a die. The object of this latter-named cavity is to give a proper adjustment to the position of the center of gravity of the bullet in firing. Small-arm ammunition in the British service is distributed in the field by means of carts designed for this service and drawn by two horses. Artillery ammunition is transported in wagons. See *Martini-Henry Rifle* and *Snider Rifle*.

BOXER FUSE.—A wooden-stock time-fuse. A coned composition channel is bored into the stock parallel to the axis, but one tenth of an inch distant from it. This channel receives the paper fuse-case. Just above the upper face of the fuse-composition is an unoccupied space from which four gas-vent channels lead to the outside of the stock above the point of the shell. Immediately above this gas-vent chamber the bore of the stock is considerably enlarged to receive the igniter. This consists of a small bronze hollow cylinder, closed at the lower end, where it is furnished on the inside with a pierced nipple for percussion-cap. The upper edge of the hollow cylinder is flanged in such a manner as to rest on the top of the stock; thereby preventing the igniter from being driven bodily into the fuse on discharge of the gun. Inside of this hollow cylinder the plunger is hung on a brittle wire (half copper and half lead).



When this arrangement is in place, the head of the fuse is covered with a piece of paper or linen luted down and shellacked. Thus far the fuse only burns for the full time for which it is pressed. In order to provide for intermediate times, two side channels are bored from the lower end of the fuse upward (one of these is shown in the drawing). Holes bored (at equal intervals) from the outside of the stock connect the exterior of the fuse with the side channels; the lowest communicating hole in each channel being bored entirely through to the fuse-composition. The channels are filled with mealed powder, and paper is pasted over the exterior of the communicating or time holes, which are arranged as shown in the drawing. The upper and lower ends of the stock are served with brass wire.

This fuse, which is virtually the English Boxer, works as follows: With a suitable tool pierce through the communicating hole, which corresponds to the number of seconds desired, into the column of fuse-composition (see arrow), then push the fuse by hand, giving it a slight twist, into the fuse-hole of the projectile, and load the gun. On the explosion of the charge the plunger, by its inertia, shears the brittle suspending-wire, and strikes the percussion-cap, which ignites the composition, and the fuse burns down to the point at which it was pierced. Then the flame flashes into the side channels, down the latter to the lower communicating hole, and thence to the bursting-charge. If for any reason the flame should not pass through the hole bored at the desired time, the fuse would still act at the end of its time of burning by igniting the charge through the lower communicating hole. If the shell strikes the object before sufficient time has elapsed to enable the composition to burn to the lower end, it is probable that the stock would be split and the whole be driven inwards; in which case it would act as a concussion-fuse. See *Fuse*.

BOXER LIFE-SAVING ROCKET.—The 12-pounder rocket used by the English Coast-guard Service is the invention of General Boxer, R.A. Three different patterns of these rockets have been made and issued. The one now in use is known as "Mark III." The Boxer rocket is composed of a head, head-clip, body, base-clip, base-plug, and diaphragm. The head is hemispherical in form, with a cylindrical tenon that fits in the front end of the rocket-case. The head-clip nearly envelops the front end of the rocket-case, with its forward edge coincident with the exterior junction of the case and head. On one side of the case the iron strap forming the head-clip is bent outwards to form a short rectangular tube, whose axis is parallel to that of the rocket. This short tube receives the front end of the rocket-stick. The body of this rocket consists of two cylinders of sheet metal (Bessemer). These cylinders are placed end to end with their axes coincident with the same straight line. The front cylinder is shorter than the other, to which and the inner diaphragm it is joined by screws passing through cases into the diaphragm. The front cylinder is filled with rocket-composition to within .4 inch of its front end. A conical-shaped cavity is left in the axial portion to furnish a large surface of inflammation. The rear cylinder is filled in a similar manner with composition, leaving a solid portion of this composition at the front end between the two cavities 1.2 inch in thickness. The cavity or "bore" of the rear cylinder is also conical in shape. The base-clip is analogous to that at the head, but is longer. It nearly surrounds the rear end of the rocket, and has a rectangular tubular projection on one side in line with that of the head-clip. The base-plug closes the rear end of the cylinder and is pierced with an axial vent one inch in diameter, through which the gas escapes after the ignition of the composition. The diaphragm is placed between and inside of the two body-cylinders, and performs the same functions for the front cylinder that the base-plug does for the rear one, and in addition serves as a seat for the assembling screws. A paper cap covers the vent, which must be broken before firing. The rocket-cases are protected on the inside from the action of the composition by a coat of anti-corrosive paint; the outside is protected and blackened by burning off oil. Since 1870 the exterior of the case is still further protected by two coats of red paint.

The following are the principal dimensions and weight of the rocket:

	Inches.	Centi-meters.
Total length	25.0	63.50
Radius of head	1.5	3.81
Diameter of rocket-case { Exterior	2.75	6.98
Diameter of rocket-case { Interior	2.6	6.6
Length of front cylinder	9.3	23.62
Length of rear cylinder	14.2	36.06
Head-clip { Length	1.5	3.81
Head-clip { Rectangular projection. { Width	1.3	3.30
Head-clip { Rectangular projection. { Depth	1.2	3.05
Base-clip { Length	2.5	6.35
Base-clip { Rectangular projection. { Width	1.5	3.81
Base-clip { Rectangular projection. { Depth	1.3	3.30
Length of clip-pin	*0.85	2.15
Diameter of vent	1.0	2.54
	Pounds.	Kilog'ms.
Weight of rocket	14.25	= 6.46

The rocket-sticks are made of pine and are 9 feet 6 inches in length. The portion of the stick that extends through the clips along one side of the rocket is square in cross-section, with a groove on the side next to the rocket to fit the curvature of the case. The stick in rear of the rocket is octagonal in cross-section. The lower end of the stick is surrounded by an iron ferrule. Two plates are placed, one at the upper end of the stick and the other at a distance from that end equal to the distance between the clips on the rocket. The lower plate has a small flange that brings up against the lower clip when the stick is inserted in position for firing; both plates are hollowed to fit the rocket-case. An iron clip-pin with the head bent at right angles is inserted in a hole through the stick in front of the base-clip, to prevent the withdrawal of

* Length of clip-pin before bending, 1.2 inch. Size of wire, No. 8 Birmington wire-gauge.

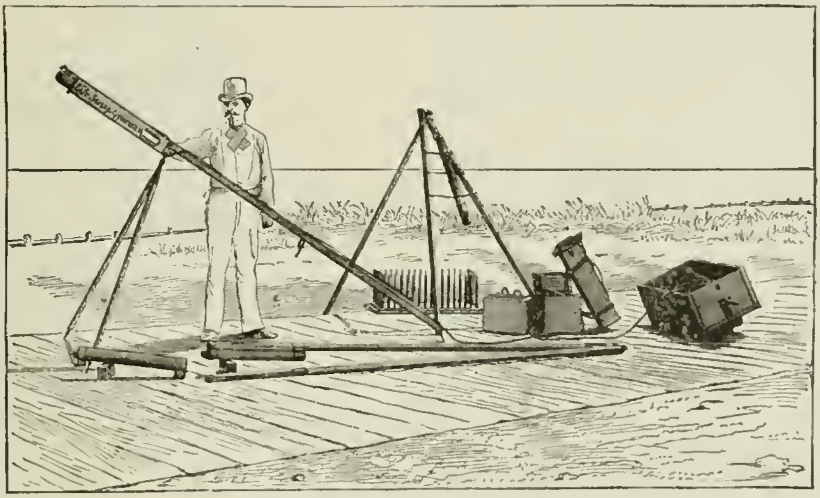
the stick in firing. The stick is partially surrounded for 18 inches below the vent by a sheathing of tin to protect it from the burning gases. Axial holes are bored in each end of the stick for the attachment of the line. These holes are curved outward from the axis until they reach the exterior of the stick on the same side. The holes are smoothed by passing a red-hot iron through them, charring the wood. The sticks are unpainted, and are packed in bundles of six each.

The stand for this rocket is known as the Boxer rocket machine or stand, "Mark IV." The material is sheet-iron, except the legs, which are of wood. This stand is lighter and simpler in construction than the older forms. The principal parts are an open rectangular trough or body, a curved trough, called by the English "a pry-pole," a horizontal axis, two legs, and a graduated arc made of brass. The rectangular trough or body receives the rocket. Its width is less than its depth. The front end is stiffened by a narrow iron strap around the outside. The upper edges are rolled over wire for the same purpose. Near the rear end, on each side, are cut subelliptical holes to admit the port-fire in firing the rocket. The body and pry-pole are connected by pieces of wrought-iron, rivets, and braces. There are two of the latter, one on each side. Two pieces of wrought-iron project from the rear end of the rectangular trough and have holes bored to receive the horizontal transverse axis. The long rounded trough or pry-pole extends into the rear end of the body for a short distance. The upper edges of the pry-pole are rolled over a large wire to stiffen them, and the trough is still further strengthened by a wrought-iron bar .5 inch thick, running along the bottom the whole length. The lower or rear end of this bar is decurved and pointed to form a ground-spike or foot. A strap with a buckle on the end is riveted to the pry-pole near the rear end, for the purpose of binding the legs to the pry-pole when they are folded up for transportation. The horizontal axis has a small swinging tablet below, through which are pierced two holes for rivets for the legs. The latter have a lateral motion upon these rivets as axes. The legs are made of tough wood. They have wrought-iron heads or sockets with slotted projections to embrace the tablet pendant from the horizontal axis. Ferrules envelop the lower ends, which are armed with pointed spikes in order to secure a firm hold in the soil when placed in position. On the right-hand side of the body, between the opening and the front end, is placed a sheet-brass quadrant, graduated and marked from 0° to 35°. The limits of elevation that can be obtained with this stand, due to its construction, are from 17°.5 to 40°. At the center of this arc is a rivet with a projecting head, around which is fastened a short string with a minute pear-shaped plumb-bob dependent.

The life-saving rocket-fuse is a frustum of a cone in shape, made of paper and covered with kamptulicon. It is 1.5 inch long and fits the vent in the base of the rocket, which is 1 inch in diameter. The fuse is covered with a paper cap tied on with twine. The bore of the fuse is filled with about an inch of ordinary fuse-composition, and burns about five seconds. The paper cap may or may not be removed before firing. The fuse is ignited by means of a port-fire.

The Boxer port-fire for life-saving apparatus has a total length of 9.3 inches, and is cylindrical in form. The exterior diameter of the case is .7 inch. One end is closed with a tin cap and a piece of kamptulicon; this cap is .5 inch long and .8 inch in exterior diameter. On one side the tin band of the cap is perforated to admit a detonating primer that enters a small space under the kamptulicon, and fires the priming of mealed powder. The exterior surface of the port-fire is painted flesh-color. A circular black spot on the cap indicates the position of the hole for the detonating primer. The time of burning of this port-fire is six minutes.

The following is the manner of using the Boxer or English life-saving rocket:



Boxer Life-saving Rocket.

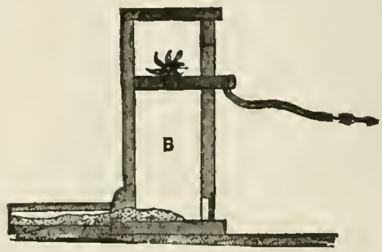
With the apparatus on the ground where it is to be used, place the rocket-stand in position, giving the necessary elevation by means of the graduated arc on the side of the trough and the plummet. Take a Boxer rocket, insert the stick through the clips, and drive in the clip-pin. Then wet about 12 feet of the end of the line and insert the end through the hole in the bottom of the rocket-stick, carry it along the stick to the hole near the upper end, draw it through and put on, first, a rubber washer and then a brass one, and tie a knot in the end, drawing the whole down snugly upon the end of the stick. It is better to tie a knot in the line after passing it through the hole in the rear end of the stick, so that in case the line burns off between the rocket and lower end of the stick the knot will catch and the line still be carried out. Remove the paper cap on the base of the rocket and insert a fuse. Place the rocket and stick in the trough of the stand, sliding them to the rear until the base of the rocket brings up against the front end of the curved trough or pry-pole. Put the faking-box, slightly inclined to the front, in rear of the stand and a little to one side. Insert a port-fire in the holder, and ignite it with a detonating primer. Advance to the stand, insert the port-fire in the opening on the side opposite to that on which the faking-box and line are placed, light the rocket-fuse, and retire towards the rear.

As soon as the rocket-composition is ignited and sufficient gas is evolved, the rocket starts, guided by the trough and the rocket-stick. After traversing a part of its trajectory, the composition in the rear cylinder is consumed, the solid part between the cylinders burns through and sets fire to the composition in the forward cylinder, giving a new impetus to the rocket and prolonging the range. See *Life-saving Rockets*.

BOXER SHRAPNEL SHELL.—This shell embodies the main features of the *Shrapnel*. The charge is placed in a chamber at the base, so that on explosion there is no tendency to increase the lateral spread of the bullets, but rather to increase their velocity and penetration. The shell has a cylindrical iron body, four longitudinal grooves inside, and is cast without a head. A tin case for the bursting-charge fits into the chamber, on the shoulder of which rests a wrought-iron disk. The shell is lined with paper and filled with balls imbedded in rosin. The balls for the smaller natures are of lead and antimony. A wrought-iron tube passes down the middle of the shell and through a hole in the center of the iron disk, to lead the flame from the fuse to the bursting-charge. The tube is tapped at the top to take a primer. A kamptulicon disk is placed over the bullets. The head is ogival in form and made of wood, covered with thin wrought-iron. The bursting-charge being confined in the tin case, the shell is not liable to premature explosion from pieces of iron breaking off the shoulder of the chamber by the shock of discharge. See *Projectiles* and *Shrapnel*.

BOXING.—Fighting with the fists. It was practiced as a manly exercise by the ancients, among whom it was an art so highly esteemed that Pollux, Hercules, and some of the other gods were represented as having excelled in it. The pugilists of the ancient games had leather thongs on their hands, sometimes loaded with lead or iron; this armature of the hand was called the *cæstus*. Of course their combats were not unfrequently attended with fatal consequences, which have resulted also in many instances of modern pugilistic encounters, although no armature of the fists is allowed. Among the Greeks the practice of boxing was at first permitted only to freemen, no slave or person attainted with crime being considered worthy to possess the high privilege of being beaten to the consistency of a jelly. Gradually, however, boxing was taken up as a profession, and its character deteriorated. Boxing was a favorite amusement of Englishmen for centuries; it is even said to have had such distinguished patrons as King Alfred and Richard III. But the golden age of pugilism as a profession in England commenced with the accession of the House of Hanover; then men calling themselves Professors publicly announced their intention of giving lessons in "the noble art of self-defense." One Professor challenged another to combat in the most bombastic language In 1726, one Ned Sutton, who announces himself as "Pipemaker from Gravesend, and Professor of the Noble Science of Defense," sneers at another Professor, whom he calls "the extolled Mr. Figg," for having by "sleeveless pretense" shirked a combat with him, "which I take," says the Pipemaker and Professor, "to be occasioned through fear of his having that glory eclipsed by me, wherewith the eyes of all spectators have been so much dazzled." He further assures the said Figg that if he can muster courage enough to fight with him, he (Figg) "will have the advantage of being overcome by a hero indeed!" Figg had an "amphitheater" in Oxford Road, wherein fights were held; and a larger one was erected in the same locality in 1742 for one Broughton, the funds being subscribed by some eighty noblemen and gentlemen. The pugilistic encounters that took place here were patronized by many of the nobility. Some faint protests against the brutality of the pastime now began to be made by the press, but these had little effect. Towards the end of the last century fights were patronized by Princes of the Blood Royal; and the Prince of Wales, afterwards George IV., was present at one at Brighton in which one of the combatants was killed. When the allied Sovereigns and their Generals went over to England in 1814, Lord Lowther treated them to a series of boxing-matches in his drawing-room, which were so highly relished that they were repeated a few days afterwards. One of the pugilists, called Jackson, became quite a hero, and made enormous sums by giving lessons to young noblemen, among whom was Lord Byron. In 1817 the Czar Nicholas of Russia witnessed a prize-fight at Coombe Warren. At the close the victor was presented to him, with whom he shook hands. This was the last time that Royalty was present at one of these disgusting spectacles.

BOX-TRAP.—A common method of firing mines is by the use of the *box-trap*. This is a box 18 inches high and 6 inches wide in the clear. The bottom consists of a piece of plank 18 by 10 inches, and its cover is fixed at one side only with a wooden pin, about which it can be turned. At 6 inches from the top of the box a horizontal slit is made in one of its sides, and grooves in the two adjacent to it, to receive



a piece of board, which ought to slide freely in this arrangement. In the lower part of the box an opening is left on the side opposite the one cut for the slide, to admit the powder-hose. To fire the train, place the box against the extremity of the tamping and secure it well; tie a string to the slide and lead it along the stanchions of the gallery on pegs driven for that purpose; put the end of the hose into the box through the hole left for it, and spread on the top of it some dry, fine powder; then put in the slide and close with earth or rags of sand-bags all communication between the lower part of the box and the branch; place a star-match of six or eight points, well lighted, on the slide; replace the cover, then pull the string, and the star will fall below and fire the mine. See *Monk* and *Rocket-trough*.

BOYAUX.—In military engineering, winding or zigzag approaches dug to form a path or communication between the different armed trenches of a siege-work, and to prevent them from being enfiladed or fired upon in flank. Each branch of an approach overlaps that behind it by about ten yards, to afford protection against enfilade, and to serve as a trench depot for trench-materials. The dimensions may be the same as those used in the first parallel, and frequently these are adopted if there is to be much use made of the approach. In both the parallel and the boyau it is recommended to slope the bottom of the trench to the rear, giving a fall of about six inches. This provides for drainage, and also affords greater protection to the men using them. See *Siege*.

BRABANCONS.—Mercenary fighters from Brabant and other countries who, in the later Middle Ages, served any who would pay them. They were poorly organized and little better than banditti.

BRACELET.—An ornament worn on the arm, generally at the wrist. Bracelets and armlets have been used by every nation, both savage and civilized, from the earliest periods to our own. They are frequently mentioned in Genesis as worn both by men and by women, both by the Hebrews and the surrounding nations. Similar ornaments were worn round the ankles, but they are stigmatized by Isaiah as marks of luxury (iii. 16). The Medes and Persians were remarkable, even amongst Asiatics, for their love for ornaments of this class. They wore not only bracelets and armlets, but ear-rings, collars, and necklaces, which often consisted of strings of valuable pearls or were enriched with other jewels. These ornaments were used to indicate the rank of the wearer, and this use has continued to be made of them in the East down to the present day. In Europe, bracelets and armlets were worn both by the classical nations and barbarians from the earliest times. The Gauls wore them; and the Sabines, as early as the foundation of Rome, had ponderous golden armlets on the left arm. The same was the case with the Samians about the same period. It does not appear that armlets were worn by men during the historical period of Greece, but ladies wore both armlets and bracelets of the most various materials and forms. Both generally passed round the arm several times, and the form of bracelet now most in fashion has been accurately copied from those twisted spirals described by Homer in the eighteenth book of the *Iliad*. Many examples of this kind of bracelet, as represented on painted vases, will be found in Sir William Hamilton's work. We are indebted to the Greeks even for the idea of giving to these spiral bracelets the form of a snake, the best models of our present goldsmiths being exact copies of antique bracelets. The goddesses of the Greeks, like the blessed Virgin in Roman Catholic countries, were represented as attired in the style of ladies of the highest rank; and the celebrated marble statue of Aphrodite, preserved at Florence, exhibits traces of a metallic armlet. Amongst the Romans, armlets were frequently conferred upon soldiers for deeds of valor, of which an instance is mentioned by Livy (x. 44). Roman ladies wore bracelets, not only for ornament, but also for the purpose of containing amulets, which were supposed to effect miraculous cures. On this principle it is said that the Emperor Nero wore on his right arm the skin of a serpent, inclosed in a golden armilla. But at Rome, also, it was chiefly as an indication of rank or wealth that these ornaments were worn.

BRACKETS.—In artillery, the cheeks or sides of ordnance-carriages. Carriages termed "bracket-trail," in contradistinction to the "block-trail" pattern, have been introduced into the English service; all the new field- and some of the siege-carriages have been made of this pattern.

BRACKET-TRAIL.—The body of the *bracket-trail carriage* consisted of two brackets, connected together by three transoms, the trail thus formed being termed a *bracket-trail*. The length of the transoms varied according to the nature of the gun, and there were two sets of trunnion-holes.

BRACONNIERE.—In antiquity, a mail armor, of the shape of a petticoat, which was attached to the cuirass, and reached from the hips to the middle of the thigh, and sometimes below the knee. Also written *Bragonnière*.

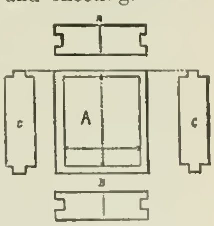
BRAKE.—A contrivance to stop motion by friction, applied mainly to wheels and hoisting apparatus. Originally it was a flexible iron band so placed that it might be drawn tightly around most of the outer surface of the revolving wheel, the friction gradually slackening the motion. In carriages curved blocks of wood were used, and pressed against the tire by a lever worked with the hand or the foot. Modern invention has given us systems of brakes that may be instantly applied to every wheel in a train of cars. For the Creamer brake, once somewhat in favor, a powerful spiral spring was the power applied. This spring was coiled in a drum through which a shaft passes, and was set free by the brakeman, or all the brakes on a train could be set free by one act of the engineer. The Westinghouse air-brake is now very generally used in America. Each carriage has beneath its floor a cylinder and piston which may be operated by compressed air; the piston acts on suitable levers and rods to set the brakes against the wheels, the brakes being also connected with the ordinary braking mechanism at the platform of the cars. Compressed air is conveyed to the cylinders by tubes leading from a reservoir at the locomotive, and this reservoir is filled by a special engine which is independent of the ordinary motive mechanism. The special engine acts automatically, starting when the pressure of air in the reservoir is below a fixed standard, and stopping when the pressure reaches another fixed standard. The engine-driver communicates the compressed air to the cylinders by the simple act of turning a valve-handle through one fourth of a circumference; the brakes are instantly "set" with great force throughout the train. A different system uses a vacuum, and the pistons beneath the cars are acted on by atmospheric pressure, when the cylinders are in communication with the vacuous reservoir. The Westinghouse and the other air-brakes serve to place the train very fully under the control of the engine-driver; permitting the stoppage of trains from high speed in a very short space. See *Pneumatic Gun-carriage*.

BRAN.—The material obtained from the outer covering or husk of grain during the process of grinding, and which is separated from the finer flour before the latter is made into bread. It is generally met with in commerce in thin scaly yellowish-brown particles, with sharp edges, and its composition in 100 parts is as follows:

Water	13.1
Albumen (coagulated)	19.3
Oil	4.7
Husk, with a little starch	55.6
Ash or saline matter	7.3
	100.0

Bread made of flour containing bran is known as *brown bread*. The main uses to which bran is put are in the feeding of horses and stock, and in clearing and brightening goods during the processes of dyeing. In the practice of medicine, bran is employed as a warm poultice in abdominal inflammation, spasms, etc., and an infusion is used as an emollient foot-bath. It is also used internally in catarrhal affections.

BRANCH GALLERIES WITH DUTCH CASES.—These galleries are of the same dimensions as small branches. The frames are made of thick plank, and are placed in the branch galleries touching each other, serving both as frames and sheeting. Each case consists of four pieces; the stanchions have a tenon at each end, fitting into notches cut in the cap and ground sills to receive them. When the gallery is an ascending or descending one, the ends of the stanchions may be cut obliquely, in order that their sides may always be vertical; or the ordinary cases may be set so as to be perpendicular to the gallery floor. For the purpose of limiting the explosive effects of mines upon the branches leading to them, and at the same time enabling the miner, acting on the defense, to push forward and open a new branch towards the crater, a portion of a branch leading towards the mine is made of heavy frames of the foregoing construction. The timber recommended for the purpose is oak, and the pieces of each frame are 12 inches wide and 4 inches thick. The portion of this strong framework, at the extremity, is solidly filled in with pieces of 4-inch scantling, from 6 to 10 feet in length. For a branch 28 inches high and 24 inches wide seven



Elevation, A. and pieces of frame of Dutch Case.

horizontal layers will be required, each layer consisting of 6 pieces. The center piece of each layer may have a rope handle at its end to allow of its being drawn out readily. Filled in this way and having earth well packed between the pieces, branches of this description will not be damaged by the explosion of mines of from 6 to 10 feet line of least resistance even when the mines are within 4½ to 6 feet of the branch. From their chief object these branches are termed by the French *rameaux de combat*. See *Gallery*.

BRAND.—The old Anglo-Saxon term for burnished swords of all descriptions.

BRANDING.—A mode of punishment practiced in England for various offenses. It was effected by the application of a hot iron, the end of which had the form which it was desired should be left imprinted on the skin. But branding by such means has long ceased, and now it is practically confined to the case of desertion from the army; the branding or marking being not done by a hot iron, but with ink or other similar preparation. By the Mutiny Act of 1858 it is enacted as follows: "On the first and on every subsequent conviction for desertion, the Court-Martial, in addition to any other punishment, may order the offender to be marked on the left side, two inches below the armpit, with the letter D, such letter not to be less than an inch long, and to be marked upon the skin with some ink or gunpowder, or other preparation, so as to be visible and conspicuous, and not liable to be obliterated." Formerly branding was employed in the case of all *clergiable* offenses by burning on the hand; and, with a view still further to repress theft and petty larceny, it was enacted that such offenders as were allowed the benefit of clergy should be "*burnt in the most visible part of the left cheek, nearest the nose.*" This additional severity, however, not having the desired deterrent effect, but the reverse, was repealed by an Act which nevertheless provided for offenders being burnt on the hand as formerly. The latter punishment, however, was entirely abolished by an Act passed in 1822. Brawling in church was made an offense punishable by having one of the ears cut off, or, the offender having no ears, by branding with the letter F on the cheek.

BRANDSCHWAERMER.—A small rocket which contains a bullet. It is fired out of a gun, and used for the purpose of setting fire to straw-thatched buildings.

BRAQUEMARD.—A comparatively short weapon of the sixteenth century. It held a place midway between a sword and a dagger, had a straight flat wide blade, very sharp at either edge, and pointed. It had on the hilt a cross-guard that curved on both sides towards the point of the weapon.

BRAQUEMART.—1. A short sword of Italian origin, used in the fifteenth century, and very much like the *anelace*. 2. In antiquity, a two-edged broad-sword. Also written *Jacquemart*. See *Braquemard*.

BRASS.—An alloy of copper and zinc, largely used for ordnance purposes, certain parts of machinery, and other ornamental and useful articles. Technically the term *brass* is extended so as to include compounds of copper and tin, as in *brass-ordnance*, the *brasses* or bearings of machinery, etc.; but such alloys of copper and tin, though styled *hard brass*, are more strictly varieties of bronze, and the present notice will be confined to the alloys of copper and zinc, or *yellow* brass. In ancient history, Biblical and profane, frequent allusions are made to the employment of brass in the construction of musical instruments, vessels, implements, ornaments, and even gates; but as no mention is made of its mode of manufacture, or even of its composition, it is doubtful if the brass of the ancients was composed of copper and zinc. In the manufacture of brass on the large scale, two parts by weight of copper to one part of zinc are used, the zinc being one half the weight of the copper; but alloys are made for particular purposes with less or greater proportions of zinc. Thus, where a material of more than ordinary tenacity is required, the zinc is reduced to one fourth the weight of the copper; and where an alloy of a hard and brittle nature, possessing little resisting power, is wished for, the zinc is increased to an amount equal with the copper, or greater. In the manufacture of brass either of two processes may be followed. The direct method is to fuse the zinc in a crucible, and gradually add the copper in pieces. But this process is attended with disadvantage, owing to the volatile and oxidizable nature of zinc. The indirect method of forming brass is that which is generally followed in England and elsewhere, and consists in heating in crucibles or pots a mixture of calamine (carbonate of zinc, $ZnOCO_2$), charcoal, and thin pieces of scrap or grain copper. The calamine is generally first calcined or roasted, so as to expel any traces of sulphur, then mixed with one fourth of its weight of charcoal, and this mixture introduced into the crucible, after which the metallic copper is diffused through the mixture by being beaten in with hammers or mallets. The proportions employed are 3 parts of the mixture of calamine and charcoal to 2 parts of copper; and when introduced into a furnace, and subjected for 5 to 24 hours to the action of a white heat, the charcoal reduces the calamine and separates the zinc, which, combining with the copper, forms 3 parts of brass, containing about 2 of copper to 1 of zinc. For ordinary purposes brass is first cast into plates of about 100 pounds weight, and ¼ to ½ inch thick, which can be readily broken up, remelted, and cast in a mold of any desirable shape or size. The crude casting so obtained is generally screwed to a turning-lathe, and turned and bored into the required form with iron tools.

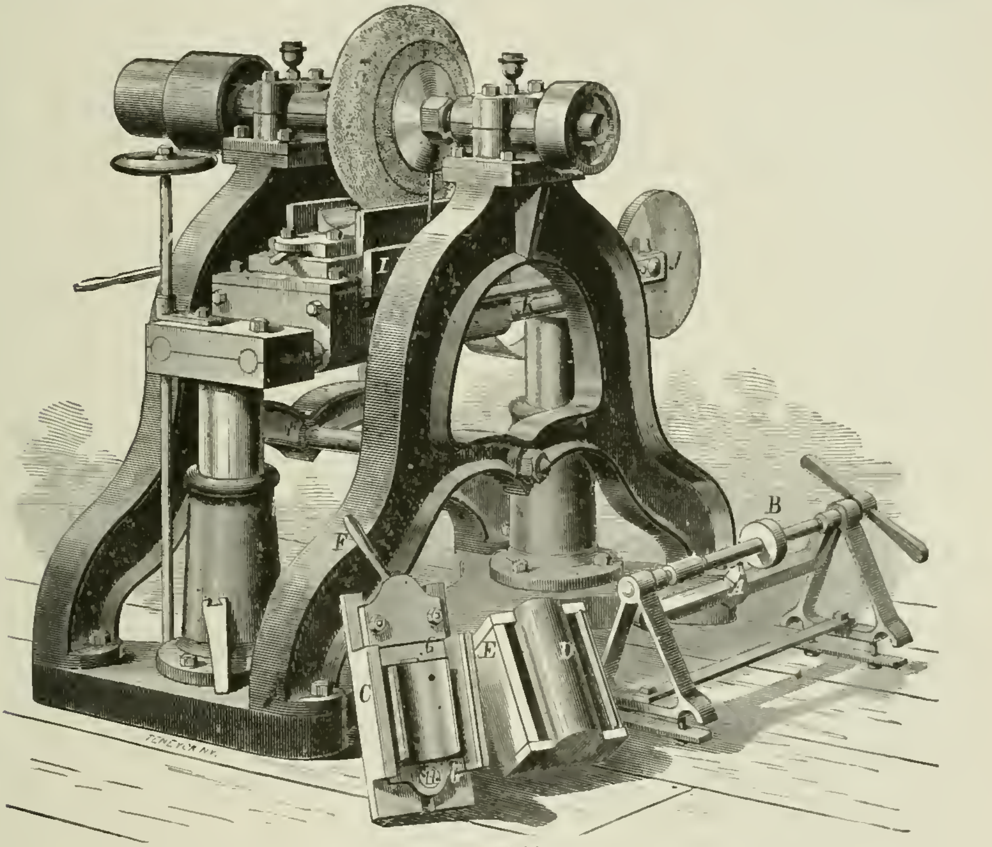
BRASSARDS—BRASSARTS.—The name of the pieces which, in plate-armor, protected the upper part of the arms, and united the shoulder and elbow pieces. *Brachiale* was the ancient name for brassards. When the front of the arm only was shielded, the pieces were called demi-brassards. Brassards or armlets, made of cloth, and worn on the arm, are now used as a badge of recognition by the *personnel* and all members of the military and international ambulances in time of war. The color of the cloth is white, with a red cross woven on it, which is the emblem of the Society for the Help of the Sick and Wounded. The armlets are issued on the commencement of hostilities by the Central Committee of that Society, and duly stamped and numbered, so as to prevent fraud. The term *brassar* is also applied to a piece of defensive armor for the arm.

BRASSET.—A casque or head-piece of armor much worn in ancient times.

BRASS-FITTING MACHINE.—The use of brasses entirely unfitted and rough from the sand results in great wear of material and of the brasses, in hot brasses and the accidents entailed thereby, in an immense consumption of oil, and in such excessive friction as greatly to increase the power necessary to draw the train. The ordinary method of fitting brasses is by the use of the lathe and file, and the work requires the labor of a skilled mechanic.

The machine represented in the drawing has not only superseded the above-named tools for the purpose, in all well-equipped arsenals, but has also rendered the accurate fitting of brasses a cheap process, requiring no particular experience or skill. The principal feature of the apparatus is found in the emery-wheels, which are originally turned and then kept true by a patented diamond tool, the latter being so arranged that it is impossible to turn by it anything except the geometrically correct circle to which the master-mechanic sets it. Wheels of 20 inches diameter are used; and though they should be worn down to the flange, it is claimed that they will still grind the full diameter desired, while a speed of from 1080 to 1800 revolutions is all that is required.

The diamond tool, A, is shown in its frame, in the engraving, detached from the apparatus proper. The tool, it will be observed, swings on a center in its frame, and can be adjusted to any arc. Once set, it can only turn the prescribed arc with accuracy. In order to avoid the necessity of the foreman having to set the tool, a gauge is also furnished. This consists of a spindle adjustable with a nut in such a way that its two points rest in the centers on which the diamond tool revolves. It is only necessary for the disk, B, turned accurately to the diameter of the bearing, to be prepared, and this the apprentice can place on the spindle, adjust the latter, and screw down the diamond tool until it touches the periphery of the disk. A nut is then fastened on the diamond tool, and the frame is lifted on the ways beneath the wheel, when the moving of the handle turns the face of the wheel to the exact circle desired.



Brass-fitting Machine.

To adjust the brass in the chuck, C, it is first set on the axle, D. The chuck is then placed on frame, E, in such a way that the V's fit. Handle F then moves a cam that clamps the brass between the jaws, G, one set of which swing on a pivot at H. The brass is thus adjusted in such a manner that, despite the imperfections in molding, it is ground accurately with the least removal of metal. The chuck, C, fits into planed guides on the table, I, and is thus brought in exact line with the motion of the wheel. The crank, J, serves to move the table to and fro on the rods, K, and the table also rises and falls on planed ways, being pressed up by springs. The hand-wheel gives vertical adjustment to the whole bed by means of a chain beneath it. There is a pulley by which a suction-fan, to remove dust, etc., may be driven. The machine is claimed to be capable of fitting from 150 to 500 brasses per day. See *Emery-grinder*.

BRATTICE—BRETTICE.—A vertical wall of separation in a mining-shaft which permits ascending and descending currents to traverse the respective compartments, or permits one to be an up-cast or downcast shaft, and the other a hoisting shaft.

BRAVI.—Those individuals in Italy, but especially in Venice, who undertook to perform any dangerous deeds for money. It is now employed chiefly to designate hired assassins. The Italians also gave the name of *Bravi* to those fanatics in the Turkish army who, after maddening themselves by opium, rushed upon the ranks of the enemy, and so met death.

BRAY.—A tower or block-house in the outworks of a fortification before the port.

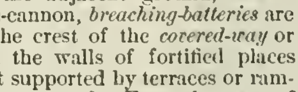
BRAYETTE.—That part of the armor which covered the abdomen. It was composed of steel plates, and ended in the tassets.

BRAZING.—The laboratory process of uniting together two pieces of brass, two pieces of copper, or one of each, by means of a hard solder partaking more or less of the composition and properties of ordinary *brass*. The edges or parts of metal to be joined are first filed bright, so as to be thoroughly clean, then there is strewed over the gap or crevice a mixture of the solder and borax. The solder employed varies in composition according to the kind of work, and may be rendered more fusible by the addition of a larger amount of zinc, but the general proportions are (1) 16 copper, 16 zinc, and 1 tin; (2) 12 brass, 4 zinc, and 3 tin; or (3) 18 brass, 3 zinc, and 2 tin. When the whole has been fused together, it is allowed to cool, and is then filed down to a coarse powder, in which state it is used. The borax is employed to form a glaze over the brightened surfaces, and thus prevent the oxidation of the metal, which would seriously interfere with brazing, and even stop the operation. An outward coating or layer of charcoal is likewise serviceable in the exclusion of the air during the brazing of large pieces of metal. Where a very high heat is required in the process, a little powdered glass is mixed with the borax. The mixture of solder and borax may be applied dry, but it is better to moisten it with water and to lay it on the filed surfaces with a spoon. The whole is then gently heated, when the water evaporates and leaves a crust of borax and solder. The work may now be strongly heated before the blow-pipe, or over a clear fire, and at a bright red heat the solder fuses and the zinc begins to burn with a pale blue flame. At this stage the solder *flushes* or becomes liquid enough to permeate the joint or crevice; but should it be tardy in acting thus, several slight taps will insure the proper result. The whole is now cooled, and, towards the close, the articles may be introduced into cold water for more rapid reduction in temperature. Pieces of metal which have undergone the process of brazing are so firmly united that they may be rolled and re-rolled without the parts yielding.

BREACH-BATTERIES.—Exposed revetments of masonry may be breached by heavy smooth-bore guns, at ranges from 400 to 600 yards, and batteries thrown up in such cases are in all respects like those for enfilading or counter-battering. When the revetments are covered from distant fire by an earthen mask, the breach-batteries must be placed on the borders of the ditch, either on the glacis or on the terre-pleins of the defenses, at points where no obstruction will intervene to prevent the fire of the guns from being directed at a point of the wall to be opened low enough to form a breach which shall be practicable to the ascent of an assaulting column. The results of the recent seiges of Forts Pulaski and Wagner are conclusive upon the question of the vulnerability of the best masonry to rifled projectiles at long ranges. The former work was breached with 30-pounder rifles at about 1700 yards, and General Gillmore, in his report, expresses the opinion that the best-constructed brick revetments can be breached with satisfactory rapidity at ranges of 2500 yards. The range of the batteries of 8- and 10-inch Parrott guns against Fort Sumter was from 3500 to over 4000 yards, from which every vulnerable part of this work that could be reached from the batteries was laid in ruins. The effect of these projectiles fired with long ranges under great angles of elevation, upon scarps covered by earthen masks placed some distance in advance of the scarps, cannot fail to be productive of much damage wherever the projectile attains the scarp, although, from the uncertainty of the fire on a hidden object, breaching under such circumstances will seldom be resorted to owing to the length of time and expenditure of ammunition that would necessarily be required to make a practicable breach in the work. These batteries must be sunk when placed on the borders of the ditches, the level chosen for the platforms being such as to subserve the object in view. The embrasures in these cases are usually cut out of the parapet, as an ordinary trench has generally to be first established as a preparatory step to commencing the battery. The forms and dimensions adopted for other sunken batteries will apply to these cases, with such modifications as may be demanded by the site of the battery, the field of fire, and the position of the point to be attained by the fire.

When a breach-battery is established either on the glacis or upon the terre-plein of a work, its guns will generally be exposed both on their flank and rear to the fire of dangerous commanding points, from which it will be necessary to cover them by traverses. The number of traverses and their position will depend upon the command and position of the dangerous points. To cover from the flank fire, if the command of the dangerous point is considerable, like that of a cavalier within the enceinte of the besieged, it may be necessary to place a traverse between every two guns, or even between each gun. The traverses used in such cases receive a thickness of fourteen feet, or seven gabions, like those for covering an ordinary trench from an enfilading fire; their length will depend upon the relative positions of the dangerous point and the exterior point of the battery to be covered; their height is usually not greater than the traverses for the ordinary trenches that serve only as communications. When the reverse of the battery is exposed it will generally arise from the salient position of some comparatively distant point, from which a slant fire may be brought to bear on this part of the battery; in which case it will generally be easy to cover the part exposed by running out, from the reverse of the battery, an end of trench, to form a wing traverse that shall intersect the lines of fire of the dangerous point upon every part exposed. The guns of breach-batteries should be so placed that the direction of their fire may be as nearly perpendicular as practicable to the line of wall to be breached; and where these lines are oblique to each other, the obliquity should not exceed 45°, otherwise the effect of the shot will be greatly diminished and the operation retarded. Besides the breach-batteries, it may be necessary to place counter-batteries on the glacis. Their object will be to counter-batter and silence the artillery of those portions of the defenses which can be brought to bear on the breach-batteries, or on the passages of the ditches. These counter-batteries will usually be so placed as to fire along the ditches of the defenses. Their arrangement, in all respects, will be the same as that of the breach-batteries. See *Batteries*.

BREACHING.—Escalade being ordinarily very difficult, particularly when the besieged are aware of the intention of the besiegers, the latter are generally compelled to destroy a portion of the face of the work to obtain an entrance. Such an opening is called a *breach;* and to effect it with artillery, particularly in a well-constructed work, where no part of the scarp-wall is visible from the adjacent ground, within effective range of siege-cannon, *breaching-batteries* are established either on the crest of the *covered-way* or on the *glacis*. When the walls of fortified places were very high and not supported by terraces or ramparts, stone projectiles were used. From the want of sufficient hardness in these projectiles, the besiegers were forced to commence battering at the top of the wall where the least resistance was offered, and gradually to lower the shot until the breach reached the wrecks already formed at the base of the wall. When the style of fortification was changed, this operation became very laborious, the ascent was very steep, and the breach was often impracticable. This method was abandoned and mining substituted. Iron projectiles superseded stone, and then a more rapid mode of effecting a practicable breach was suggested and confirmed by experience. Vauban recommended increasing the size of the hole first formed, by continually firing at its sides until the wall should fall; but the ball was found to glance into it and injure but slightly the untouched portion of the revetment. The best mode, however, as found by experiment, is to cut the wall up into detached parts, by making one horizontal and several vertical fissures, and *battering* each part down separately, as indicated in the drawing. The easiest manner of making the cut is to direct the shots upon the same line, and thus form a series of holes, somewhat greater than a diameter apart, and then to fire a second series of shots, directed at the several intervals between the first, and so on, until an opening is made completely through the wall.



The first cut is made horizontally, and finished, which will be known by the earth falling through it; the vertical cuts are then made, there being one at each end of the intended breach. These cuts are commenced at the horizontal cut, and raised until the wall, isolated from its supports, sinks, overturns, and breaks into pieces, which become covered by falling earth. If the earth be sustained by its tenacity, loaded shells are fired into it, which, acting like small mines, cause it to fall, and make the breach *practicable*, or of easy ascent. If the portion of the wall between the vertical cuts should not be overthrown by the pressure of the earth behind, it must be detached by a few volleys of solid shot, fired at its center. This will speedily bring it down in a mass. The moment the wall is down and the parapet destroyed, the breach will be as perfect and the slope as easy of ascent as it can be made by the fire of the batteries. It is important to determine the height of the horizontal cut above the bottom of the ditch, for, if this height be not properly chosen, the breach may be difficult if not impracticable. If too high, the ramp composed of the débris will be intercepted by a portion of the wall; if too low, the opening will be masked by the débris and the formation of the cut impeded. The most suitable height is nearly equal to the thickness of the wall where the cut is established. The thickness, where not known, can be deduced from the dimensions necessary to be given to the wall, to resist the pressure of the earth of the rampart and parapet. The time necessary to make a breach depends on the size of the breach to be made, the material of the scarp, the number of guns, etc. For a breach of 20 to 30 yards in length, at 40 yards from the battery, 1500 shot of large caliber will be required; but when the battery is at a greater distance, a greater number of projectiles will be necessary on account of the diminished accuracy and penetration. Thus, at 500 or 600 yards 9000 to 10,000 may be needed. See *Effects of Projectiles, Penetration*, and *Projectiles*.

BREACH-KNIFE.—A weapon used as late as the eighteenth century. It was especially common in Austria and in other parts of Germany, but in reality it was nothing but a *scythe-knife*.

BREACH OF ARREST.—A crime usually punishable with cashiering. The Articles of War provide that officers charged with crime shall be arrested and confined in their barracks, quarters, or tents, and deprived of their swords by the Commanding Officer. And any officer who leaves his confinement before he is set at liberty by his Commanding Officer shall be dismissed from the service.

BREAD.—In camps and in barracks of any size in England the bread for the army is baked on the spot by bakers of the Supply Sub-department of Control Organization. Though perhaps a little rough in its manufacture, the article supplied is made from the best ingredients, and is genuine and wholesome. On a march, the Control Bakeries supply bread at the several halting-places. In smaller barracks, bread has to be obtained by contract, but the most vigorous supervision is exercised to secure proper quality. Formerly army-bread was notoriously bad. A contractor would sometimes send in a tender so low, in order to obtain the contract, that he could not possibly make good bread at a profit; and then he relied on small fees paid him by the soldiers as a means of obtaining better. This discreditable state of things was ascertained by a Committee of Inquiry some years ago; it was found that the average of army bread was not equal in quality to that of work-house bread. Steps were forthwith taken to remedy the evil; experiments were made to determine whether troops could bake their own bread in the field, and the result was the adoption of the present system of army baking. With the improvement of the bread a visible amelioration in the health of the soldiers has taken place. In the United States army the troops do the baking both in barracks and in the field.

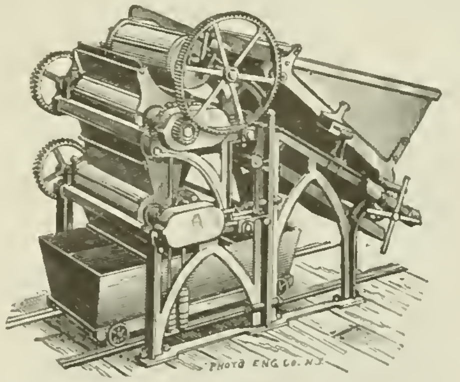
BREAD AND WATER.—The diet of prisoners and parties under charge of the guard. An authorized military punishment.

BREAK.—1. A change from the general direction of the *curtain* of a fortification near its extremity, in the construction with orillons and retired flanks. 2. A commutator or apparatus to interrupt or change the direction of electric currents.

BREAKER.—A cup-shaped covering, usually made of lead, which serves to break a tube of glass or plaster of Paris at the proper time for igniting the charge in fuses of certain construction. See *Prussian Fuse*.

BREAKING-DIAMETER.—The diameter of a piece at the instant of rupture may be called its "breaking-diameter." This would remain the same for the tangential strain; but if we consider the transverse strain only, this diameter increases with the length of stave. For a certain length of stave under pressure, say two or three calibers, the breaking-diameter due to the transverse strain would be the same as the breaking-diameter for the tangential. In this case there would be a tendency to rupture both tangentially and transversely, and the resistance of the metal would be called fully into play in both directions. For greater length of staves the breaking-diameter due to transverse strain would be greater than that due to the tangential, and the piece would rupture tangentially before reaching its transverse "breaking-diameter," and therefore the transverse resistance would not be called fully into play. For shorter staves the reverse would be the case.

BREAKING-DOWN MACHINE.—The powder, having been incorporated, is taken from the mills in open tubs and placed in small magazines, where it is allowed to remain for a day, in order to give the viewer time to examine the quality of the cake, and to compare the production of one mill with that of another, for it is found that that part of the charge which has been subjected to the last few revolutions of the runners is generally a little drier than the rest; therefore allowing the whole to remain exposed for a short time tends to equalize the moisture, from two to three per cent of which greatly assists the operation of pressing. The incorporated powder, in the condition of soft cake, has now to be broken up into pieces of a uniform size, so that the spaces between



Breaking-down Machine.

the plates in the press-box (hereafter described) may be equally filled and the powder subjected to the same amount of pressure over its whole surface. Reducing the mill-cake to meal of a uniform size also assists in mixing any portions that may be more dense than others, due to their having been under the runners and receiving the full effect of the incorporating operation up to the last.

The breaking down of the mill-cake is effected by the breaking-down machine, which consists of two gun-metal side frames, supporting two pairs of gun-metal rollers, the one pair being immediately under the other. These rollers are 7¼ inches in diameter, and have a total length for operating upon the cake of 2 feet 6 inches. The surfaces of the upper pair have grooves of 1.05 inch pitch, cut longitudinally upon them to a depth of ¼ inch. These rollers work at a speed of twenty-five revolutions per minute, and motion is imparted to them by means of a main driving-shaft and spur-gearing connected with the motive power. The back roller of each pair works in a sliding bearing, and is pressed forward to its opposite roller and kept up to its work by means of weighted levers. This is a safety arrangement, and is provided in order to admit of the rollers opening to allow any large quantity of the cake, a hard lump, or any foreign substance, to pass freely through them, thus preventing injury to the machinery, and possibly an explosion. There is also a scraper attached to each pair of rollers for removing from them as they revolve any powder that may adhere to their surfaces.

To prevent the dust spreading about the building when the machine is at work, the rollers are inclosed in sheet copper and gun-metal casings; these also act as spouts, and guide the meal into the boxes placed underneath the machine for its reception.

The working of the machine may be described as follows: The incorporated mill-cake is brought from the magazines, and placed in a wooden hopper that holds about 700 lbs. Underneath the open side of this hopper works an endless band of strong canvas, having strips of leather stitched across it at 4 inches apart. This band passes over two drums, the upper one being driven from the gearing of the machine, so that when in operation this band revolves, and carries a portion of the mill-cake with it from the hopper, and discharges it over the upper drum between the first and uppermost pair of rollers. After being crushed and passing through these, it falls into the second pair immediately underneath, where it is further crushed or broken up into pieces of the required size. From these it falls into the spout, and is conveyed to the boxes placed underneath for its reception.

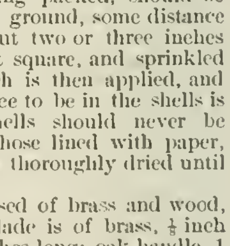
When the hopper has been filled with mill-cake, the attendant retires to a place of safety, and then sets the machine in motion. After working for about half an hour—which is sufficient time to break down an entire charge of 700 lbs.—he, from his place of retreat, stops the machine, and, after waiting for a few minutes, enters the house, empties the boxes, and removes the powder before refilling the hopper. The meal, as it is taken from the boxes, is conveyed in tubs, and placed in other small magazines, from whence it is taken as required to the press-house for the purpose of undergoing the next process. All these dangerous operations are carried on in separate buildings, well removed from each other; and, as a matter of precaution, the machine is entirely constructed of gun-metal and wood, excepting the shafts, which are of wrought-iron encased in copper. See *Gunpowder*.

BREAKING GROUND.—In military operations, the first excavation of the earth to form intrenchments, as at the commencement of a siege. It is applied also to the striking of tents, and quitting the ground on which troops have been encamped.

BREAKING ON THE WHEEL.—A very barbarous mode of inflicting the punishment of death, formerly in use in France and Germany, where the criminal was placed on a carriage-wheel, with his arms and legs extended along the spokes, and the wheel being turned round, the executioner fractured his limbs by successive blows with an iron bar, which were repeated till death ensued. There was considerable variety in the mode in which this punishment was inflicted, at different times and in different places. By way of terminating sooner the sufferings of the victim, the executioner was sometimes permitted to deal two or three severe blows on the chest or stomach, known as *coups de grâce;* and occasionally, in France at least, the sentence contained a provision that the criminal was to be strangled after the first or second blow. Mercy of this kind was, however, not always allowed to be shown to the victims of the wheel; when Patkul, the envoy of Peter the Great, was put to death on the wheel by order of Charles XII. of Sweden, it is said that the officer in command of the guard was cashiered by the Swedish king in consequence of having allowed the head to be struck off before life was extinct in the mangled limbs. The punishment of the wheel was abolished in France at the Revolution; in Germany it has been occasionally inflicted during the present century, on persons convicted of treason and parricide.

BREAKING UP AMMUNITION.—In breaking up small-arm ammunition, the tables should be arranged against the sides of the room, and in front of them, on the floor, boards one foot wide are secured on edge, so as to leave a space of three feet between them and the tables, inside of which the workmen stand and the scrap paper is thrown. By these means the center of the floor remains clear, and should be kept wet. Each workman should be provided with small wooden boxes or copper pans, one for powder, one for caps, and one for bullets. The tables should be kept as clean as possible, counter-brushes being provided for that purpose. A square copper box, with screw top and a capacity of about 100 pounds of powder, is placed at one side of the room; into this the men empty the powder obtained; a large copper funnel, 18 inches wide at the top, is used to prevent the powder from spilling on the floor. When the box is full, it is carried to the magazine on a hand-barrow, the contents packed in barrels and piled up. One man is detailed to collect, count, and pack the caps, sweep the floor, and keep it wet, etc. Powder should be removed from the tables and emptied in the box very frequently. No more cartridges than are actually needed to work on, one box for each man, should be allowed in the shop at a time. A space on the table three feet wide is allotted to each man, a partition one foot high being the dividing-line. The box containing cartridges is placed on the table to the left; about 20 packages are opened at a time, the cartridges emptied into one end of the bullet-pan, which should be set directly in front of the workman. Take a cartridge with the thumb and forefinger of the right hand, remove the bullet and drop it in its pan, and empty the powder in the receptacle intended for it. Burnside's metallic, Maynard's metallic, Smith's foil and rubber, Gallagher's paper and wrapped metal, and all other metallic cartridges are broken up by the hand-breaker, unless it be a cartridge otherwise provided for. Brass shells, before being packed, should be taken to an open place on the ground, some distance from the buildings, spread out two or three inches deep in a space about 10 feet square, and sprinkled with a little powder; a match is then applied, and any powder which may chance to be in the shells is thus burned out. Brass shells should never be soaked in water, especially those lined with paper, for they are never afterwards thoroughly dried until melted in the crucible.

The *hand-breaker* is composed of brass and wood, and is 7 inches long. The blade is of brass, $\frac{1}{8}$ inch thick, 1 inch wide, and 4 inches long; oak handle, 1 inch square, edges rounded, and 5 inches long. A slot 2 inches long is sawed into one end of the handle; into this slot 2 inches of the blade is inserted; two holes are bored through for rivets that firmly secure the blade in its place. A hole of the size to suit the ball of the cartridge to be broken up is drilled through the projecting end of the blade about $\frac{1}{2}$ inch from the end. In using this instrument hold it firmly in the left hand over the bullet-pan; insert the bullet-end of the cartridge in the hole and pry upward; the bullet drops out and the powder is disposed of as previously directed.



When breaking up shell-cartridges with a wad between the bullet and powder, the bullet should be removed from two or three hundred before working at the powder. A small brass pick and scraper combined is used, with the edges and point sharpened, with which the wad is removed and the interior of the shell scraped.

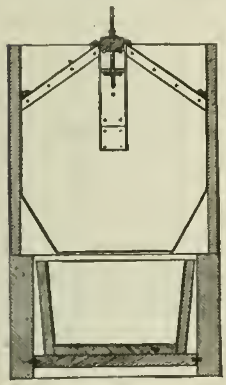
The following-described machine, consisting of a *box*, *drawer-frame*, *drawer*, *magazine*, *firing-bolt*, and *firing-bolt bar*, is used for breaking up metallic cartridges:

The *box*, 2 feet wide, 4 feet long, and 3 feet deep, is lined with ½-inch boiler-iron. The lining should taper inward toward the bottom from both ends and sides, forming an oblong-shaped funnel, the bottom opening being about 1 foot wide by 3 feet long. At each end of the box inside, screwed on about the center, is an upright cleat, oak, 2½ inches wide by 2 inches thick; it extends from the bottom edge of the box to within 1 inch of the top. A rabbet 1 inch deep and 1½ inch long is cut out of the front of the cleat at the top; the shoulder thus formed serves as a rest for the magazine, and the top of the cleat answers the same purpose for the firing-bolt bar. The cleats are covered with the same kind of iron as the box is lined with. The iron should be cut in strips and screwed on. The front is covered first, the covering extending from the bottom of the rabbet to the lower end of the cleat. Cover the sides the same way, except that the strips extend to the top edge of the box; this will form a receptacle at the top end of the cleat, and serve as a slide for the plate. The small plate is then riveted to the large one, the rivet-holes coming between the large ones. The holes for the cartridges are then drilled through the small plate, and should be a little larger in diameter than the cartridge, but not so large as to destroy the shoulder or bearing for the flange of the shell.

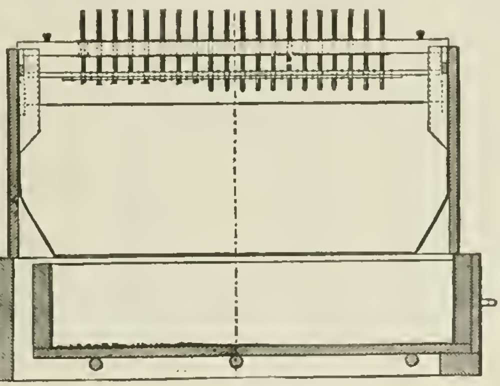
The *firing-bolt bar* is made of wood, white oak, 2½ inches wide, 2 inches thick, and about 2 inches longer than the magazine. Holes for the bolts should be bored so that they will come directly opposite the holes in the magazine. Care must be taken to have this correct. Iron washers are screwed on the under and upper sides of the bar over each hole, to prevent their wearing by the action of the bolts. (No. 2 washers for bolts are just the size.)

Firing-bolts are made of ½-inch round bar-steel. They are 7 inches long; about 6 inches are turned off in the lathe to fit the holes in the bar; the other inch forms a head, which is the firing-end of the bolt. About 2 inches from the other end a hole is drilled through to receive a pin. The bolts are then put through the holes in the bar and pinned. This gives them a play of 4 inches. The firing-end of the bolt-head end should be hard, and the striking end soft.

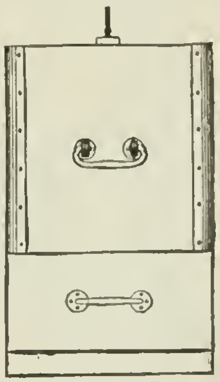
The *frame* upon which the box rests is made of 2-inch pine, and is 1 foot high (the box is designed to set inside this). Two sides and one end are closed. Cleats are nailed inside, about 1 inch from the top



Section.



Section.



End View.

magazine and bolt-bar that will prevent them from shifting out of place. The cover of the box is made of the same kind of iron as the lining, and in two parts, forming front and back covers; they rest on cleats screwed on the ends of the box inside, and extend from the top edge of the perpendicular cleat to the front and back of the box, the lower end being about 10 inches below the top edge of the box; the covers thus rest on an angle of about 45°. The top edges of the cover should fit snugly against the sides of the firing-bolt bar, but not so as to prevent its being taken out and replaced freely. The back cover may be made fast, as it is not necessary to remove it; the front one, however, has to be removed at every discharge of the magazine, and for this reason has to be a little loose. Oak strips 1 × 2 inches are screwed on the tops of the covers at the lower and upper edges to prevent the iron from warping; the upper one on the front cover also serves for a handle.

The *magazine* is made of iron, has two plates riveted together, the large or upper plate to be ½ inch thick, 2½ inches wide, and long enough to fit in the box lengthwise, its end resting on the rabbet cut in the cleat, the small or lower plate to be ¼ inch thick and 1½ inch wide. Twenty holes, ¾ inch in diameter, are drilled through the large plate on a center line from end to end. They should be one inch apart and commence about 6 inches from the ends of the edge. Upon these the box rests. The other end of the frame is left open for the drawer.

The *drawer* should be made of $\frac{3}{16}$-inch boiler-iron and water-tight, and so constructed that when it is in its place under the box the top edges, both ends, and sides will extend as far as possible inside the lower edges of the lining of the box, thus preventing the bullets and pieces of copper from dropping behind the drawer.

Three men are required to operate the machine: one to load, one to fire, and one to eject the fired shells from the magazine. An open box 5 feet long (an ordinary musket-box answers the purpose) is set at the end of the machine, to the right, across the opening, and about 9 inches from each end. Toward the center a flat strip of ¼-inch bar-iron is attached, the ends projecting about 10 inches over each side of the box. These are to rest the magazine on when being charged, and when the shells are being ejected. They should be far enough apart to catch the magazine about 2 inches from the ends, so as not to interfere with the holes. Three or four magazines are required; also two small hammers, punch, etc.

Everything is now ready to commence operations. The loader (operator No. 1) seats himself at the front of the shell-box, takes a handful of cartridges in his right hand and charges the magazine; passes it to the firing-operator (No. 2), who places it on its rest in the firing-box; takes the firing-bolt bar (which may be placed on the back cover when not in use), sets it on the magazine so that the heads of the bolts drop into the holes; throws down the front cover, that has in the mean time been lifted, takes the hammer from a convenient place and strikes each bolt one smart blow in quick succession. He then lifts the cover and rests it against the front of the box inside, takes out the firing-bolt bar, and lays it on the back cover; takes out the magazine and passes it to operator No. 3, who sits directly opposite the loader. No. 3 then examines it, to ascertain if any of the cartridges have missed fire; if so, he takes them out and places them in a small box for that purpose, turns the magazine, small holes up, punches the remaining shells out into the open box, and then slides it across to No. 1; the other operations in the mean time continuing. The drawer may contain water or not. There is less smoke, however, when water is used, as the ignited powder is sooner extinguished. When about 5000 cartridges have been exploded, the bullets are removed from the drawer and washed, and whatever pieces of copper are among them picked out. Three men can break 10,000 in 8 hours. All primed cartridges, rim and center fire, can be broken up by turns the bag wrong side out and cleans it. The strapped shot are taken to the door of the laboratory, where the shot which still require cleaning are separated from their sabots and immersed in the tub of water; after standing some time they are washed and cleaned; the others remain strapped. The serviceable, reparable, and unserviceable cartridge-bags are separated from each other; the last are immersed in water and used for rags; the pieces of twine are tied up in bundles; the shells are put aside to be unloaded and cleaned in a like manner.

The breaking up of fixed ammunition requires many precautions, and should never be done in the magazine, but as much as possible in the open air. Never have but little powder and a few cartridges in the shop at one time.

Canisters.—Turn up the slit ends of the canisters by means of a small chisel; take off the cover and pull out the balls and sawdust into a box by means of a hook; take out the bottom plate and straighten the cylinder with a mallet on an anvil.

Port-fires—Split the paper; take out the composition, and pulverize it by rolling for two hours. It may be made to burn more or less quickly by adding mealed powder or sulphur.

End View.

the above process. The firing-ends of the bolts should be pointed for the latter. Of course the larger the cartridge the more necessary it would be to have the box larger and stronger.

An improvement is contemplated for the purpose of preventing the pieces of copper from dropping among the bullets. This improvement would necessitate the enlargement of the box, and instead of one drawer three would be required. The box would be partitioned off lengthwise into three compartments, the top edges of the two center partitions to be about 2 inches below the points of the bullets as they hang in the magazine. The pieces of copper always strike the cover and fly towards the front and back of the box, and would consequently drop down the side compartments, the bullets dropping down the center one.

Breaking up Unserviceable Stores.

Fixed Ammunition for Cannon.—1 paulin; 1 box; 2 barrels; 1 knife; 2 brushes; 1 punch; 1 hammer; 1 scraper; tow; a tub half full of water, to clean the balls; stools.

One man holds the cartridge over the box, while another cuts the twine near the knot, takes off the strapped shot, brushes it, and stands it on the paulin on its sabot; the first man pours the good powder into a barrel, the caked powder into another,

Unloading Spherical Case and Shells—Bormann Fuse.

The fixtures consist of tables, protector, water-boxes, drill-presses, drill-braces, drills, etc., as shown in the drawing. The *table* on which the protector is placed is about 3 feet high, and is necessarily heavy, the top being 6 feet long, 2½ feet wide, and 3 or 4 inches thick. The *protector* is composed of iron; the bottom and top plates have bent ends, 4½ feet long and 12 inches wide. Near each end, leaving space enough between them and the bent ends for the admission of the end plates, two 1-inch bolt-holes are drilled; and 18 inches from each of these, towards the center, corresponding-sized holes are drilled, making eight bolt-holes in each plate. These holes are extended through the table. The bottom plate is laid on the table, bent ends up, and its front edge flush with the front edge of the table; the end plates (18 inches long, 12 inches high) are set edgewise on the bottom plate against the bent ends; the top plate is laid on, bent ends downward. The bolts are passed through from beneath the table, thread-end upward, the nuts are adjusted and screwed down to keep the plates together, and the middle or partition-plates are fixed in position. Two partition-plates are necessary in consequence of the front plate having a hole in the center, a partition being placed each side of the hole. Three compartments are thus formed in the protector, but the middle one being useless is filled in with a block of wood. A hole 1¼ inch in diameter is drilled through the top plate over the center of each of the working compartments for the entrance of the drills. The lower edge of the front plate rests on wooden supports; the upper edge projects about 1 inch above the surface of the top plate; it is held in position by four braces, one lower and one upper, at each end. The outer ends of the braces are bolted to the corners of the plate, and the inner ends are clamped together by means of a screw-bolt and nut; the bolt passing through the table and bolt-braces. The *water-boxes* are made strong, about 7 inches deep. They are 16 inches long and 10 inches wide, outside measurement. The ends are 4 or 5 inches thick. Having the box in the same position in its compartment every time it is replaced is essential; and for this purpose strips are made fast to the bottom plate to serve as guides for the box to slide between. The *drill-presses* are fixed to the table at each end of the protector and have sliding arms. The thread-end of the perpendicular bar passes through the table, and by means of a nut is firmly fastened. The sliding arms have set-screws, one to make it fast to the perpendicular bar, and one at the other end to press on the drill-brace. The press is so attached to the table that the points of the set-screws are in a direct line above the drill-holes in the top plate. The *drill-braces* are iron; one end having a socket for the drill, and the other end is countersunk for the point of the set-screw. The *drills* are steel and are about 10 inches long; the small ones are ¼ inch wide at the drill-end and pointed; the large ones are 1¼ inch wide and ⅛ inch thick at the drill-end. The blade has a round blunt point projecting from its center, and is straight each side of the point, with slightly beveled opposite edges. A smaller table is used in the operation of removing the iron plugs, the water-box for this purpose being screwed fast to the surface of the table; a small iron wrench with two teeth to fit the holes in the plug is used. A bench-vise should be attached to this table. A small hand-punch, monkey-wrench, heavy riveting-hammer, and a small ½-inch cold-chisel are necessary tools. A tub or iron pot to hold water, in which to place the shells after having the plugs removed, is used. When *case-shot* are being unloaded, a heavy hand-hammer is needed to strike the shell on the outside so as to crack the casing inside.

All *spherical projectiles* can be unloaded by the above plain; and if the following directions are carefully followed explosions cannot possibly occur:

First. Fix the shell firmly by means of a wooden wedge in the water-box. Be sure that the quantity of water in the box is sufficient to cover the fuse; then slide the box in its compartment in the protector so that the location of the fuse is in a direct line beneath the drill-hole.

Second. Place the point of the small drill on the center of the fuse, and set the other end into the socket of the brace, lower the brace on the drill to avoid displacing the point; bore the hole through the fuse and iron plug, if a Bormann fuse; remove the drill and work the water into the powder with a brass wire; set the large drill in the same manner as the small one, and remove enough of the fuse to uncover the entire surface of the iron plug; remove the shell from the box and put in the water-tub.

Third. The shell is taken from the tub by another operator, who secures it in the fixed water-box, and with the cold-chisel cuts through one side of the fuse; he then strikes one end of the ring at the cut and drives it in toward the center of the iron plug; this will detach it from the thread of the shell. With the toothed wrench extract the iron plug. The shell is replaced in the tub from whence it is subsequently taken and the powder removed.

Three men can unload from 100 to 115 shells, Bormann fuse, in 8 hours; and four men can unload the same number of case in the same time. See *Ammunition.*

BREAST-HEIGHT.—The *interior slope* in fortification, sometimes called the *breast-height*, is the part against which the assailed naturally lean in the act of firing. It has usually a slope of three perpendicular to one base. This is a result of experience, being the most convenient one for a soldier leaning forward to fire over the parapet. See *Field-fortification.*

BREAST-LINE.—The rope connecting the pontons of a military bridge in a straight direction.

BREASTPLATE.—In ancient armor, a plate of iron, steel, or other metal, so fastened as to protect the chest or front of the wearer. The back-plate, in like manner, was worn to protect him from attack from behind. In modern European armies, almost the only representative of the breastplate is the front half of the *cuirass*, worn by the *cuirassiers* in certain foreign States, and by the Household Cavalry (Life-guards and Horse-guards) in England.

BREASTWORK.—In fortification, a hastily constructed earthwork; not so high as to need a *banquette* for the defenders to stand upon, but sufficient to afford shelter when they are standing on the level of the ground and firing over the crest. The dry ditch or trench from which the earth has been taken to form the breastwork affords an additional defense. A breastwork is midway between a *parapet* and an *epaulement* in size and importance.

BREECH.—The mass of solid metal behind the bottom of the bore of a gun extending to the rear of the base-ring. The *base* of the *breech* is a frustum of a cone or spherical segment in rear of the breech. The excess of metal at the breech is to enable the gun to withstand the shock occasioned by the explosion of the gunpowder. Small-arms have also an increase of metal at the breech. See *Cannon.*

BREECH-BLOCK.—A movable piece at the breech of a breech-loading gun, which is withdrawn for the insertion of a cartridge and closed before firing, to receive the impact of the recoil. This is the great problem of the breech-loading gun. There are at least one hundred species of breech-blocks, classified according to the mode of moving the block relatively to the barrel, or the barrel to the block. See *Springfield Rifle.*

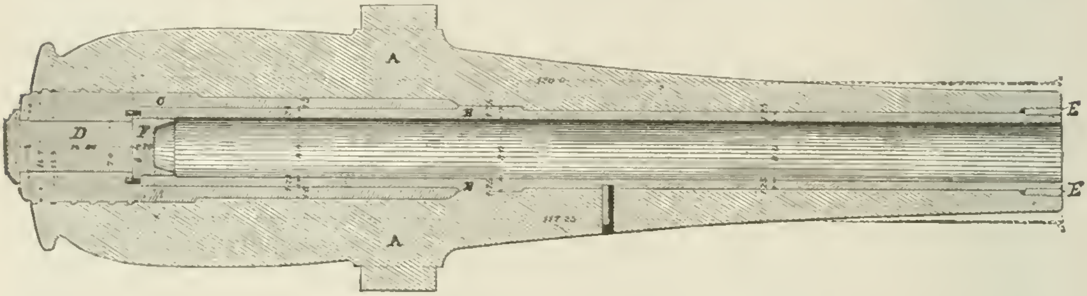
BREECH-CASING.—A component part of most machine-guns. It is usually a hollow cylinder, extending from the front end of the lock-cylinder to the rear portion of the frame. Flanges on its sides rest on and are screwed to the frame; near the rear end is a partition called the *diaphragm-plate*, which divides the cylinder into two parts and separates the lock-cylinder and revolving-gear. In the forward division are placed the cams for forcing forward and drawing back the locks. See *Gatling Gun.*

BREECHING.—1. The breeching of a gun or carronade is a strong rope by which the recoil of the gun is checked at such a point that the muzzle is brought wholly within the port-hole, where the seamen can sponge and reload it. 2. Harness adapted to the wheel-horses of gun-carriages, *near* and *off*, for the purpose of facilitating the stopping of a gun in motion. Breechings, near and off, are strengthened with a lay of leather.

BREECH-INSERTION.—The difficulties of securing perfect weldings in coiled wrought-iron tubes have led in some instances, in the history of the employment of linings constructed in the manner and on the present plan of muzzle-insertion, to the development of grave accidents in service, tubes being blown out and the muzzles torn off, all from defective welds. The most satisfactory and secure remedy for this imperfection undoubtedly lies in the provision of a shoulder on the tube (in front of the charge), the gun being recessed for its reception. An otherwise strong and durable construction, embodying this feature, must accordingly have an important advantage over the present plan of muzzle-insertion, in which no adequate provision can be made to prevent the destructive effects of a tube being blown out. This accident is likely to occur if all the welds are not sound—a perfection which it is impossible, from the nature of the construction of coiled wrought-iron tubes, to uniformly and certainly attain. The uniform success of our present guns is in a measure due to excellence of work and care in manufacture; but it is evident that a decided improvement attains, if we can have perfect immunity from the defect alluded to above, while securing a perfectly reliable construction in other respects. A consideration of the question has led to the construction of a gun on an improved plan of *breech-insertion*, having, it is believed, more durability than the present plan of muzzle insertion, and securing the other advantages above quoted. The imperfections of breech-insertion, in alterations heretofore made, have arisen from the mode of construction employed, to wit, separating the breech-plug from the strengthening tube shrunk on the inner tube or lining; also from the solid construction of the plug. The throwing of the entire longitudinal strain on to a breech-plug by depriving it of all assistance from the longitudinal strength of the enveloping jacket produces a line of longitudinal weakness at the junction of the tube and plug, where the longitudinal and tangential strains, under fire, combine to produce rupture. This fact is well established by experiments in England.

In the construction under consideration, the jacket is shrunk on the tube, and extends continuously with tion of the general features of the construction. It will be seen that the jacket (1.5 inch thick) extends to the front a distance of about 40 inches from the bottom of the bore, thus reinforcing the inner tube (1.25 inch thick) to a greater length than in the case of the B tubes of the present constructions, and consequently fully strengthening it over all the space where the pressures are at all dangerous.

The drawing represents a 10-inch Rodman smoothbore gun, with its lining inserted from the breech. The gun is essentially composed of three parts: (A) the original 10-inch smooth-bore, bored out to receive the lining; (B) a lining tube of coiled wrought-iron (welded), with a jacket (C) of wrought-iron with its hollow base or plug extending to the face of the breech; and the breech-plug (D). The bottom of the tube is closed by a wrought-iron base or cup (F). A shoulder, on the inner tube, prevents the tube from being thrust forward by the effects of repeated firings, or blown out from imperfect coil-welds. A screw collar, E, at the muzzle, gives additional security, resisting any forward thrust of the metal of the tube in front of the shoulders. It will be seen that the play between the cast-iron body and tube and jacket does not exceed .01 inch for a length of 88 inches from the muzzle, nor .004 inch from this point to the commencement of the screw-thread. The greatest diameter of the tube and jacket is 14.7 inches. The diameter of the tube from the muzzle-collar to the first shoulder is 10.5 inches. The maximum thickness of the tube and jacket is therefore 3.35 inches, and the minimum thickness of the tube is



Ten-inch Rodman Smooth-bore Gun, with Lining inserted from the Breech.

a uniform thickness from a point a short distance in front of the trunnions to the breech-cup of the inner tube, and thence, with an increased thickness, clear through the breech to its face. This unbroken continuity, and the yielding, hollow, wrought-iron breech thus formed, give all the strength desirable at the bottom of the bore to resist the combined longitudinal and tangential strains at that point; and the breech portion of the jacket, by its hollow form being permitted to expand in unison with the tube when the latter is distended under the strains of discharge, avoids the danger of rupture liable to result from the rigidity of a solid, unyielding breech. A square-cut plus thread cut on the breech portion of the jacket corresponds with a minus thread cut on the cast-iron, each to form the union of one with the other. The area of cross-section of the wrought-iron is such as to have its strength proportional to the strength of the thread on the cast-iron, reference being had to the relative strength of the two metals. The breech portion of the jacket, it will be observed, is so constructed as to overlap the bottom of the tube and the exterior portion of its cup. The longitudinal thrust consequently is, at this point, principally borne by the wrought-iron jacket, and not by the secondary breech-plug, simply used to close the hollow part of the former. By these arrangements, the greatest resistance is secured to longitudinal strains. A breech-plug of cast-iron completes the construction of the breech. The inner tube, *shouldered* and closed at the bottom in the usual manner, completes the mention 1.25 inches. The rifling of the gun consists of 15 lands and grooves, each of equal width.

Width of lands and grooves.....	.8377	inch
Depth of grooves...............	.075	"

Twist uniform, one turn in 40 feet. The rifling stops at a point 10 inches from the bottom of the bore, and the diameter of the unrifled portion of the bore is equal to that of the rifled portion across lands. The old vent is closed (the copper bushing having been removed) by a wrought-iron screw-plug, and 2.75 inches nearer the muzzle a new one was bored, parallel to the vertical plane through the axis of the bore, and distant therefrom 2.50 inches. The axis of the vent enters the bore at 3.5 inches from the bottom. See *Converted Guns* and *Ordnance*.

BREECH-LOADER.—A fire-arm that receives its load at the breech. Breech-loading small-arms of the new system may be divided into *simple breech-loaders* and *repeaters*. The principal parts peculiar to the former are: 1st. The *movable breech-block*, by which the chamber is opened and closed; 2d. The *breech-frame* upon which the breech-block is mounted and united to the barrel; 3d. The *chamber*, with its counterbored recess, to receive the rim of the cartridge; 4th. The *firing-pin*, which transmits the blow of the hammer to the priming of the cartridge; 5th. The *extractor*, by which the empty case is removed after firing. In addition to these parts, the repeater has a magazine attatched to it to contain a certain number of cartridges, which are successively brought into the chamber by peculiar mechanism.

The foregoing-named parts may be said to be essential to all breech-loading arms in which the metallic cartridge is used; the different ways in which they are combined mark the different systems now in vogue. These combinations have reference chiefly to the modes of operating and locking the breech-block. The breech-block may be operated in two ways: 1st, by *rotation*, where it swings on a hinge; 2d, by *sliding*, where it moves in grooves. The former mode is generally to be preferred, as the rubbing surfaces are small, and the power is applied at the end of a lever: in the same way that it is easier to close a hinged door than a sliding one. In the rotating breech-block, the position of the hinge has an important influence on the facility of operating the block, inserting the cartridge and withdrawing the empty shell, and the most suitable position is deemed to be in front of the center of the block. In this case the motion of opening and closing the block is natural and easy, the cartridge is pushed into its place by the block, and a very simple retractor serves to withdraw the empty shell after firing. The Allin (Springfield altered), Berdan, Millbank, Lamson, Remington, Laidley, and others belong to this class. In the last two named the hinge is below, in the others it is above, the axis of the block. In the Snider (Enfield altered), Warner, Maynard, and others the hinge is on the side of the block; while in the Peabody, Roberts, and others it is in rear. In the Prussian Needle, the French Chassepot, Root, Meigs, Sharp, and other guns the breech-block is made to slide. There is another system, however, in which the breech is opened by moving the barrel. This system is better adapted to sporting than to military guns.

The following are among the more important conditions to be fulfilled in constructing a breech-loading gun of the new system, viz.: 1st. The strength and union of the parts should be such as not only to resist repeated discharges, but the bursting of a cartridge-case, which sometimes occurs from defective material or workmanship. 2d. The locking of the breech-block should not only be secure, but all the parts by which it is effected should work freely—without sticking. 3d. The parts should be so arranged that the hammer cannot strike the firing-pin until the breech-block is properly locked. 4th. The piece should not be carried loaded with the hammer resting on the firing-pin. 5th. Avoid, if possible, the necessity of bringing the hammer to the full cock in order to unlock the breech-block. 6th. The working parts should, as far as possible, be covered from dust and water. 7th. The extractor should be so arranged as to require no cuts or openings in that part of the chamber which surrounds the body of the cartridge-case.

In relation to muskets and fowling-pieces, Mr. Greener, of Birmingham, who has written much on the subject, disputes the usefulness of breech-loading; he denies that it is more safe, more accurate, or more forcible than muzzle-loading; while certain advantages which it may possess are, he thinks, counterbalanced by the greater cost of the weapon. The relative merits of breech- and muzzle-loading

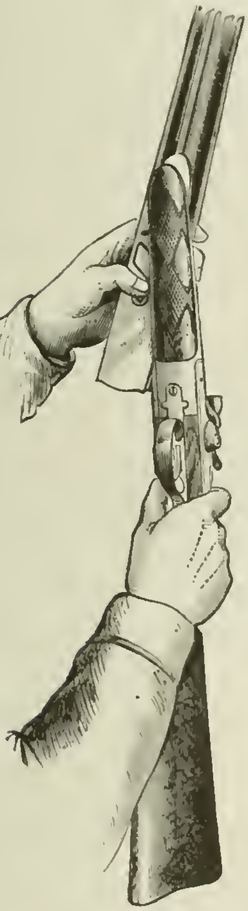


Fig. 1.

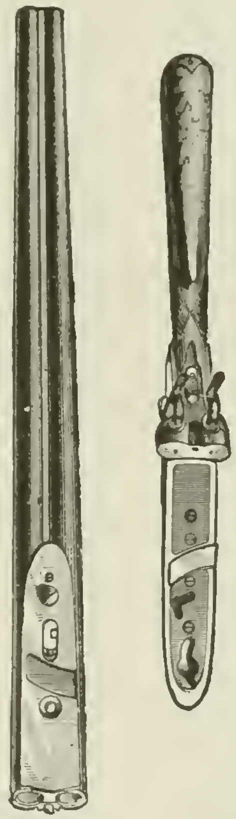

Fig. 2.

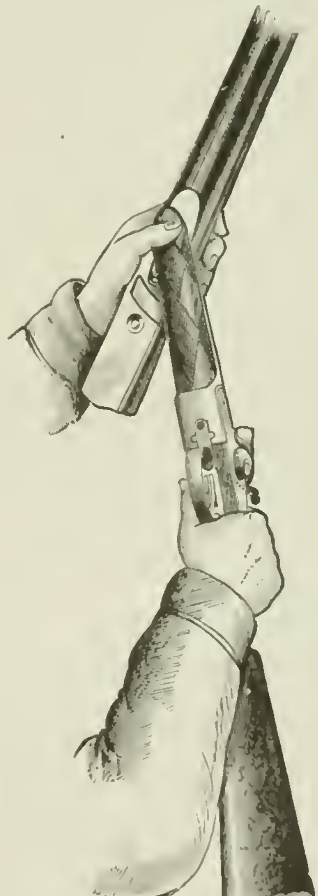

Fig. 3.

fowling-pieces were tested in 1859–60 by various trials, under the management of the editor of *The Field*, and resulted in favor of the breech-loaders. The demand for the latter has, in consequence, enormously increased. The drawing illustrates the Fox breech-loading gun, one of the most satisfactory arms yet invented. Fig. 1 shows the position when about to detach the barrels; Fig. 3, when about to attach the barrels; and Fig. 2 shows the stock and barrel apart. The various breech-actions and distinguishing features are noticed in various parts of the Encyclopedia, in connection with certain kinds of ordnance and small-arms expressly constructed on the breech-loading principle.

The introduction of breech-loaders in the United States dates properly from 1865, from which date muzzle-loading arms were no longer manufactured at the Springfield Armory. A short time before the late Rebellion, the Government tested a number of breech-loading guns, such as the Burnside, Cosmopolitan, Gallagher, Joslyn, Merrill, Maynard, Smith, Lindner, and Sharp. None of these are now used except the Sharp gun, which has been adapted to the metallic cartridge. During the war the Spencer rifle was much used by the U. S. cavalry; it has a magazine in the butt of the stock, holding 7 cartridges that are admitted one at a time by the movement of the trigger-guard used as a lever. The shell of an exploded cartridge is expelled by the same movement. It may be used also as a single breech-loader, but the magazine must first be shut off. The Henry gun (not to be mistaken for the Martini-Henry) has the magazine under the barrel. By movements of the lever 17 metallic cases or cartridges can be brought into the chamber in succession. This gun, like the Spencer, can be used as a single breech-loader by shutting off the magazine. It has been changed, however, by O. F. Winchester, and is now termed the Winchester gun. Among other magazine-guns may be mentioned the Ball, Fogarty, and Gardner guns. The well-known Remington gun is a single breech-loader, and has an iron receiver that is screwed to the breech of the barrel, in which the breech-block and lock are to be found. It uses metallic-cased cartridges, and has been adopted by the Governments of Egypt, Spain, and several other countries.

In 1866 the Secretary of War called a Board of Officers, General Hancock acting as President, to report the form and caliber which should be adopted for breech-loading muskets and carbines, and the method of converting muskets from muzzle-loading to breech-loading arms. After an examination of 22 different breech-loading muskets and 17 different breech-loading carbines, the Board reported the best caliber for muskets to be .45 of an inch, the best charge of powder from 65 to 70 grains, and the best weight of ball from 480 to 500 grains. In 1869, a Board of Officers, presided over by General Schofield, was called to meet at St. Louis to select the six best patterns of muskets for infantry and carbines for cavalry. After examining a great number of different breech-loaders, they reported that the only guns suitable for military service were those of the Remington, Springfield, and Sharp systems. These guns were tried accordingly until 1872, when, in compliance with an Act of Congress, a Board of Officers, General A. H. Terry as President, was appointed to meet in New York and Springfield, "to recommend a breech-loading system for muskets and carbines to be adopted for the military service, which system, when so adopted, shall be the only one to be used by the Ordnance Department in the manufacture of muskets and carbines for the military service." After testing over 100 breech-loading guns, the Board recommended (May, 1873) that the Springfield breech-loading system be adopted for military service, and this report being approved, that system is now used by the Government for the U. S. army and militia. This breech-loader has a receiver screwed to the breech of the barrel. The shell of the exploded cartridge is ejected by a combined cam and spring through a motion of the hinge in the opening of the breech-block. The firing-pin goes through the breech-block in an inclined direction from the nose of the hammer at the side to the center of the rear of the chamber, where it strikes the head of the cartridge, exploding the fulminate when its rear end is struck by the hammer. See *Springfield Rifle*.

BREECH-LOADING CANNON.—Intimately connected with the subject of the different systems of rifling is that of the advantages and disadvantages of breech-loading for cannon. There are strong arguments both for and against the use of the breech-loaders—some nations using them altogether, and others not at all. A principal advantage claimed for the breech-loading guns is rapidity of fire, but the result does not seem to have been attained in the large guns. The gun can be loaded when run out, without exposing the men, and worked in a smaller space by limiting the recoil. Any ignited substance left in the bore can be seen and removed; and there is no danger of the projectile not being home. The breech-loading gun may be made longer, occasionally, which is a great advantage where there is difficulty in burning the powder; moreover, a large powder-chamber may be employed for the better burning of the charge. The advantages of the compressive system of rifling may be claimed in favor of breech-loading.

The breech-loading cannon is heavier and more expensive than one loading at the muzzle. There are more parts to be damaged. In heavy guns, far from there being any increased facility in loading, considerable force has to be used and applied in a very careful way to the breech-closing apparatus, or the gun may be rendered temporarily unserviceable. Escape of gas, fouling or corrosion of the closing surfaces, and injury to the delicate Broadwell ring or gas-check, are among the contingencies that may arise in service. Much additional labor and outlay are required to construct and fit up interchangeable hollow screws or sliding stoppers; to fit and renew gas-checks; to apply opening and closing apparatus, which cannot be very simple, but which must be very strong and durable; to fabricate, keep clean, and maintain all these parts on such a plan that two or three men can manipulate them with ease and certainty, and without unusual risk of disaster from excitement or carelessness; and of such size and strength that the heaviest projectiles can be fired, with large charges of powder.

The adoption of a system of working and loading guns by hydraulic power must have an important bearing upon the question of the comparative merits of breech- and muzzle-loaders. One of the chief advantages claimed for breech-loaders is that any length of bore can be adopted without increasing the difficulty of loading, and that therefore a higher duty can be obtained from the powder. It has also been urged that a gun of larger size can be worked in a given turret as a breech-loader. Successful mechanical methods for loading at the muzzle would seem to negative these advantages. The suppression of windage and the power of placing the vent in the breech-block are important advantages claimed for breech-loaders. The vent is a serious trouble in very heavy guns, from its rapid erosion by the gases of discharge. But it is claimed that the windage can be effectually suppressed in many muzzle-loading systems of rifling and projectiles, and an arrangement has been devised for stopping altogether the passage of gas through the vent, thus removing the difficulty of its erosion. See *Ordnance*.

BREECH MECHANISM.—The mechanism used for opening and closing the breech of a fire-arm and securing it against the escape of the gas. In small-arms this is readily accomplished. The use of the metallic cartridge-case renders any special gas-check unnecessary, as the case itself by being expanded against the walls of the chamber serves the purpose. The various mechanisms used in small-arms have been classified as follows: 1st. Fixed chamber; 2d. Movable chamber. The second class is now obsolete. The fixed-chamber class is subdivided into—1st. Barrel moves; 2d. Breech-block moves. The first class comprises many of the shotguns in use; the second, the best known of military arms. Under this latter class are the following subdivisions: 1st. Sliding block; 2d. Sliding and rotating; 3d. Rotating about an axis. We find excellent guns under each of these classes, which are further subdivided as to the direction of the motions. The Sharp may be taken as typical of the first of these classes, the Hotchkiss magazine-gun of the second, and the Springfield of the third. A similar classification may be made for breech-loading devices in heavy ordnance, but the problem here is not so simple. The pressure is much greater, the masses of metal much larger, and the cartridge must be used without a case to check the gas. Breech-loaders were impossible until the problem of checking the gas had been solved. The inventor of the first successful gas-check was an American, L. W. Broadwell, now residing abroad. The term "Broadwell ring" has been applied to all similar devices. This is a steel ring which fits in a recess reamed out in the rear of the chamber and abutting upon the breech-block. The inside of the ring is so shaped as to be pressed by the gas outward and backward, thus closing both the space outside the ring and between it and the block. Broadwell is also the inventor of a breech mechanism which, with a few modifications, is that used by Krupp for all of his guns. The breech-block slides horizontally through a rectangular slot in rear of the chamber. In the Armstrong breech-loader, the block called the vent-piece is taken out and put in through a rectangular orifice on the top of the gun. It is locked in place by a hollow breech-screw. The French use a breech-screw with the threads cut away in longitudinal rows. The female screw being similarly arranged, a very small rotation enables it to be entirely withdrawn. Among American devices are Thompson's, a breech-block which rolls to the side and opens or closes the bore: Sutcliffe's, a cylindrical block, with its axis parallel to the one hanging on a pin projecting from the front periphery of the hollow screw,—the block is raised and locked by turning the screw, and falls into a recess below when the screw is half turned back: Mann's, in which the gun rotates upward about the trunnions something like a shotgun: and many others.

BREECH-PIECE.—A solid forging of wrought-iron. It is bored, turned, and shrunk on to one end of the barrel. The breech-piece of the larger natures is welded to the coil in front of it.

BREECH-PIN.—A plug screwed into the rear end of a barrel, forming the bottom of the charge-chamber. It is frequently called a *breech-plug* or *breech-screw*. See *Blank*.

BREECH-SCREW.—A screw composed of a body, tenon, and tang, employed to close the bottom of the bore. The screw usually fits into the thread cut in the breech-piece, and is worked forward or backward by the lever and tappet so as to press home or release the vent-piece. It is bored hollow to allow of the charge being passed through in loading the gun; the diameter of the hollow is rather larger than that of the powder-chamber. It is made of steel for 20-pdrs. and lower natures of gun, of wrought-iron or steel for 40-pdrs., and of wrought-iron faced with steel for the 7-inch guns. See *Breech-pin*.

BREECH-SIGHT.—With the exception of mortars, all modern pieces are furnished with two sights, a front one and a rear one. These are situated either on the *line of metal*, or slightly to the right of it in a plane parallel to the plane of fire. The front sight is securely attached to the piece by means of a screw, and for the heavier class of guns is over the axis of the trunnions. The rear sight is on the breech, fitting into a socket attached to the piece with screws, and when the gun is to be discharged is removed from the socket. For the 10- and 15-inch guns the breech-sight is without graduation, and serves merely to give direction to the piece, the elevation being given by means of the *elevating-arc*, or, when practicable, with the quadrant applied in the muzzle.

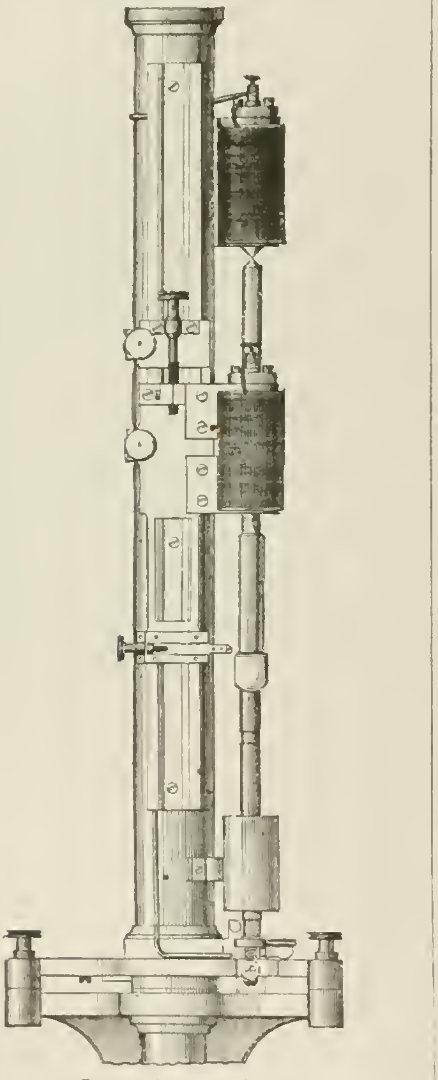
For siege and Parrott guns the breech-sights are graduated to correspond to degrees and parts of degrees of elevation of the axis of the bore, and have a slide to move up or down. This slide has a screw-thread cut on one end of it, upon which works a nut with four short arms; through each of these arms is a small hole for sighting. The screw upon the slide is for the purpose of giving lateral motion, when allowing for drift. Each kind of gun has its particular breech-sight, but, as there are in service many of old or experimental pattern, they should be verified for the particular pieces upon which they are to be used. This is done by directing the piece at some well-defined point at a distance of 1000 yards or more, and on the same horizontal plane with the axis of the trunnions. A straight-edge and spirit-level applied to the face of a trunnion suffice for this operation. Place the slide of the breech-sight at any degree of the graduation, and, sighting through it at the object, give the piece the corresponding elevation. Insert the gunner's quadrant into the bore, and ascertain from it the inclination of the axis of the piece. If the reading on the breech-sight corresponds to that of the quadrant, the former is correct. The line of sight passing through the zero of the breech-sight is parallel to the line of fire.

For 10- and 15-inch guns an *elevating-arc* is used. This consists of a strip of brass attached to the base of the breech parallel to the ratchets. It is graduated into degrees and parts of degrees, and a pointer, attached to the ratchet-post, indicates the elevation or depression of the piece. When the pointer is at zero, the axis of the piece is horizontal. Besides the graduation on the arc, the ranges in yards for the ordinary charges for shot and shell are given. In batteries for garrison and sea-coast defense, where the platforms are fixed, the line of metal may be considered as permanent; but with siege-guns, mounted on traveling-carriages, the wheels are liable to vary in position from unevenness of ground or unequal settling in newly-constructed platforms. This line is constantly changing, and approximates the higher wheel in proportion to the difference of level between the wheels; hence, to secure accuracy of fire, allowance must be made by observing where the shots strike and correcting the aim accordingly. Deviation from this cause is always towards the side of the lower wheel.

BREECH-WRENCH.—A wrench employed in turning out the breech-pin of a fire-arm.

BREGER CHRONOGRAPH.—This apparatus, or a modification of the Le Boulengé chronograph, is intended to measure the interval of time, T, which elapses between the successive ruptures of two electric currents. It is principally employed to determine the velocity of projectiles, in which case two vertical frames are placed in front of the gun, on each of which is stretched the conducting wire of one of the two currents. In traversing the frames the projectile cuts the circuits and causes the chronograph to act. The distance, D, between the frames being known, the mean velocity of the projectile during the time, T, is $V = \frac{D}{T}$. When T is compressed between 0^s.05 and 0^s.15 the conditions are favorable, although the apparatus may be used to measure a shorter time.

The chronograph consists of a vertical column, to which are affixed two electro-magnets; one magnet is actuated by the current of the first frame and supports an armature called the chronometer; the other is actuated by the current of the second frame and supports an armature called the registrar. The chronometer is a long cylindrical brass tube terminating at its upper extremity in a piece of soft iron and bearing at its lower extremity a steel bob. It is surrounded by a zinc or copper cylinder called the recorder. The registrar is of the same weight as the chronometer, and is a tube with soft iron and bob. The cores of the electro-magnets and the soft iron of the armatures terminate in cones slightly rounded at their vertices in order that the armatures when suspended can take a vertical position. When the registrar is set free it strikes a horizontal plate, which turns upon its axis and releases a spring furnished with a square knife, which strikes the recorder and



Breger Chronograph.

leaves an indentation upon it. If the two currents be ruptured simultaneously the indentation is found upon the recorder at a height, h, indicating that since the chronometer commenced to fall the time t has elapsed. $t = \sqrt{\frac{2h}{g}}$. It is evident that t is the time required for the apparatus to operate; it is a systematic retardation inherent in the instrument. A special organ, called the disjunctor, permits the simultaneous rupture of the circuits to be produced, so that the time, t, is always known. A very simple device is resorted to in order to render it constant. If the current of the registrar is not ruptured until after that of the chronometer, and if an interval, T, has elapsed between these ruptures, the time during which the chronometer will fall before receiving the indentation of the knife will simply be augmented by T; and calling H the height of the indentation, we will have

$$t + T = \sqrt{\frac{2H}{g}}.$$

Thus the determination of any interval, T, always comprises two operations: the measurement of the time, t, required for the instrument to operate, and that of the time, $t + T$. The difference of these two measurements gives the time sought. This indirect method of ascertaining the result is the characteristic of the instrument and explains its accuracy. When the rupture of the currents is produced by the projectile, the portion D of the trajectory between the targets is regarded as rectilinear, and the mean velocity, V, is

$$V = \frac{D}{\sqrt{\frac{2(H-h)}{g}}}.$$

A table may be calculated giving the values of V for different values of D and H. If D, h, and H have been accurately measured and the disjunctor has ruptured the currents at precisely the same instant, the velocity, V, will be subject to no error, provided, however, that the time required for the operation of the instrument has remained the same at the time of disjunction and of experiment. The time necessary for the operation of the instrument is composed, first, of that which elapses from the instant the registrar commenced to fall until the blow of the knife is given to the recorder of the chronometer, and this first part will necessarily be the same in two successive operations if the element of the recorder which receives the mark falls in the same vertical line. From the instant that the current is ruptured until the armature is free to fall, a time, θ, elapses which is called the *retardation of demagnetization;* therefore the time, t, includes also the algebraic difference $\theta' - \theta$ of the retardation of demagnetization of the registrar and chronometer; but as both electro-magnets are similarly constructed, as the weights of their armatures and the currents that actuate them are equal, as, in a word, they are in the same magnetic state, the times θ and θ' are sensibly equal. In fact, these times do vary with the mode of rupture, and consequently when a projectile is substituted for the disjunctor, but by the same quantity, as everything remains the same in the two electro-magnetic systems. It will be remarked that it is not necessary that the times θ and θ' should be exactly the same, but only that their difference should remain constant in the successive operations in which the instrument is used. The suspension of the armature is effected in the same manner as with the original instrument. In the instrument supplied to the United States by Mr. Hotchkiss and constructed by Mr. Froment, several details have been improved. 1st. The magnets have been provided with a movable core, worked by a set-screw and counter-screw. This allows a more perfect regulation of the currents than when the rheostat only is used. 2d. The instrument is provided with a spherical spirit-level, which allows to place it vertically without difficulty. 3d. The knife, trigger, and indexes are all provided with set-screws, enabling them to be perfectly and easily adjusted. One of the most important points being the constancy of the currents, Mr. Froment has studied a special modification of the Callot battery for the use of the chronograph. Each battery is actuated by a battery of forty elements, coupled in four series of ten. This battery will work for several months without any perceptible variation. See *Le Boulengé Chronograph.*

BREITHAUPT FUSE.—This fuse, sometimes called the Field-artillery fuse, resembles the Bormann in its general appearance, and is made of a mixture of tin and lead. The body of it is formed like that of the Bormann; but the outside has no screw, and it is placed in the eye of the shell by means of a projection from the bottom, which is threaded, and which screws into a corresponding aperture at the bottom of the eye. The composition is laid in exactly the same kind of a channel, which communicates with the magazine in a somewhat different way from the Bormann fuse. At the top two mortises are placed, in which the prongs of the screw-driver fit when screwing or unscrewing the fuse from the shell. In the center is a socket with the thread of a screw to receive the end of the *pressure-screw*, which is made of iron. The stopper and regulating disk is cast of the same kind of metal as the fuse, and has through its center a cylindrical hole for the passage of the pressure-screw. A small priming-chamber, in the form of a hopper, is placed at the side, one of the lateral projections of which, marked with a red line, serves as an index to regulate it. A small projection on its surface gives a hold to the finger to turn the disk on its axis, in order to bring the index opposite the required point on the scale of the fuse. A piece of pliable leather or skin is pasted on the under surface of this disk, in order to insure contact throughout and preserve the composition from moisture. The composition is pressed into its place by machinery. It is meal-powder for Shrapnel fuses, but ordinary fuse-composition for the fuses of other shells. In the first case the fuse burns 7 seconds; in the second, 14 seconds. The regulating scale is a rondelle of white paper pasted on the outside upper edge of the fuse. It is made like a dial, with strokes, half-strokes, and quarter-strokes, radiating from the center, corresponding to intervals in the combustion equal to 1 second, ½ second, ¼ second, and ⅛ second. The rondelles are cut with a stamp-iron or punch. Care must be taken in pasting the scale on to make the zero of it coincide with the edge of the solid part where the magazine-vent debouches into the composition-channel. The priming consists of a small strand of quick-match, bent double, with the bend fixed in the priming-chamber by means of a paste of meal-powder. The ends are free, so that when the priming is uncapped the ends project outside the little hopper-shaped chamber. The priming-cap is a small circular-sided trapezoid of gold-beater's skin, which is pasted over the priming-chamber by its four edges to protect the priming as well as the fuse-composition from dampness. A rondelle of soft leather is cut out and fitted on the bottom of the fuse around the bottom stem, as a packing to the joint between the shell and fuse. The magazine and vent leading to the fuse-composition are filled with fine powder, and the bottom closed with a thin sheet of lead, kept in its place by four notches; a coat of varnish being given to the outside to keep out moisture.

It is an improvement to engrave the scale upon the metal itself instead of placing it on a strip of paper, which in service is liable to be worn or torn off, or the graduation made illegible. This fuse was invented after the Bormann and Baden fuses had been extensively adopted by different nations, and the great objection to its adoption was the extensive changes required in the *eyes* of the shells already manufactured. This difficulty was obviated, however, by transforming the Baden into the Breithaupt fuse by means of some slight changes which did not affect the form or exterior dimensions, nor its scale or composition-channel. See *Fuse*.

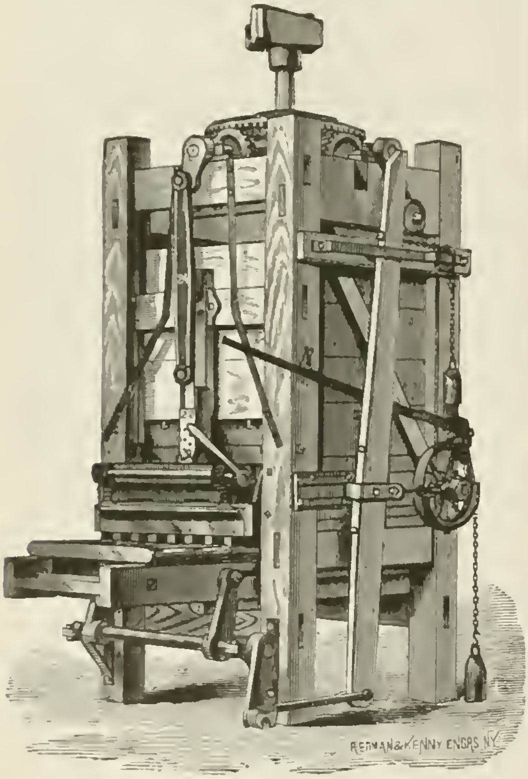
BREVET.—In the British army, a promotion of officers, now strictly limited in its application, but before 1854 a recognized though occasional mode of conferring a large measure of general promotion throughout the army. It took place under various circumstances. If no special cause interfered, a general promotion by brevet used in former times to be made once in about six years; but in more recent years it was limited to very special occasions, as a coronation, the birth of an heir to the throne, the termination of some great war, etc., and was limited to officers who had some particular claim to promotion. The officers so promoted obtained an increase of rank, and in some cases pay, even if they had never served in the field. A brevet was determined on by the Cabinet, and carried out by the Commander-in-Chief. The officers expected it, as one of the implied conditions on entering the service, and it had formed part of the British military system ever since the time of James II.; but it was unsatisfactory, because the flow of promotion caused by it was arbitrary, uncertain, and much liable to abuse. There were brevets, arising out of the various circumstances above indicated, in 1837, 1838, 1841, 1846, 1851, and 1854. On these occasions, Lieutenant-generals, Major-generals, Colonels, Lieutenant-colonels, Majors, and Captains received a promotion of one grade in rank. On one of these occasions, 200 Colonels were at once made Major-generals. The higher the rank the higher the pay, as a general rule; and therefore the cost to the nation is always increased for a time after each brevet. Thus the brevet of 1837 occasioned an annual increase of £11,000; that of 1838, £7000; of 1841, £15,000; of 1846, £21,000, etc.; but it must not be forgotten that death and sales had in the intervals cleared off perhaps an equal number of officers at the higher rates of pay. In 1854 the new Major-generals alone involved an additional charge of £18,000 a year. This description applied before 1854. In that year general brevets were abolished, a fixed establishment of General Officers being substituted. The only brevets now are obtained by service of five years as Lieutenant-colonel (making the officer brevet Colonel without increase of pay); by distinguished service in the field, applicable to Lieutenant-colonels, Majors, and Captains (carrying the substantive pay of the higher rank, except in the case of the Lieutenant-colonel); and by succession, when a death occurs among the establishment of General Officers. In this last case there is no brevet promotion to the rank of Colonel, but the senior Major in the whole army and Marines becomes a brevet Lieutenant-colonel without increase of pay, and the senior Captain a brevet Major with 2*s*. a day extra. Officers become Major-generals, in accordance with their seniority as brevet Colonels, and it will be seen, from the above description, that the brevet rank of Colonel, which is the stepping-stone to Major-general, is obtainable *by service only*.

In the United States army the brevet is a commission giving an officer a nominal rank higher than that for which he has a salary. A great number of these honorary titles were bestowed during and after the Civil War.

BRICHE.—A machine of war used in ancient times to throw stones; now obsolete.

BRICKS.—The earliest examples of this branch of the ceramic art were doubtless the sun-dried bricks of Egypt, Assyria, and Babylonia. Remarkable to say, many of these, which, in a northern climate, the frosts of a single winter would destroy, have been preserved for some 3000 years by the dry, warm atmosphere of those countries. Sun-baked bricks of ancient date are also found in the mud walls of old towns in India. Kiln-baked bricks must have been the products of a later time; but they are found in all the chief ruins of ancient Babylonia, where they were often used to face or bind together walls of sun-dried bricks, and occasionally they were even ornamented with enameled colors. Burnt bricks were employed in the foundations of the Tower of Babel (Gen. xi. 3). These ancient bricks, whether baked by the sun or by fire, were all made of clay mixed with grass or straw. The ancient Greeks, probably owing to their possessing plenty of stone, cared little for building with burned clay; but most of the great ruins in Rome are built of brick, and the Romans appear to have introduced the art into England. Interesting historical information has been obtained from the impressions on Roman and especially on Babylonian bricks. In many instances the Roman bricks found in England have been removed from their original position, and employed in the construction of buildings of later date. The earliest instance in which bricks of the modern or Flemish make occur in England is Little Wenham Hall, in Suffolk, 1260.

Clay suitable for the manufacture of common bricks is an abundant substance, but there is a great difference in the nature and quality of the clays found in various localities. The basis of clay consists of hydrated silicate of alumina, with a varying proportion of other mineral matters, chiefly free silica (sand), iron, lime, magnesia, and potash. Great advantage is derived from digging clay in autumn, and exposing it all winter to the disintegrating action of frost. This is not always attended to, but when neglected the bricks made from it are apt to be unsound,



Brick-making Machine.

and faulty in shape. The next process is that of tempering or mixing the clay into a homogeneous paste, which is sometimes done by the spade, but more commonly in the pug-mill (at least in England), or by crushing between a pair of rollers; often, indeed, both are employed. In making bricks by the old hand process, the shape is given by a mold either entirely of wood, or of wood faced with metal, and without top or bottom. This admits of the clay being pressed into it by a tool called a plane, which is also used to produce an even surface on the upper and lower beds of the brick, by working off the superfluous clay. Sand is used to part the wet clay from the mold and the table on which it rests.

Although hand-made bricks are still very common, yet machinery is now always employed when large quantities are required. Brick-making machines are of two leading kinds; one class of them being constructed to work the clay in a wet plastic state, the other class requiring it to be in a semi-dry condition. Of the two sorts, the wet-clay machines are the simpler, cheaper, and can be worked by less-skilled workmen. On the other hand, the dry-clay machines, which make the bricks by forcing the clay into molds by strong pressure, shorten the process, as no time is required for drying them. The bricks so made, too, are not only of a more perfect shape, but they can be molded into any form, and may even be made highly ornamental at a very slight additional cost.

One of the best-known brick-machines is that which bears the name of the inventor, Martin, and is represented in the drawing. It is automatic in its construction, grinds and tempers its own clay, and is particularly adapted to the working of hard and heavy clay. It does its own molding, and delivers the bricks in front, ready for the carrier to place them on the yard. The molds are delivered by the power of the machine while the press is on; therefore it does not draw up the bricks while delivering, but molds them stiffer than any other machine, and delivers them with good, square corners and well-defined edges. The lever connected with the haul-out is arranged with a movable center, held by a friction-pulley, so that, should any stone or hard substance get into the mold, or the mold be in any way obstructed, the lever simply moves forward, giving time to remove it without stopping the machine, and preventing the breaking of molds or any part of the machinery. Then, by raising the small lever connected with the friction-pulley, the center moves back, and the machine operates as before. The capacity of the steam-power machine is 4000 bricks an hour, and the horse-power 2500, although in many instances it has largely exceeded that number.

The green bricks, after being carefully dried, either in the sun or by artificial heat, are usually baked in a kiln with a suitable arrangement of fires and flues. Kilns are of many forms, and the time required for firing in them varies from 40 to 60 hours for common red and white bricks, while for some fire-bricks 150 hours are necessary. Where kilns are not used, bricks are burned in clamps, the clay requiring to be mixed up, in the process of tempering, with a quantity of ground coal sufficient to burn them. A good test of the character of a clay is obtained by the result of firing. The average contraction in the kiln for prepared clays is 7½ per cent. If a brick contracts much more than this, the clay is too fusible; if less, then it is likely to be of an open porous body, which retains its shape well during the firing process. All brick clays contain iron, and the color of a burned brick almost entirely depends on the amount of it which is present; thus clays containing less than 1 or 1½ per cent of iron change in the kiln to various shades of cream-color and buff, whilst those containing more than 2 per cent range in color from yellowish fawn to dark red. Blue bricks are made from the same clay as the red, by controlling in a peculiar way the supply of air in firing, and by carrying the heat slightly further. It is asserted by some that the red is changed to the black oxide of iron in the process. Fire-bricks are made from clay as free as possible from oxide of iron and alkaline substances, so that there may be no tendency to fuse in the kiln, however high the heat. Fire-clays are abundant in the coal-measures, some of fine quality being found about Newcastle and Glasgow, but the most celebrated is that of Stourbridge, which is exported to all parts of the world.

Mortar composed of lime and sand is the common cement for brickwork. It should be equally and carefully applied; and the bricks wetted, in order that the mortar may adhere more firmly, by being absorbed into their pores. The force with which good mortar is capable of adhering to bricks is very remarkable. It is found to be the greatest in old structures that have been exposed to the continuous action of water. Such bricks are said to be "water-bound" by workmen, and can scarcely be separated without breaking the bricks. A fundamental principle to be rigidly observed in laying all kinds of brick is, that *no two con-*

tiguous perpendicular joints shall fall immediately below each other. The mode of arrangement of the bricks to effect this is called the *bond;* a layer or stratum of bricks is called *a course.* Bricks laid with their lengths in the direction of the course, and their sides to the wall-face, are called *stretchers;* those laid across the line of the course, with their ends forming the wall-face, *headers;* a layer of headers, a *heading course;* of stretchers, a *stretching course.* The two kinds of bond almost exclusively used in England are the English and Flemish bond. English bond consists of alternate stretching and heading courses; Flemish bond, of a stretcher and header laid alternately in each course. English bond is the strongest; Flemish bond, the more ornamental; and they are used accordingly. There are two other kinds of bond occasionally used—*herring* bond and *garden-wall* bond. The former is applied to form the core of thick walls, where Flemish bond is used for the facing. A course of bricks is laid obliquely at an angle of 45° to the face of the wall; then above it another course at the same angle, but inclined in the opposite direction, so that the joints may cross the first. This is considered to add to the strength of Flemish bond, but is objectionable on account of the triangular interstices necessarily left between the oblique bricks and the bricks of the facing. Garden-wall bond is only used for 9-inch walls, and formed by laying three stretchers and one header, and so on in each course. In order to strengthen Flemish bond, bands of hoop-iron are sometimes laid flatwise between the courses. This "hoop-iron bond" has superseded the old practice of using bond-timbers, which were inserted the whole length of the wall. The hoop-iron should be slightly rusted, to secure the complete adhesion of the mortar.

In constructing arches of brickwork much care and skill are required. A wooden centering is always used; and when very rude work only is required, common bricks are laid upon the centering, and the gaping interstices at the upper ends filled with rough brick wedges. For better work each brick has to be properly beveled, according to the curve. When semicircular arches are made, all the bricks require an equal bevel, and therefore bricks molded uniformly to the required angle may be used; but for other curves, and for flat arches, each brick has to be separately shaped by the bricklayer. In order to do this, a drawing of the required arch is made of the full size on a board; the bricks are laid upon this side by side, and shaped to the lines of the drawing; they are then transferred to their corresponding place in the structure. The bricks are first rudely shaped by the *brick-axe*, then finished on the *rubbing-stone*, a piece of rough-grained stone about twenty inches in diameter. In all kinds of brick, the walls should be built up level throughout, in order that the *settlement* may be equal. An unequal settlement may produce a rupture of the wall.

BRICOLE.—An improved kind of traces used by the French in drawing and maneuvering artillery; analogous to the old drag-rope, but having the addition of a leather strap or girdle with a buckle, to which the drag is affixed, and an iron ring and hook at the end to drag by.

BRIDGE.—In gunnery, two pieces of timber which go between the two transoms of a gun-carriage. Not used in the United States service. See *Bridges.*

BRIDGE-CRANE.—Cranes of this type are designed for operation by hand or power. As constructed for general yard-use, a bridge-crane consists of a stationary bridge, supported at each end by a suitable trestle, and provided with a trolley moving transversely on the bridge. The load is carried by a running block suspended from the trolley, and the mechanism for hoisting and traversing is attached to one of the vertical frames or trestles near its foot. Cranes of this construction are built of capacities of from 2 to 12 tons for operation by hand, and of any desired capacity for operation by power. There is another form of bridge-crane, in which one end of the bridge is supported by a building and the outer end by a frame or trestle, so that the frame is available for transferring weights into or out of the building. In some cases a crane of this type is placed between two adjoining buildings, its ends being supported by the adjacent walls of each building; while in other cases the bridge of the crane is carried through the doorway of a building, so that the load can be transferred from a truck or car outside of the building to some point within it. When arranged for operation by hand it is built entirely of iron, and is provided with mechanism substantially identical with that of the jib-crane, to which reference is made for further particulars. The same mechanism is utilized for hoisting and lowering at several speeds, and for causing the trolley to travel upon the bridge. When arranged for operation by power the operating mechanism is located within the building, and driven by power taken from the line shafting. The levers for controlling the several motions are placed upon the wall of the building at any convenient point within, and arranged so that they may be used from either of the several floors. The operating mechanism is substantially identical with that employed in the power traveling-cranes. Cranes of this type are available for yard-uses of all kinds in connection with foundries, machine-shops, quarries, etc. They are particularly available for loading and unloading heavy artillery from cars, and are an excellent substitute for the pillar-crane. As compared with the latter they have the advantage of not requiring any foundation except that necessary to resist the direct pressure due to the load. They may be made to span two or more tracks and are thus available for transferring loads from one car to another, or from a car to a truck or platform. See *Cranes* and *Rotary Bridge-crane.*

BRIDGE-EQUIPAGE.—The United States bridge-equipage is composed of two distinct trains,—the reserve and the advance trains. The former is intended to accompany large bodies of troops in the field, and is provided with the material for the construction of bridges of sufficient capacity to pass large armies with their heaviest trains over rivers of any size and capacity. For these the French ponton is adapted. The advance-guard train is intended for the use of light troops, such as advance-guards, cavalry expeditions, etc. It is organized, both as regards material and carriages, with a view to rapidity of movement. At the same time it is capable of furnishing a bridge which will fulfill all the requirements of troops engaged on such service. For this train the canvas ponton is adapted. See *Bridges.*

BRIDGE-HEADS.—The works planned for the defense of a river will depend on the object to be attained, whether it be simply to prevent the enemy from crossing, or to give the assailed the means of a secure communication with the opposite shore.

The points most favorable to the passage of the enemy are fords; and when the river is not fordable, the points where an elbow is formed, the re-entering being towards the enemy. To guard these weak points, works should be placed in a suitable position to prevent the enemy from approaching the opposite bank; and in the case of a ford, every obstruction should be accumulated on these, and the plan of the works should be so arranged that their fire can be concentrated on the ford; and, if the assailed have cavalry, a free space should be left between the water and the works for the cavalry to act on; the object being to charge the enemy whilst crossing the ford in disorder.

To keep open a free communication with the opposite shore, it will be necessary to throw up works there of sufficient strength to allow the assailed time to effect a safe retreat, should they be attacked by superior forces. As these works serve to cover the bridges in the rear, they are termed *têtes-de-pont*, or *bridge-heads.* The best points to erect a bridge-head are the bends, or elbows of the river, the re-entering being towards the assailed. The reasons for selecting these points are that the bridge-head may be protected by a good flank and cross fire from the opposite shore, which from its shape is most favorable for this purpose; secondly, from the manner in which elbows are formed, the point occupied by the bridge-head will commonly be commanded by the opposite shore, and should the enemy succeed in obtaining possession of the bridge-head, he will have all the disadvantages of a commanded position; thirdly, the elbow is not only unfavorable to the enemy, by preventing him from placing a battery in a position to destroy the bridge, but it also may prevent floating bodies, thrown into the current by the enemy with the same view, either by their shock, or by fire, from coming directly in contact with the bridge, as the chances are that those bodies will strike one or the other shore before reaching the bend.

The plan of a bridge-head should be carefully studied on the ground; and it should, as far as practicable, satisfy the following conditions: 1. Admit of a defense until all the troops have effected a safe passage. 2. Cover the bridge from the enemy's artillery, so that the retreat may not be cut off by the destruction of the bridge. 3. Be suited to the end in view; if, for example, its object is to afford the means to small detachments of making incursions on the opposite shore, a small unimportant work will be all that is required; but if a large corps is to pass, either in retreat or to act offensively, then the works should be arranged with wide intervals, to allow the troops to debouch in mass, and display readily in order of battle. 4. The flanks of the works should rest upon the banks, to prevent their being turned; and, when practicable, they should be protected by flanking arrangements from the opposite shore. 5. A strong interior redoubt should secure the bridge against an attempt on the part of the enemy to obtain possession of it by storming the works.

The practicability of obtaining flanking arrangements from the opposite shore will materially affect the plan of the bridge-head. If the breadth of the river is over one hundred yards, not much reliance can be placed on a flanking arrangement for musketry; and if the breadth is from 600 to 800 yards, it will still admit of a very effective flank fire of artillery, but not greatly beyond this. For an unimportant work, therefore, which can be flanked by musketry from the opposite shore, a redan or a lunette will be a very suitable form; and if the work can only be flanked by cannon, a priest-cap, as shown in Fig. 1, or a redan, with *crotchets*, or flanks, near the extremities of the faces, and perpendicular to them, arranged for musketry, will be a very suitable form. Neither of these works, however, admits of sufficient strength to cover a very important point, whose loss might compromise the safety of an army or the success of a campaign. The best arrangement for this purpose is either a *horn-work*, shown in Fig. 2, or a *simple* or *complex crown*. The horn-work, like the priest-cap, is best adapted to a position where the shore for some distance is nearly a straight line. It consists of a bastioned front nearly parallel to the shore and at a suitable distance from it to give the work sufficient interior capacity, and of two wings which close the flanks. When the flanking from the opposite shore is inefficient, a crotchet is added to each wing to defend its ditch and sweep in flank the approach to it. This work is only suitable where a large detachment holds the point it defends.

The simple crown consists of a central bastion, and two half-bastions near the banks. In planning this work, the banks which protect the central bastion should be longer than the other two, as it is hardly probable that the enemy will attempt an attack on any other point but the salient. The batteries on the opposite shore should sweep the ground immediately in front of the faces, and cross their fire in advance of the salient. The complex crown-work consists of a polygon of three or more sides, on each of which a bastion-front is constructed. If the bridge-head is to cover the maneuvers of a large army, either advancing or retreating, a strong simple crown, with a system of detached lunettes, about 600 yards in front of it, presents a very suitable arrangement. The lunettes may be arranged as in the system of General Rogniat. The central bastion of the crown-work should be armed with a strong battery of heavy guns to protect the lunettes; and heavy batteries, on the opposite shore, should sweep the ground between the lunettes and crown-work. If there are islands in the river near the works, they may be fortified with advantage to flank them. Besides the arrangements already mentioned, intervals of from ten to twenty yards should be left between the shore and the works, for the troops to defile through; the interior is covered by a traverse in rear of the interval. A small defensive stockade should be formed immediately at the head of each bridge, to enable a company of picked men to defend it until the bridge can be cast loose from the shore. An interval of at least 100 yards should be left between the bridges, if more than one is used, and about the same distance should be left between each bridge and the wings of the work. There are no works that demand more care in their plan and construction than têtes-de-pont on important points. They should receive a strong profile so as to command all the approaches, and be flanked, so as to render an open assault impracticable.

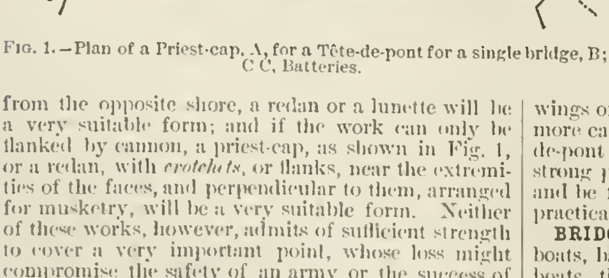

Fig. 1.—Plan of a Priest-cap, A, for a Tête-de-pont for a single bridge, B; C C, Batteries.

BRIDGE OF BOATS.—A military bridge formed of boats, barges, etc. As there are a variety of shaped boats, there are many rules for their construction, taking into consideration the species of rivers to be bridged, the pressure of the water, etc. In India, bridges of boats are generally formed from the boats of the country. They are united to each other at a distance of about 6 feet, and anchored; they are then connected by planks and thus afford a safe passage.

BRIDGES.—An army moving forward oftentimes finds its march interrupted by a large stream or river, intersecting the general line of advance. The army may be crossed over either by fording, by ferrying, or by bridging the stream. Which of these methods should be adopted will depend upon the depth of the stream, its width, the character of the bottom, the strength of the current, and the means at hand.

When wishing to cross a narrow but deep and rapid river, on the banks of which trees grow long enough to reach across, one or more should be felled, confining the trunk to its own bank, and letting the current force the head round to the opposite side; but if the river be too wide to be spanned by one tree—and if two or three men can in any manner be got across—let a large tree be felled into the water on each side, and placed close to the banks opposite to each other, with their heads lying up-streamward. Fasten a rope to the head of each tree, confine the trunks, shove the heads off to receive the force of the current, and ease off the ropes so that the branches may meet in the middle of the river, at an angle pointing upward. The branches of the trees will be jammed together by the force of the current, and so be sufficiently united as to form a tolerable communication, especially when a few of the upper branches have been cleared away. If insufficient, toward the middle of the river, to bear the weight of men crossing, a few stakes, with forks left near their heads, may be thrust down through the branches of the trees to support them. Fig. 1 shows the positions of three trees, *a*, *b*, *c*, judiciously selected and felled so as to have their tops unite in the current at *d*.

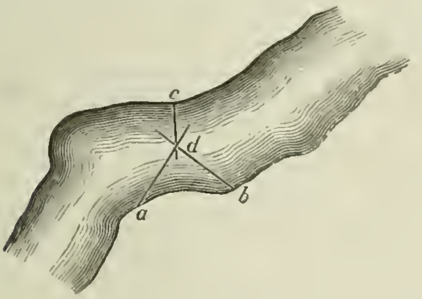

FIG. 1.

When a river which cannot be forded must be crossed by animals and carriages, a bridge becomes necessary; and in all cases it is better, if possible, to cross by a bridge than by a ford, unless the latter be exceedingly shallow. Military bridges may be of three kinds: 1st. Fixed structures of timber. 2d. Floating-bridges. 3d. Flying-bridges. Timber bridges may be either supported on piles or on trestles. Pile-bridges are the most secure, and where bridges are required to remain in use for a considerable period, as those which may be constructed on the lines of communication of an army, with its base of operations, this form of bridge will generally be adopted. To construct a good pile-bridge over a considerable river much skilled labor is necessary, and an ample supply of materials essential. When the bottom of the channel is firm, and the river not subject to floods, a pile-bridge may be constructed without difficulty, and will be very durable. The piles must be driven by an engine, which may be constructed of an 8-inch or 10-inch shell run full of lead, suspended by a rope over a pulley. This may be worked by hand, and will drive piles to a depth sufficient to allow of the passage of the heaviest artillery over the bridge. The pulley of the pile-engine should be supported on a framework some 16 feet high, which may be made to act as a guide to the shell during its fall, and also for the pile while it is being driven. This framework should be erected upon a large flat-bottomed boat. If such a boat is not to be procured, a raft must be made to answer the purpose. When timber of a considerable length can be procured for the joists of the bridge, it will be advisable to make the intervals between the piers or rows of piles as great as the length of the joists will allow, so that the current of the river may be impeded as little as possible, and its action on the bridge be reduced to a minimum. By this arrangement, too, as much space as possible is given for the passage of floating bodies, and the danger of their damaging the bridge is proportionately diminished. When all the piles have been driven as far as the power of the engine can accomplish, they must be sawn off to the same level, and the superstructure of timber be strongly and carefully fitted. With bays of 20 feet and a roadway 14 feet wide, there must be at least five or six beams not less than 7 inches by 8. With wider bays, timbers of larger dimensions will be necessary. The planking should not be less than 2 inches thick, laid transversely. Bridges on piles, for the passage of infantry over shallow rivers only, may be expeditiously constructed, as the piles may be slight—6 inches in diameter would suffice—and they can be driven by hand by heavy mauls, or by two men using a beetle. Here the pile is set and kept in its place by means of two spars of planks resting their extremities upon a stool placed on the bank. A plank is then laid across, on which one or two men may stand to drive the pile. The weight of the men may be increased, if necessary, by stones placed on the platform assisting to force the piles into the ground. When one row of piles is placed, and the floor laid to a cross-beam fixed upon them, another row may be set and driven in the same manner, fixing the stool on that part of the floor which will thus have been completed. Piles driven in this way may be safely depended upon to bear infantry with a front of two or three files in open ranks, not keeping step.

When rivers are shallow and not liable to sudden floods, and when their channels are firm and even, very useful bridges may be constructed on trestles. Trestles for this purpose should each consist of a stout transom or ridge-piece some 8 inches square and 16 feet long; to this should be fitted four legs adapted to the depth of the river slanting, outward from the vertical, and strengthened by diagonal bracing. For large bridges it will be found advantageous to add an additional pair of legs to each trestle. These, from the difficulty of fitting six legs to the uneven surface of the bottom of the river, should not be attached until the trestle is placed in position; they should then be driven into the bed of the river, and their upper extremities should be firmly nailed to the ridge-piece. When the different parts of the trestles are all prepared beforehand, they can be speedily put together and the bridge completed with great expedition. Fascines may be used for flooring where plank cannot be obtained. If there be a strong current, a cable should be stretched across the river on each side of the bridge, and the trestles be firmly lashed to them. It may, moreover, sometimes be necessary to load the trestles with shot or stones, to keep them in their position until the flooring is laid upon them.

Boats of almost any kind will make a serviceable bridge. For wide rivers the boats should be large. The boats of which a bridge is constructed should, if possible, be nearly of the same size, unless they are all very large, and then variations in dimensions will be of little consequence. Should some be large and some small, the passage of large bodies of troops, of heavy guns and ammunition-wagons will depress them unequally, causing the flooring of the bridge to assume an irregular line, straining and injuring, and in some cases fracturing, the timber and destroying the bridge. When boats all of the same size cannot be obtained, the larger boats should be placed at wider intervals, so that they may sustain a heavier weight, proportioned to their greater capacity, during the passage of troops, and be depressed to an equal distance with the smaller. The superstructure will consist of balks of timber laid across the gunwales of the boats, and securely fastened, and the flooring of planks laid transversely over. A certain rigidity results from this arrangement, by which, if the boats were subject to much motion, the bridge would be speedily destroyed. In tidal rivers, where a considerable swell must generally be encountered, this manner of securing the timbers will not answer. In this case it will be found advantageous to erect a trestle or support in the center of each boat, over which the timbers may be bolted to each other: thus each boat will be allowed independent motion, and this will not endanger the fracture of the bridge. The boats should be moored head and stern, and should be kept at their relative distances by timbers fixed at the head and at the stern, stretching across the bays, so as to remove unnecessary strain from the timbers of the bridge. The timbers should be as nearly as possible square, and of dimensions proportioned to the space of the intervals. With good timbers, 8 inches by 6, 20 feet may be allowed from trestle to trestle. The width of the bridge should also be proportioned to the dimensions of the timbers. With five balks of 7 inches by 8, the bridge should not exceed 14 feet in width. If too wide there will be danger of the beams being broken by the overcrowding of troops on the bridge.

When there is no regular ponton-train, and boats cannot be procured, rafts may be used in place of

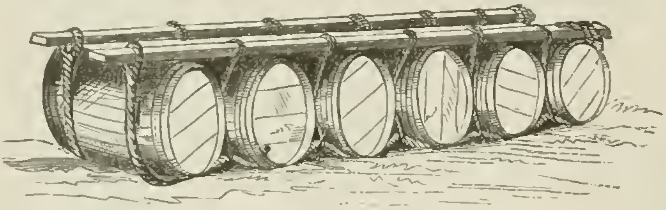

FIG. 2.

boats. These rafts may be made of *casks*, which, if properly arranged and securely lashed, will answer all the purposes of pontons. To make the raft, the casks are placed in a row, side by side, with the bungs up; two rails or saplings called gunnels are laid along them about four inches from each end. Slings of strong rope are passed under the casks, from end to end of the gunnels. The ends of the sling should be made fast to the gunnel, by means of the *bowline* and *fisherman's bend*. Between the casks there are brace-lashings, as shown in Fig. 2. In the absence of sufficient rope the gunnels must be nailed or spiked to the casks; but the use of nails or spikes in rafts or floating bridges is to be avoided when possible, as they admit of insufficient play. To determine the number of casks required to construct a raft that will support N pounds, find the solid contents of one cask in cubic inches and multiply it by the specific gravity of water. From the product subtract the weight of the cask; the remainder will be the weight it will support without sinking. Take a sufficient number of casks to bring this weight up to N pounds.

Unfordable streams may be readily crossed by means of flying-bridges or rafts, when there is sufficient current and when ropes and timber are handy. The flying-bridge or raft may be successfully navigated by attaching it to a swinging cable made fast up stream, or by making it fast to a traveler running on a cable stretched across the stream. In the first case, the lower end of the cable should terminate in a bridle. On leaving the shore, the end of the bridle farthest from it is gathered in, while the other one is slackened, and the raft shoots across the stream. To re-cross, the end of the bridle farthest from the shore is hauled in and the other again slackened. The same may be effected by means of rudders as shown in Fig. 3, the cable being made fast to the raft about one third of its length from the bow, while it is kept headed obliquely up stream. The principle of action in this case is the same as that of a kite in the air. In the second case, the cable stretched across the stream must be carefully secured when the current is great. The maximum pull of the raft will be SV^2, in which S is the area of the immersed side of the raft in square feet, and V the velocity of the current in

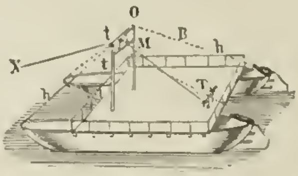

FIG. 3.

feet per second. To insure proper progress, the velocity of the current should not be less than two miles per hour. Referring to Fig. 4, the component of the force of the current which tends to force the raft directly across the stream may be readily traced. If the raft is kept on the course MN, and the current is running in the direction AX, it is plainly seen how such a force, AB, is divided into two components, AC and AD, acting parallel and perpendicularly to MN. The component AD is again subdivided into two components, AE and AF, acting parallel and perpendicularly to AX. DE = AF is the component of the power of the current tending to force the raft across the stream. To produce the best effect, the side of the raft should be kept at an angle of 55° with the direction of the current, or BAC = 55°. The cable may be taken across the stream by a swimmer, or by means of a lobstick—made by splitting a stick, inserting a rock or pebble, and lashing the stick with twine. A small line is first made fast to the cable, the end of which is sent across; whereupon the end of the cable is drawn over. Under certain circumstances, the small line may be sent over by means of an arrow, rocket, or kite.

The mountain streams, during the seasons of high water, remain above the fording-stage for several weeks, and often render it necessary, when time is an important element, to cross them by swimming or ferrying rudely-constructed boats or rafts. Timber rafts may be quickly constructed in a wooded country. The size and description of the timber must determine the number of layers there should be. The cubic contents, in feet, of round timber = L ($G^2 \times .07958$), in which L = length of the log in

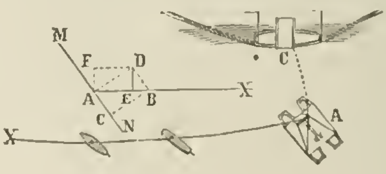

FIG. 4.

feet, and G is the mean between the girths at both ends in feet. The floating power of any log may be readily calculated when the specific gravity of the wood is known. The raft of logs has little buoyancy, wants general manageability, and is inapplicable when the passage of a river is likely to be contested with animation. Its merits are that, at the expense of time, it can be constructed with less experienced workmen; it saves carriage, as it can only be made of materials near the spot. It is, however, an indifferent substitute for boats, pontons, or casks. An independent raft will require two rows of trees, at least, to float as many men as can stand upon it, and the logs are best bound together by withes or ropes, and stiffened with cross and diagonal traces.

As shown in Fig. 1, large trees may be felled to enable infantry to cross narrow streams, placing them so that their butts may rest upon the banks with the tops directed obliquely up the stream; if one is not long enough, others may be floated down so as to extend across, being guided and secured by ropes: a footway may be formed by laying planks, fascines, or hurdles over them, and their branches should be chopped off nearly to the level of the water and intertwined below; poles also may be driven into the bed of the river, to aid in supporting the trees by attaching the boughs to them. *Wheel-carriages* used to form a foot-bridge may be connected by beams; or a single pair of wheels with an axletree to admit two strong posts may be attached and placed in the center of the stream if it is not too wide. Poles reaching from each bank may be secured to the posts, and the wheels would act as a trestle. With a flooring over the poles, a slight bridge could be rapidly constructed for an advanced-guard. *Hide boats* are made of four buffalo-hides strongly sewed together with buffalo-sinew, and stretched over a basket-work of willow or cottonwood 8 feet long and 5 feet broad, with a rounded bow, the seams then being covered with ashes and tallow. Exposed to the sun for some hours, the skins contract and tighten the whole work. Such a boat with four men in it draws only four inches of water. *Inflated skins* have been used since the earliest times for crossing, and if four or more are secured together by a frame, they form a very buoyant raft. *Canvas* (rendered water-proof by a composition of pitch 8 lbs., beeswax 1 lb., and tallow 1 lb., boiled together and laid on quite hot) will serve as a raft or ponton, if placed over framework or wicker work. See *Military Bridge* and *Ponton*.

BRIDGE-TRAIN.—A bridge-equipment or ponton-train, consisting of a military bridge composed of portable boats.

BRIDLE.—An instrument with which a horse is governed and restrained, consisting of a head-stall, a bit and reins, with other appendages, according to its particular form and uses.

BRIDLE-ARM PROTECTOR.—The term for a guard used by the cavalry, which consists in having the sword-hilt above the helmet, the blade crossing the back of the head, its edge directed to the left and turned a little upwards, in order to bring the mounting in a proper direction to protect the hand.

BRIDLE-BIT.—Bridle-bits are of great antiquity, as is proved by the Egyptian and Assyrian paintings and sculptures. Xenophon (400 B.C.) describes several kinds, smooth, sharp, and toothed. The curb is a modern invention, and was introduced into England from the Continent in the reign of Charles I. Etruscan and Grecian sculpture represent the bridle substantially as we yet have it. The Greeks had a severe bridle, armed with teeth, which came over the nose like the *cavezon*, a European bit but little known among us. Another rough bit was also known as a *lupaton*, owing to its sharp prongs like wolves' teeth. Bridle-bits may be classed under three heads: *snaffles*, *curb-bits*, and *stiff bits*. The snaffle has two bars, jointed together in the middle of the mouth, and has rings at the ends for the rein. It sometimes has cheek-pieces, to keep the ring from pulling into the mouth of the animal. The curb-bit consists of the *cheek-pieces* or *branches* with eyes for the *cheek-straps* and for the reins, and holes for the curb-chain; a *mouth-piece*, uniting the *cheek-pieces* and forming the bit proper; sometimes a *bar* uniting the lower ends of the branches; and a *curb-chain*. In the Mexican bit, the curb-chain and its strap are replaced by a curb-ring. By means of the branches of a bit a leverage is obtained upon the horse's jaw, the curb-chain behind the jaw forming the fulcrum. The Whitman bit with snap-hook attachment, used in the United States army, is to be commended for its lightness, elegance, economy, and, above all, strength. It combines the common riding-bit and bradoon-bit in one, makes it easier for the horse, and at the same time invests the rider with a greater control over the horse than by means of other bits. With a proper halter this bit only requires a pair of reins and curb to form a perfect bridle. A large number of contrivances have been patented for giving a greater command over the horse, by means of pulling the bit upward into the angle of the mouth instead of pulling against the jaw.

BRIDLE-REIN.—A rein passing from the hand to the bit, or from the check-hook to the bit; or, in wagon-harness, from the top of the hames to the bit. The bridle-rein may be a *check*-rein, *gag*-rein, or a *riding-bridle*-rein; the latter a *snaffle* or curb-rein, according to the kind of bit.

BRIDOON. The snaffle-bit and rein used in European military equipments in connection with a curb-bit which has its own rein. In the United States the term is sometimes applied to a simple snaffle without cross-bars, and having a rein attached to its rings.

BRIGADE.—In the military service a brigade is a group of regiments or battalions combined into one body. When a British army takes the field, it is customary for three battalions to form a brigade, and two brigades a *division*. Thus, at the battle of the Alma each of the five divisions of British infantry comprised two brigades; and of these ten brigades, nine consisted of three battalions each, the tenth being somewhat stronger. It is nothing more than a temporary grouping, which can be broken up whenever the Commanding Officer thinks fit. The Household Troops, comprising the Horse-guards, Life-guards, and Foot-guards, are sometimes called the *Household Brigade*.

In the United States army the brigade may be formed in one or two lines. The distance between the lines varies both with the nature of the ground and the state of the action. If on the offensive, the second line is held at close supporting distance; if on the defensive, it is held at sufficient distance in the rear to enable the first line to reform behind it, and to prevent the enemy from passing over it with the first line, should that line be driven back. Battalions are designated from the right when in line, and the head when in column, *first battalion*, *second battalion*, and so on. If in two lines, the battalions of the first line are designated from the right *first* and *second*; those of the second line, *third* and *fourth*. If in two columns, the battalions last in the front line are designated from the head of the column *first* and *second*; those of the second line, *third* and *fourth*. These designations change whenever, in facing to the rear, the left of the line becomes the right, and the rear the head of the column. The battalion movements incident to the commencement and completion of all brigade evolutions, the advance in line, and all movements in double time, are executed in the cadenced step. The remainder of the time, unless otherwise ordered, each Colonel marches his battalion in the route-step. When not in the route-step, Colonels cause their pieces to be carried habitually at a *right shoulder*. The brigade is formed on the principles of successive formations, and is presented to the General by the Adjutant-general, as explained for the Adjutant of a battalion, the Colonels repeating commands. The General takes post, facing the line, about seventy yards in front of its center.

At forms of ceremony the pioneers are posted twelve yards to the right of the first battalion, the band twelve yards from the right of the pioneers. In the evolutions the band, and the regimental bands, take any position prescribed on the parade-ground. In line of battle, composed of several brigades, the Generals of brigade place themselves about seventy yards in rear of the centers of their brigades. In column, they hold themselves at the heads of their brigades. In brigade evolutions, the General goes wherever his presence is necessary. The General is attended by his personal Staff; the Adjutant-general riding on his left, his Aides-de-camp in rear, the senior on the right. On the march, the remaining members of his Staff march according to rank in rear of the Aides-de-camp, the senior of each rank on the right.

The Colonels, unless otherwise directed, repeat all the commands of the General. Each preparatory command of the General is repeated as soon as it is given; the last preparatory command having been repeated, the Colonels at once add such commands, and execute such movements in their battalions, as may be necessary before the general movement. The General looks to the prompt execution of these preparatory movements, and rectifies every error that may be committed by the Colonels. The Lieutenant-colonels and Majors repeat the general commands, and the commands of execution, as often as the wind or noise of arms may prevent them from being easily heard from one battalion to another.

In successive formations, the line of battle is determined by Staff-officers, three in number, in the following manner: The first officer, at the preparatory command of the General, posts himself at the *point of rest* for the first battalion, facing in the direction the line is to extend; the second posts himself, facing the first, at the *point of rest* for the second battalion; the third posts himself, covering the other two, at the *point of rest* for the third battalion; the first then moves at a gallop and posts himself for the fourth battalion Should there be more than four battalions, the Staff-officer for the second, as soon as the head of this battalion arrives, hastens to mark the point for the fifth, and so on. If the formation be central, the *points of rest* are marked in both directions from the battalion first on the line. In brigade evolutions, successive formations embrace, besides the formation from column into line, *changes of front, formation into line from echelon, and the formation from line into single and double rank.*

In the British service the artillery is divided into two brigades, which consist of seven batteries each, under the command of a Colonel.

BRIGADE DEPOT.—The headquarters of a sub-district of the army. Under the new localization of the British army, the military districts of Great Britain and Ireland are divided into 12 districts, which are subdivided into 70 infantry and 12 artillery sub-districts, and 2 cavalry districts. The infantry sub-districts, as a rule, correspond with the several Counties into which the United Kingdom is divided. In connection therewith the following arrangements have been made: To each infantry sub-district are assigned 2 battalions of Infantry of the Line, one of which is ordinarily at home, and the other abroad. The battalions are linked together for the purposes of enlistment and service. In each infantry sub-district is located a brigade depot under the command of a Lieutenant-colonel, composed of 2 companies from each of the Line Battalions assigned to the sub-district. The Line Battalions, Militia Battalions, the Brigade Depot, the Rifle Volunteer Corps, and the Infantry of the Army Reserve, constitute the infantry sub-district brigade, and the whole, with the exception of the Line Battalion, are under the command of the officer commanding the brigade depot. A Lieutenant-colonel is appointed to each artillery sub-district, and he is invested with the command of the Auxiliary and Reserve Forces of artillery of the sub-district. The cavalry of the Auxiliary Forces is divided, as before stated, into two districts. A Lieutenant-colonel is appointed to each district, who is invested with the command of the Yeomanry regiments and of the corps of Light Horse and Mounted Rifle Volunteers within his district. The regiments of Guards, the 60th Rifles, and the Rifle Brigade are outside the sub-district organization—i.e., they have no special connection with any territorial sub-district. The depot of the Guards continues as at present constituted. The 60th Rifle Brigade have one consolidated depot at Winchester.

The above explains the organization, as laid down by the warrant, for the maintenance of the sub-districts. It is further directed that in exercising authority over the auxiliary and reserve forces, officers appointed to command must remember that these forces have been enrolled under conditions very different from those of the regular army. They must therefore take great care not to exceed the powers conferred upon them by law, and, in exercising the powers which they do possess, must endeavor to carry with them as far as possible the opinions of the Commanding Officers of the Auxiliary Forces. In all cases of doubt, the warrant says, they will do well to refer to the Inspector-general of the Auxiliary Forces. It is ordered in the Queen's Regulations that "a mess shall be established at the headquarters of each brigade depot, which will be credited with one fifth of the contributions of the Company Officers of each Line Battalion belonging thereto, assessed agreeably to paragraphs 32 and 33, as well as with the annual subscriptions of the officers of two companies thereof. The Lieutenant-colonel, the Major and Staff will pay subscriptions only. The two companies of the Line Battalions will bring, on joining a brigade depot, a sum of 50*l.*, for the purchase of such articles of equipment as may be necessary, or in lieu thereof a sufficient amount of mess property." The plan adopted in forming the brigade depots was to associate with the militia of each County certain Line Battalions, selecting as far as possible such regiments as had any connection with the County, besides such volunteers and army reserves as may be in each brigade district. Each brigade has its depot stationed permanently in the district it belongs to; the Line Battalions are moved as the service may require, one being at home and the other abroad; the militia are embodied periodically as heretofore; but all recruits for either branch of the service are intended to pass through the same hands, and to receive their training together. The Cavalry, Artillery, Engineers, Guards, and Rifles are exceptions to these arrangements, and remain not localized.

BRIGADE-INSPECTOR.—An officer whose duty it is to inspect troops in companies before they are mustered into the service.

BRIGADE-MAJOR.—A military officer who exercises duties, in a brigade, analogous to those of the Adjutant of a Regiment. He attends to matters of discipline, and to the personal movements of the men. When regiments or battalions are brigaded, a Brigade-major is appointed, usually from among the Captains. He conveys orders, keeps the rollster or roster, inspects guards and pickets, and directs exercises and evolutions; but he nevertheless remains on the books of a particular regiment, and returns to his regimental duties when the brigade is broken up.

BRIGADIER—BRIGADIER-GENERAL.—An officer in rank next above a Colonel. He commands a brigade. In the British service the Brigadier is an officer of a regiment (usually a Colonel or Lieutenant-colonel), who, for a limited time and for a special service, is placed upon brigade duties. He is then a General or Commander of a Brigade, which usually contains his own regiment as one of the number. When the brigade is broken up, he falls back to his Colonelcy, unless his services lead to his promotion to the rank of Major-general.

BRIGAND.—A species of irregular foot-soldiers, frequently mentioned by Froissart. From their plundering propensities comes the modern use of the term. Sometimes written *Brigans*.

BRIGANDINE — BRIGANTINE. — An article of armor worn during the Middle Ages. It was an assemblage of small plates of iron, sewed upon quilted linen or leather, and covered with a similar substance to hide the glittering of the metal. It formed a sort of coat or tunic. The brigandine was named from the *Brigans*, a kind of light-armed irregular corps, employed something like the Cossacks and Bashi-bazouks of recent days, and, like them, addicted to marauding and pilfering; hence the word *brigand*.

BRINS D'EST.—Large sticks or poles resembling small pickets, with iron at each end. They were used to cross ditches, particularly in Flanders.

BRISE-MUR.—A heavy piece of ordnance which was used during the fifteenth century to batter down walls, etc.

BRISURE.—In fortification, any part of a rampart or parapet which deviates from the general direction.

BRITANNIA METAL.—The present composition of britannia metal at Birmingham is usually 90 tin + 8 antimony + 2 copper, without any zinc or bismuth; although some manufacturers deviate a little from this formula, by adding one or both of the metals last named. The manufacture was begun at Sheffield by Hancock and Jessop, in 1770; it reached Birmingham towards the close of the century, and made gradual progress. At first the articles were made by stamping with dies, and soldering up into form; this being a slow operation, rendered the articles expensive. Afterwards the curious process of *metal-spinning* was introduced; and this, with the subsidiary operation of swagging, rendered a great reduction in price possible. In the spinning process, a thin sheet or piece of britannia metal is placed upon a wooden model shaped like the article to be made; the model is made to rotate in a lathe; and burnishers and other tools are employed to press the yielding metal into all the curvatures of the model. Ductility is an essential quality to the attainment of this end with the metal; how complete it is may be seen in such articles as britannia-metal teapots and dish-covers, the principal forms of which are not given by hammering, stamping, or casting, but by spinning. Besides spinning and swagging, the processes include stamping, soldering, casting, and polishing. When electro-plating was introduced, an increased use of britannia metal arose, as it forms a good ground or basis for the deposited silver. Britannia-metal spoons and ladles, made by casting, stamping, and burnishing, have been nearly driven out of the market by German silver; but the former metal is largely used for many purposes in the laboratory.

BRITISH ARMY.—Like other modern armies, the British army originated in the feudal system. When regal power, tempered by a Parliament, superseded that system, the people, according to their rank in life, were expected to provide themselves with certain kinds of weapons and defensive armor. The Justices of the Peace were empowered to see to these military duties of the people. When the nation was either actually engaged in war, or apprehensive of invasion, the Sovereign issued commissions to experienced officers, authorizing them to draw out and array the fittest men for service in each County, and to march them to the sea-coast, or to any part of the country known to be in most danger. It was in the time of Henry VIII. that Lord-lieutenants and Deputy-lieutenants of Counties were first appointed as standing-officers for assembling and mustering the military force. During the earlier years of the Tudors, contracts were made by the King with "Captains," who undertook to provide, clothe, and feed so many fighting-men for a given money-allowance: but the power intrusted to the Lord-lieutenants gradually changed this system, in relation at least to home-defense. In the reign of Charles I. the important question arose whether the King of England did or did not possess the right to maintain a military force without the express consent of Parliament. This question was all the more bitterly discussed when the King billeted his soldiers on the people. After the troubles of the civil wars and the commonwealth, Charles II. found himself compelled to agree, on his restoration, to the abandonment of all the army except a kind of body-guard or household brigade of 5000 men, sanctioned by the Parliament. In the thirteenth year of his reign he succeeded in obtaining a statute declaring that "the sole and supreme power, government, command, and disposition of the militia, and of all forces by sea and land, and of all forts and places of strength, is the undoubted right of His Majesty; and both or either of the Houses of Parliament cannot nor ought to pretend to the same." Both Charles II. and James II. found, however, to their mortification, that this statute did not in effect give them so much real military command as they had wished and intended—because the Commons, by holding the purse, virtually held the power.

It was in the time of William and Mary that the real basis for the modern British army was laid. The declaration of rights settled, in positive terms, "that the raising and keeping of a standing army in time of peace, without consent of Parliament, is contrary to law." The first Mutiny Act was passed in 1689, to last for six months only; but it has been annually renewed ever since, except in three particular years; and it constitutes the warrant on which the whole military system of England is exercised by the Sovereign, with the consent of Parliament. Since then, with only three interruptions, the Ministers of the Crown have annually applied to Parliament for permission to raise a military force, and for money to defray the expenses. The Sovereign can make war, and can bestow military employments and honors; but the Commons, as the representatives of the tax-paying nation, provide a check on the grasping by courtiers of military privileges. The law on army regulation has been revised, and the British army made the subject of special legislation in the Army Discipline Bill passed in 1879. The great distinction between the British army and that of almost every other State in Europe is that the service is *voluntary*. The subjects of the Crown engage, by free choice, to serve in the army for a definite number of years. In the rare cases where forced service by ballot is obtained, it is in the militia, not the regular army. The British soldier has much hard colonial life to bear, and many long voyages to make; he is, moreover, almost entirely shut out from the chance of being a commissioned officer. As a consequence, the ranks are mostly filled from the more necessitous classes of the community—by those who, from want of steady habits or of education, are the least fitted for industrious pursuits; whereas in France and many other foreign countries the profession of arms is regarded as an honorable one, of which even the private soldier feels proud. Mr. De Fonblanque, comparing the peace establishments of the chief European armies in 1857, found that of England to be the smallest in ratio to population, but the most costly in relation to its strength. The English ratio was 1 in 128; the French, 1 in 95; the Prussian, 1 in 80; the Russian, 1 in 72; the Austrian, 1 in 68. An English private soldier costs the country £52 per annum; French, £36; Prussian, £31; Austrian, £18 10*s*.; Russian, £13 5*s*. The English cost per man is still higher now than it was in 1857, on account of increased attention being paid to the well-being of the soldier.

The British army, in all its completeness, is supposed to be commanded by the Sovereign, assisted by the Secretary of State for War in some matters, and by the Officer Commanding in Chief in others. The component elements are the Household Troops; the Infantry of the Line; the Cavalry of the Line; the Ordnance Corps, comprising artillery and engineers; other bodies of native troops, maintained out of the revenues of India; the Militia; the Yeomanry Cavalry; the Reserve; the Volunteer Artillery and Rifles; and sometimes, during war, Foreign Legions. The "peace establishment" of the British army varies according to the political aspect of affairs abroad, and to the strength of the economizing principle at home. In 1814, when England was engaged in tremendous contests abroad, the regular army reached 200,000 men, exclusive of Fencibles, Foreign Legions, and Militia. In the first few years after the termination of the great war against Napoleon, the reductions in the British army involved the compulsory retirement of no less than 10,000 military officers, who thereupon went on half-pay; these, by filling vacancies, transfers, and deaths, have nearly disappeared. The elasticity which permits the enlargement or contraction of the army arises from varying not so much the number of regiments as the number of battalions in a regiment, of companies in a battalion, or of men in a company. If we compare the strength of the regular army at various periods between 1820 and 1879, we shall find that the actual number of regiments has varied but little, the difference of strength being made up in the three modes just mentioned.

The strength of the British army declined from 1815 to 1835, since which last-mentioned year it has increased. These augmentations have been occasioned partly by the contests in China, India, Kaffraria, Persia, the Crimea, Afghanistan, and Zululand, and partly by a sense of insecurity amid the vast armaments of the Continent. In comparing the strength of the forces at different periods, much confusion is apt to arise from different modes of interpreting the words "British army." This designation may include the whole of the Royal troops in India, whether supported out of Imperial or of Indian revenues; it may include the Militia, the Volunteers, the Yeomanry Cavalry, the Foreign Legions—or it may exclude any one or more of these. The "British army" and the "Military Force of the British Empire" are often treated as convertible terms; to the production of much confusion where actual numbers are given. In the following table, relating to the official year 1879–80, it is shown of what component elements the British army consists. The Militia and the Volunteer Corps are not here included.

	Home and Colonies.	India.		Total British Army.
Horse-artillery	3,131	2,478	=	5,609
Cavalry, including Household Cavalry	12,907	4,312	=	17,219
Artillery	19,225	9,667	=	28,892
Engineers	5,198	428	=	5,626
Infantry, including Foot-guards.	76,366	45,768	=	122,134
Service Corps	2,990	.....	=	2,990
Colonial Corps	2,485	.....	=	2,485
Army Hospital Corps	1,745	.....	=	1,745
Additional force in consequence of reinforcements to Natal	3,900	.....	=	3,900
	127,947	62,653		190,600

Under the column "India" are included only those troops of the Royal army which are *lent* to India, and paid for out of Indian revenues; the other military forces in that region are enumerated under East India Army. Of the total 190,600, 7980 are officers; 16,550 non-commissioned officers, drummers, and trumpeters; and 166,070 rank and file. There are voted for the use of this army 11,325 horses. The total cost cannot well be estimated per head; because, besides pay and sustenance for the soldiers, there are stores and wages for fortifications and military buildings, military weapons and combustibles, and the various kinds of half-pay and pensions. The total expenditure sanctioned by Parliament may, however, conveniently be thrown under four headings, and given in round numbers as follows:

Pay and allowance of combatants	£4,944,200
Auxiliary and Reserve Forces	1,258,500
Stores and works of every kind	6,817,200
Pensions, Militia, Volunteers, etc	2,625,800
	£15,645,700

This is the charge for a *Peace* Establishment, in which to admit of expansion for actual war, the upper ranks (which cannot be summarily created) are disproportionately large.

All the component elements of the army, in *personnel* and *matériel*, and the organization and duties of the troops, will be found noticed under their proper headings. See *Army*.

BRITTEN GUN.—This gun has five shallow grooves, and the projectile is *expanding*, being made of iron, but having a lead envelope and a wooden sabot. The shell loads easily, being less in diameter than the bore; but when the gun is fired, the gas drives the sabot against the envelope and expands the lead into the grooves, so that the shot acquires a rotatory motion. The wooden sabot is now replaced by an iron *shoe-piece*, which is soldered to the soft-metal envelope; it is not liable, like the sabot, to partial separation, and serves to protect the soft metal.

BRITTEN PROJECTILE.—The most novel and valuable part of this projectile is the fastening of a lead ring to an iron shot, by zinc solder, so firmly that the explosion will not strip it off. The process of coating is as follows: The iron projectile is heated to a dull-red heat, dipped in sal-ammoniac, which thoroughly cleans the surface, held for about two minutes in a bath of melted zinc alloyed with antimony, and then placed in a bath of melted lead, hardened with zinc or tin, for three or four minutes. It is finally placed in an iron mold, and lead from the last bath is poured around it. The projectile, thus coated, is squeezed out of the mold by a screw. A wooden plug, usually screwed to the bottom of this projectile, is driven against the lead, and causes it to expand into the grooves. The amount of projection on the ring, as the projectile was formerly constructed, regulated the pressure of the lead against the bore, and was adjusted so as to just stop windage without wasting power or straining the gun. See *Britten Gun*.

BRIZURE.—A term used with Brisé and Brizé, in Heraldry, to indicate that a charge is bruised or broken. See *Rompu*.

BROACH.—A tapering steel tool, of prismatic form, and whose edges are used for reaming out holes. It is particularly used by armorers in enlarging holes in the small parts of fire-arms, etc. When smooth, it is no longer a broach, but a burnisher, and is used for burnishing pivot-holes. The number of sides vary: the smaller the number, the more salient is the edge. The end of a broach has as many facets as the shaft has sides, and the tang is 4-sided.

BROAD ARROW.—The English Government mark, stamped, cut, or otherwise fixed on all solid materials used in Her Majesty's ships or dock-yards, and on government stores generally, in order to prevent embezzlement. The origin of the mark is obscure. Previous to the year 1698, the Naval Authorities prosecuted a dealer in marine stores, for having in his possession certain stores bearing the *broad arrow* of His Majesty. The defendant allowed the evidence against him to go on, and when asked what he had to say, replied that it was *very curious* that the king and he, as a dealer, should both have the same private mark on their property. The receiver of stolen goods was acquitted, and this led to the passing of the Act that persons in possession of naval stores or goods of any kind marked with the *broad arrow*, or other marks therein mentioned, and usually employed in marking naval stores for the navy, shall forfeit all such goods and £200, and also pay costs. The mark is for iron, wood, etc., while the color-thread is for sailcloth and ropes, which enables the Government to identify the smallest piece of such articles.

BROAD-AXE.—A military weapon used in ancient times. Now obsolete.

BROADSWORD.—A sword with a broad blade, for cutting only, not for stabbing, and therefore not sharp at the point, like a saber. It is but little used in the service. This weapon is better known under the name of *claymore*.

BROADWELL RING.—A steel ring fitting into a lodgment called the ring-recess. The pressure of the powder-gas expands the ring against the walls of the bore and the face of the screw-plug, thus preventing the escape of the gas. The French guns of old model had the gas-check fixed to the axis of the breech-plug, but this led to difficulties of working, particularly when using very quick powder, and when the initial velocities become considerable. These guns had two lodgments for the gas-check, the one nearer the breech being reserved for the time when degradations of the bore at the other had occurred sufficiently to prevent a complete closure. This change was very efficacious in prolonging the life of the piece, and only required a shorter axis for the new gas-check. In the model of 1871 only one lodgment is made in the gun; the gas-check is of the same shape, but is placed by hand in the lodgment, and driven up by the breech-screw. It remains in place throughout the firing. The central opening is made of the same diameter as the powder-chamber, and the side is strengthened by a projection. It freely admits the passage of the ammunition. In the large guns the gas-checks are made of copper, and in the small ones of steel. If destroyed, they are easily renewed.

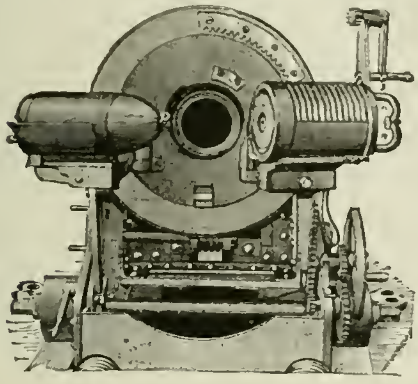

FIG. 1.

The screw-plug is made of steel, and around its circumference is cut a screw-thread, corresponding to the one cut around the screw-box in the tube; the plug and screw-box are reciprocally slotted in three places, so that it can be shoved down to its bearings by hand before engaging the threads. In cutting the slots on the plug, the outer thread is not cut through, and prevents the plug from entering beyond the point where the threads will take each other fairly. The plug is revolved by means of a rack and pinion, one on the end of the lever-handle and the other on the face of the breech. Two turns bring the handle vertical with the blanks on the plug opposite the full threads in the screw-box. The plug is withdrawn from the screw-box, and slides on to a curved bracket hinged to the right side of the breech, on which it is swung around, leaving the breech clear for loading. A bronze bearer, hinged to the other side of the breech, can now be swung around and pushed into the screw-box. This serves to guide the projectile and cartridge clear of the threads, as shown in Fig. 1. On the inner face of the plug a circular nose-plate is fitted, which is held in position by the nose-plate stem which passes through a hole in the center of the plug, and is set up with a screw-nut in the recess of the plug. The vent is axial through the center of the nose-plate stem: there is no vent-check. To obviate the danger resulting from a neglect to screw up the plug when the breech is closed, the lock-laniard, which has a bob on it, is made to pass through the eye, *c* (Fig. 2), of a piece of iron fixed to the breech. When the handle is not in its place, that is, when the plug is not properly screwed in, a spring, *b*, closes the eye and does not allow the bob to pass. When the handle is in position with the plug screwed up, it opens the eye and allows the bob to pass, when the gun can be fired. See *Gas-check*.

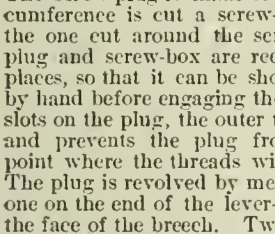

FIG. 2.

BROILING.—A convenient and expeditious mode of cooking small pieces of meat, by troops in the field, by laying them on a gridiron over a bright fire, or even on the coals themselves. This is perhaps the most primitive mode of preparing meat for eating, as may be supposed from the great ease and simplicity with which the operation is managed. Broiling is, in fact, a quicker sort of roasting. The albumen of the outside being sealed up at once, the meat is rendered extremely nutritious, and therefore this process is much to be recommended. But to broil meat so as to preserve its odor, juice, and flavor requires care. The meat should be prepared for the gridiron by being beaten slightly with the rolling-pin, trimmed of superfluous fat and skin, and cut so as to look well on the dish. The fire should be perfectly clear, and of a red-hot surface to answer to the size of the gridiron, that all parts of the meat may be equally cooked. Just before setting the gridiron over, some salt should be sprinkled on the fire to prevent the flare. The gridiron should be perfectly clean and smooth, being always rubbed when it is put away; and, before using, it should be warmed, greased with suet, and rubbed again with paper. When it is placed on the fire, the back should be higher than the front. The meat should never be touched with a fork, but turned rapidly with the broiling-tongs; and when sufficiently done, should be served immediately on a very hot dish, being seasoned according to taste. In large ranges in the garrison there should be a broiling-stove, and an apparatus for broiling suited to it; by this the heat of the fire can be easily regulated. But for all ordinary purposes, a fire of charcoal, or of common coal, and a grooved gridiron to preserve the gravy, are all that is necessary.

BROKE.—The sentence of a Court-Martial depriving an Officer of his commission, or a Non-commissioned Officer or Warrant-officer of his warrant. Also said of a Non-commissioned Officer being reduced by order.

BROKEN LINE OF BATTLE.—A line of battle in which some of the fractions, as brigades, divisions, etc., are separated by the nature of the ground so that it is not practicable to form upon it a continuous line. This arrangement is sometimes known as a line of battle *with intervals*. It follows that in a line of battle of this kind, the different corps or divisions, being separated from each other, cannot give that mutual aid and assistance which is so essential to success. It is therefore an arrangement which is not to be recommended except under peculiar circumstances. When used, it is more generally employed for a defensive than for an offensive battle, and especially under the circumstances where it becomes necessary to give a great extent to the line of defense. Although the fractions on the same line cannot come to each other's assistance, great care is taken to have the reserve so placed that it may have free and easy access to all parts of the line.

BRONCO.—The name applied to the Mexican pony, extensively reared and used west of the Rocky Mountains. The power of endurance of these animals is very great, and they are well adapted to the cavalry service in the rugged and arid country of the Western frontier.

BRONZE.—Bronze is a mixture or alloy of copper and tin. That particular sort of bronze formerly used for guns is often called gun-metal, and consists of about 90 parts of copper and 10 of tin. Bronze is a tough and tenacious metal, but when cast or founded in the ordinary way it is comparatively soft and is easily indented and damaged by the projectile. When heated, as, for instance, by rapid firing, this metal becomes still softer and so more readily damaged. For the small smooth-bore guns formerly used in the field bronze answered tolerably well, as the weight of shot was comparatively small; but with rifled guns using much heavier charges, bronze is not found to be a sufficiently good material. Besides the faults above mentioned, which are inherent to bronze cast in the ordinary way, even when the casting is sound, this alloy has the serious defect of never being quite homogeneous. The tin has a much lower melting point than copper (442° F. as compared to 1800° F.), while its specific gravity is also very different (and although definite alloys can be found, they are not represented by the above proportion, nor such as would answer for gun-metals). While cooling, the two metals forming the alloy seem to separate more or less from one another, the tin liquating or sweating out in parts and causing white spots or blotches called "tin-spots," which are readily acted upon by the powder-gas and eaten away, leaving flaws or holes in the bore of the gun. In rifled guns this defect is much more serious than in smooth-bore pieces, for the grooves cut in the bore lay open a further surface and expose more tin-spots, while the powder-gas acts with greater force (on account of the larger charges and heavier projectiles used), and eats away the spots more quickly. With smooth-bore bronze guns much inconvenience was occasioned by the softness of this alloy, especially when heated by rapid firing; and as experience was gained concerning rifled ordnance in the field, it was found that the defects inherent to ordinary bronze were, as mentioned above, still more serious in such pieces. Their accuracy was affected by much firing, and the greater pressure in the powder-chamber quickly developed flaws by burning out the tin-spots. The cutting of the grooves also laid bare many of these spots, which otherwise would not have been apparent.

Various attempts have been made to discover a modification of bronze, or some analogous alloy, sufficiently hard, elastic, and strong for the purpose required; but as yet, unless the bronze-steel mentioned below be a success, all these attempts have failed. It has also been attempted to improve its quality both in hardness and homogeneity by altering the proportions of the two constituents, and by adding small portions of other metals or non-metals, such as manganese and phosphorus. Phosphor-bronze containing small quantities of phosphorus has been extensively tried, and gives a metal of more uniform character and also stronger than bronze. In 1872 an exhaustive trial was undertaken at Bourges by the French Government with 4-pdrs.; four of these pieces were cast, two being of ordinary bronze and two of an alloy of phosphor-bronze. The superiority of the latter over the guns cast from ordinary bronze was so slight that the Committee carrying on the experiments concluded that any advantages were more than neutralized by the necessity of adding the phosphorus in very exact proportions, and so further complicating the manufacture of bronze guns. Colonel Rosset, of the Italian Artillery, Superintendent of the Arsenal at Turin, has for some years past been carrying on a series of interesting trials with regard to bronze and other metals in the Arsenal at Turin, where a 7.5c. gun of phosphor-bronze was tested in comparison with others of ordinary bronze. This gun stood the trial well, and the alloy from which it was cast (in an iron mold) showed a tenacity of about 25 tons per square inch. Notwithstanding this, however, Colonel Rosset concluded that it was not advisable to employ such an alloy in gun-manufacture on account of the unstable character of phosphorus; and the great difficulty of securing uniformity of result in the mixture of this element with bronze. Russia, too, has been making much advance in the working of bronze, and is manufacturing some powerful experimental field-guns (Lavroff guns) of this alloy treated in the same way as described with regard to the Austrian "Uchatius" field-pieces.

In Austria great attention has always been paid to bronze and analogous alloys, and General Von Uchatius, the Director of the Gun-foundry at Vienna, has for years studied the subject. In a lecture lately delivered by him, he tells us that about three years ago his attention was particularly called to a fragment of bronze, cast under pressure, which the Archduke William had brought from Russia. He found the properties of this metal so far superior to those of bronze cast in the ordinary way that he was led to researches which resulted in his casting bronze in an iron mold, or chill-casting, and at the same time chilling the interior of the mass by means of a core of solid copper, or otherwise. This bronze, which is an ordinary alloy, containing 8 per cent of tin, can be forged cold, and possesses many of the properties of steel, and has, consequently, been termed "bronze-steel"; it possesses, however, apparently, the advantage over steel of being a safer material when employed alone. The following table exhibits the mechanical properties of United States bronze:

Nature.		Composition.	Density.	Tenacity per sq. inch.	Limit of elasticity per sq. inch.	Elongation.		Hardness.
						Ultimate.	Elastic.	
				Lbs.	Lbs.	Per ct.	Per ct.	
U. S. Navy guns	Breech square	90 parts copper	8.765	46,500				
	Gun-head	10 parts tin	8.444	27,400				
Do.				60,000				
U. S. Army field-guns	Gun-head samples		8.497	29,859				
	Small bars	90 parts copper	8.557	42,754				4.57
	Finished gun	10 parts tin	8 766					5.94
	Small bars		8.800	52,000				
Reed brass (South Boston Iron Company)		Copper, zinc	8.4142	55,800	9,000	24	100	6.27
West Point foundry bronze, for life-saving mortars		90 parts copper	8.7972	50,831	17,000	56	200	4.57
		10 parts tin			20,000	42	200	5.24
South Boston Iron Company bronze, condensed by mandreling		Uncondensed	8 3512	35,810				5.40
		Condensed	8.7065	51,571				18.00

The work done in stretching to the elastic limit, and the point of fracture, is less for ordinary bronze than for wrought-iron of maximum ductility, and for low steel. This defect, added to the costliness of bronze, to the various embarrassments experienced in the casting of large masses, its softness and consequently rapid wear and compression, and to its injury by heat, has not warranted its employment for large calibers and high charges. The mean ultimate cohesion of bronze, according to European authorities and the experiments of the United States Government, is about 33,000 pounds per square inch. Rifled bronze guns would be naturally more liable to rapid deterioration than smooth-bores, as the weights of projectile and charge are much greater in the former in comparison to the area acted upon, and consequently the local heating at the seat of the charge is much more intense, thus tending to separate the copper and tin more or less from each other, forming those tin-spots and porous patches which injure the strength of the material. The reduction of windage also, in the rifle-gun, would tend to increase this local heating, and it must be remembered that bronze becomes hot very easily, and tin melts very soon (442° F.); moreover, the grooves in a rifle-gun open out many tin-spots which would remain unexposed in a smooth-bore. See *Cannon-metals, Compressed Bronze,* and *Phosphor-bronze.*

BRONZE GUNS.—The circumstances of chief difficulty and importance in the manipulation of bronze affecting the production of cannon are: 1. The chemical constitution of the alloy as influencing the balance of hardness and tenacity. 2. Its chemical constitution and other conditions influencing the segregation of the cooling mass of the gun when cast into two or more alloys of different and often variable constitutions. 3. The effect of rapid and slow cooling and of the temperature at which the metal is fused and poured. 4. The effect due to repeated fusions and to foreign constituents in minute proportions entering the alloy. In bronze, sufficient hardness must be secured to resist longest the abrasions of projectiles and deflagration of powder; along with the greatest ultimate tenacity, there must be certain rigidity and ductility with ultimate cohesion; hardness and rigidity increase with the proportions of tin; ductility and tenacity with that of the copper, but not in direct ratio; specific gravity increases with copper. The fusibility is greater than copper, and less than tin; ultimate cohesion less than that of tough copper, but greater than that of tin; ductility greater than tin, but less than copper; hardness greater than either. In consequence of the difference in the fusibility of tin and copper, the perfection of the alloy depends much on the nature of the furnace and treatment of the melted metal. By these means alone the tenacity of bronze has been carried at the Washington navy-yard as high as 60,000 lbs.

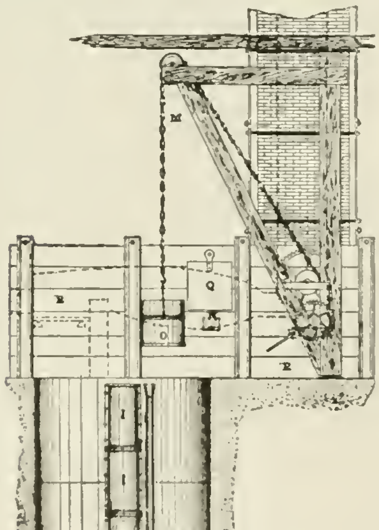
The first step in the fabrication of bronze guns at the foundry is to make an accurate working drawing of the gun, on a convenient scale, showing all lines clearly and with all its dimensions distinctly marked. The subsequent steps vary according to the method proposed to be used in casting. Formerly bronze guns were cast in loam or sand molds, but these have been superseded by a thick mold of cast-iron, called a *chill*. When cast in chills, bronze is denser, stronger, and more uniform than in sand; there is less liability of a separation of tin, or forming of a tin-copper alloy differing from bronze. A description of the process of casting in sand will supply details required for an understanding of the chill-casting. *When a casting is desired in sand*, a wooden pattern of the gun is made, following the shape of the drawing, but larger in all its dimensions, both by the shrinkage of the casting and also by the amount allowed for finishing, of never less than 1 inch over the finished diameter. The pattern is also made longer than required for the gun-casting, to form a sinking-head of a diameter about equal to that of the gun at the muzzle, and with a volume or weight, for ordinary guns, about one third that of the whole casting. This sinking-head supplies fluid metal to the casting as the latter cools, and receives any cinder or dross that would otherwise remain in and injure the casting. The sinking-head is cut off as soon as practicable after casting. The *pattern* is formed by planing the surfaces of moderately thick, clear plank, and gluing pieces of different widths together, the widest next the center of the pattern, until a sufficient thickness is obtained for each half the entire pattern, divided longitudinally. Two or more steadying-pins are then fixed in one half of the rough pattern, with corresponding holes in the other half, the surfaces having been fitted neatly to each other. The halves are clamped firmly together, carefully centered and turned in a lath to the proper dimensions. All projecting parts not annular must be attached to the pattern in separate pieces fitted to the turned surfaces of the partly finished pattern. Thus, separate pieces are turned for the trunnions, including the rimbases, the sight-masses, etc., and fastened to the pattern in their proper positions by pins in the wood, so that they may be readily removed. The whole pattern is carefully finished and smoothed with sand-paper, the angles and corners well rounded, and varnished to protect the wood from the moisture of the sand. The pattern and loose pieces are legibly marked.

The *flask* is longer than the entire pattern including the sinking-head, and contains sufficient sand around the pattern to permit proper ramming and to make the mold sufficiently secure, leaving room enough for the runner or gate at the side of the pattern. The flask is of hexagonal shape, divided longitudinally in two parts; each half has strong longitudinal flanges, and is strengthened crosswise by ribs running from flange to flange. Each side of the half flask which adjoins the flange is solid, but the third side, which lies uppermost in molding, is open save where the ribs cross it. This opening from one end to the other is for ramming, and is closed by movable plates, which are held down upon the sand by means of wedges driven under the ribs. For *molding*, half of the pattern is laid upon a flat surface—"follow-board"—which is somewhat larger than the flask. The latter is placed over the half pattern. Well-tempered sand mixed with clay and beer-lees is then rammed uniformly all around and over the pattern, so as to be of equal density and hardness throughout. The loose plates are then keyed down, the flask raised and turned over, and the surface of the sand closely sprinkled with fine, unadhesive parting-sand. The second half of the pattern is laid exactly on the first and kept in place by the steadying-pins; the other half of the flask put on, keyed to its fellow, filled with sand, and rammed evenly round as before and its plates keyed down. The two halves of the flask are then separated, the pattern removed, the main runner cut with a suitable tool along the sand on the surface where the flasks part, being made funnel-shaped at the top. Half the runner lies in each part of the flask, the main gate is cut from the bottom of the runner into the mold, and other gates above it. The main gate is cut tangent to the circumference of the mold, that the metal as it rises may receive a rotary motion. The mold is put into a drying-oven, raised to a high heat, 300 degrees or more, and thoroughly dried. The whole surface of the sand-mold is carefully coated with a wash of graphite, fire-clay, and molasses and water, and the mold dried again for a few hours. When it is ready for the casting the flask is placed in the pit upright on end.

When a chill is used, the process is as follows: The chill conforming to the curves of the pattern unites the functions of the flask and of the sand-mold, and by its high conducting power rapidly extracts the heat of the metal cast within it. The working draught of the gun being made as before, a drawing of the chill is made giving the dimensions required. From this the pattern is prepared, so much being added to every dimension, that when cold after casting the interior sizes of the chill may be those required by the casting of the gun. The chill is best divided longitudinally into halves on a plane at right angles to the trunnions, and also horizontally into two, or, if the gun is long, into more sections, the lower two of which, one on each side, contain the recesses forming the trunnions and rimbases. Four pieces are provided with flanges for clamping them together. An additional section, added for the cascabel, is made with a broad flange upon which the whole chill when keyed together securely stands. The gun-casting proper is thus inclosed in a cast-iron mold, and is quickly chilled. The sinking-head is molded in dry sand, that it may remain liquid to feed the casting as long as possible. The pattern for the sinking-head is a cylindrical piece of wood, of proper diameter and length, which is placed within a long cylindrical flask, open at both ends, and withdrawn after the sand has been rammed around it. This flask, or "pot," is made, fitted, and fastened to the top of the chill. Two patterns are requisite for the chill proper, and one for the base. They are made from the proper drawing like those for ordinary sand-castings, the internal dimensions being fixed as in the method previously described, by the shrinkage of the alloy and the amount left for finishing. The walls of the chill may be from 2½ to 3¼ inches thick. After the castings are made they are carefully smoothed or bored out when practicable; and all corners, especially in the trunnion-molds, likely to retain gas or to catch dross in casting are carefully smoothed over and rounded.

When a casting is to be made, the parts of the chill are cleaned, fastened together, covered inside with a wash of fire-clay, molasses and water, and heated to a moderately high heat in an oven. At casting, the chill is brought out and the sinking-head mold keyed to it. The metal may be poured direct into the mold or through a separate runner at the side opening into the chill at the bottom. If poured direct, the stream falls from the top straight downward from a small box lined with sand, which receives the metal from the ladle. If a side runner is used, it is divided longitudinally; the halves are fastened together by flanges and bolts. The base of the chill is fitted to receive the runner, which is, at the bottom, contained in a cast-iron box bolted to the chill and leading horizontally into the opening. Each half of the pipe receives the sand for the runner, which is also molded as above and dried in an oven. The side runner has the advantage of keeping the metal cleaner in the casting through the rotary motion imparted by the stream flowing into the mold tangentially, but it is apt to leave the sinking-head too cool, and hence the latter is, in any case, best poured direct after the mold or chill has been filled above the top of the gun.

For casting it is most convenient to place the chills or flasks in a pit, P, in such a position as to be easily reached by the crane-ladle, O, used for pouring. The



pit may contain several chills at once, and the crane, M, commands both the furnace and the pit. As soon as the bronze is melted the ladle is brought beneath the tapping-hole, N, the metal tapped into it, and the ladle swung around over the chills. *The furnace* is reverberatory, fired with soft bituminous coal, and is so constructed that the metal as it melts runs into a pool at the end furthest from the fire, thus removing it from the immediate action of the flame. The bottom of the furnace is made of fire-clay rammed hard. A door of convenient size is placed in the side of the furnace for charging, taking samples of molten metal for test, etc., and the tapping-hole is usually placed under it for convenience of access. The furnace is charged by laying the metal selected, which may be either old guns or sinking-heads, or new copper, or chips from the lathe, on boards on the bottom of the furnace, distributing it carefully so as to expose all pieces properly to the flame, that they may come into fusion at about the same time. The copper is charged as bought in pigs, but guns and heads are cut up into pieces of convenient size. The tin is charged in the shape of small ingots recast for the purpose, about 12 inches long by ½ inch square.

The composition of the charge is varied to suit the metal used, but the total weight must be sufficient to cast the gun and sinking-head and leave some surplus. For the 3½-inch rifle cast in 1876 the charge was as follows:

	Pounds.
Old guns cut up....................	2650
New copper in ingots................	830
Tin, in small bars.............	104
Total	3584

The whole casting weighed 3126 pounds, for a finished weight in the gun of 1322 pounds. The riser when cut off weighed 700 pounds, and there was a waste in the furnace of 1.6 per cent. After the old bronze or copper has been charged, the furnace is closed and fired up gently at first and more strongly as the metal sinks down away from the flame, which must always be kept smoky, i.e., of a reducing character. When the bronze or copper is melted the tin is added; it is thrown into the bath at different points and worked under the surface as much as possible, as it floats buoyantly till alloyed. The bath may be stirred thoroughly with an iron bar, or, if much old metal be used, with a pole of green wood. After the metal is wholly melted it is kept in fusion for some time—about half an hour—in order that a thorough alloy may be effected, and a proper temperature be reached for casting. The alloy is examined for its cold fracture by means of specimens taken out of the furnace in a small ladle. When the fracture is brought to the proper yellow-red color, judged by experience, and the heat has reached the proper point, the bronze is ready for casting. For the gun above quoted, the furnace was lighted at 8 A.M., the metal melted at 10.25 A.M., and the casting was made at 11.30 A.M., or in 3 hours and 30 minutes in all.

The tendency of bronze to separate into alloys of different composition is so strong that specimens taken at different heights in the mold exhibit very different densities and strengths. A series of specimens cast in the same sand-mold with the gun and contiguous to it, but separate from the gun-casting proper, showed a constant decrease of strength from the cascabel to the sinking-head, as follows:

AVERAGE.	Bottom of sinking-head.	Side specimen A.	Side specimen B.	Side specimen C.	Finished gun as a whole.
Density	8.440	* 8.597	8.660	8.686	8.649
Tenacity........	26,760	39,364	41,974	43,062	....

The average density of one hundred and twenty-four 24-pounder bronze howitzers, made for the Navy Department in 1863 and 1864, between the South Boston foundry-numbers 1417 and 1693, was 8.722, and average tenacity 50,041 pounds per square inch. The averages of forty-five guns, from No. 434 to 478, inclusive, were density 8.653, and tenacity 33,665 pounds per square inch. On the other hand, nine guns included in the first series, and made between foundry-numbers 1556 and 1615, exhibited an average density of 8.804, and an average tenacity of 60,610 pounds to the square inch. See *Dean Field-gun, Ordnance,* and *Uchatius Gun.*

BRONZE-STEEL.—This name is given to the metal obtained by the process of General Von Uchatius of the Austrian service, and Lavroff in the Russian service. The metal is obtained by casting bronze in a chill-mold and forging it cold. The guns are made by casting on a core in a chill mold. The gun is then inclosed in a steel casing, and the bore expanded by forcing in steel mandrels slightly tapered, and gradually increasing in size, by which the diameter of the bore is increased 5 or 6 per cent, and the hardness increased. This has the effect of putting the interior metal in a state of compression, and the exterior in a state of tension, while the metal has almost the strength, hardness, and elasticity of steel. See *Bronze* and *Steel.*

BRONZING.—The process of covering articles so as to communicate to them the appearance of ordinary bronze. Gun-barrels are bronzed by acting upon them with the chloride or butter of antimony (*bronzing* salt), or with hydrochloric or nitric acids, when the surface of the iron gets partially eaten into and covered with a thin film of oxide; after which the gun-barrel is thoroughly cleaned, oiled, and burnished. A brownish shade is thus communicated to the barrel, which protects it from rust and at the same time renders it less conspicuous to an enemy. In the bronzing operation known as the Damascus, the barrel is treated with dilute nitric acid and vinegar, to which sulphate of copper has been added. The result is that metallic copper is deposited irregularly over the iron surface; and when the latter is washed, oiled, and well rubbed with a hard brush, a very pretty appearance is communicated to the barrel. See *Browning.*

BROOKE HOOPED GUN.—A cast-iron gun, hooped with wrought-iron rings. Although slightly hooped, the fine quality of material insures considerable endurance. One gun is stated to have fired double charges without injury. The 7-inch gun (all other calibers are similar in design) is used with 14 pounds of powder and an 80-pound shell. The following are its particulars:

Total length	146.05	inches.
Length of bore	119.90	"
Length of wrought-iron reinforce	30.00	"
Length muzzle to center of trunnions	80.50	"
Length center of trunnions to forward end of reinforce	10.90	"
Diameter of bore	7.00	"
Diameter of muzzle	14.55	"
Diameter of cylindrical part of casting under reinforce	27.20	"
Diameter over reinforce	31.20	"

The rifling consists of seven grooves $\frac{1}{10}$ inch deep, very slightly rounded at the corners, with one turn in forty feet. The grooves vanish as they approach the chamber. The gun resembles Parrott's in shape and construction, except that the reinforcing band is made up of rings not welded together. See *Ordnance.*

BROTH.—An infusion or decoction of vegetable and animal substances in water. It is customary in the army to use more or less meat, generally ox-flesh, with bone, and certain vegetables, as cabbage, greens, turnips, carrots, peas, beans, onions, etc. The whole are mixed together in cold water, heat slowly applied, and the materials allowed to simmer for some hours. The meat yields up certain ingredients, whilst others are retained in the residual flesh. The following will illustrate this: Ox-flesh heated with water yields to the water albuminous matter, gelatine, kreatine, extractive matters or osmazome, lactic acid, salts, fat, and saccharine matter; and leaves in the boiled meat fibrin, coagulated albumen, gelatinous tissue, fat, and nervous matter. The vegetables yield albuminous constituents, coloring and mucilaginous matter, and volatile oils and salts. The real nutritive material present in broth is less than is generally thought, though it aids in satisfying the cravings of the appetite. In the hospital, however, the form of broth known as beef-tea is of great importance, as it affords the weak and sickly stomach a light palatable article of diet at a time when stronger food would do the weakened system much harm.

BROUGHTON GUNS.—A variety of very excellent arms bearing this name have been invented and tested, —three of which compare very favorably with the well-known arms of their respective systems.

No. 1 is a breech-loading rifle having a fixed chamber closed by a movable breech-block rotating about a vertical axis at 90 degrees to the axis of the barrel, and not in the plane of the axis of the barrel (all to the right and in front). This piece is opened by drawing back the firing-bolt to cock the piece, and pressing down on the thumb-piece to liberate a spring-catch in the breech-block from its notch in the receiver, and to allow the block to swing outward and forward until nearly parallel to the barrel. The guard is connected with the receiver by an undercut groove in front and a spring-catch in rear, and when detached from the gun carries with it the lock complete.

No. 2 is a breech-loading rifle having a fixed chamber closed by a movable breech-block which rotates about a horizontal axis at 90 degrees to the axis of the barrel, lying above the axis of the barrel and in front. This piece is opened by cocking the piece so as to withdraw the nose of the hammer from the counter-bore of the firing-pin hole, and then pressing forward the latch-lever, which passes through the firing-pin, until the head of the pin is disengaged from the corresponding cavity in the receiver, and the breech-block is free to swing upward and forward over the barrel. The action does not differ materially from that of the Springfield.

No. 3 is a breech-loading rifle having a fixed chamber closed by a movable breech-block which rotates about a horizontal axis at 90 degrees to the axis of the barrel, lying below the axis of the barrel and in front, being moved from below by a lever. By the first motion of depressing the lever, which is pivoted on the breech-block near its rearmost corner, its upper end presses back the locking-brace from under the lock. It thus allows the block to swing downward and backward, as soon as by the continued motion of the lever it strikes the under surface of the block so as to cause its revolution about the block-pin, and to expose the chamber for the insertion of the charge. As the locking-brace is pushed back it also brings the hammer to the half-cock.

BROW-BAND.—A band of a bridle, head-stall, or halter, which passes in front of the horse's forehead, and has loops at its ends, through which pass the cheek-straps.

BROWN BESS.—A very ancient and quite renowned smooth-bore fire-arm. This musket helped to win the battles of Marlborough and old Fritz, of Wellington and Napoleon, and figures largely in military history.

BROWN BILL.—The ancient weapon of the English foot-soldiers, resembling a battle-axe.

BROWN COAL.—A mineral substance of vegetable origin, like common coal, but differing from it in its more distinctly fibrous or woody formation, which is sometimes so perfect that the original structure of the wood can be discerned by the microscope, while its external form is also not unfrequently preserved. In this state it is often called *wood-coal;* and it sometimes occurs so little mineralized that it may be used for the purposes of wood, as at Vitry, on the banks of the Seine, where the wood-work of a house has been made of it. From this to the most perfectly mineralized state it occurs in all different stages. It is often brown or brownish black, more rarely gray. It burns without swelling or running, with a weaker flame than coal; emits in burning a smell like that of peat, and leaves an ash more resembling that of wood than of coal. Wherever it occurs in sufficient abundance it is used for fuel, although very inferior to common coal. *Bovey coal,* so called from Bovey Tracey, in Devonshire, where extensive beds of it occur, and where it has long been wrought, is brown coal, and often exhibits the woody structure very beautifully. See *Coal.*

BROWNING.—Browning is the coating given to a gun to protect it from the action of the atmosphere, and to prevent the surface from reflecting the sunlight. The process of browning small-arms consists in forming a coat of rust, with a mixture of such materials as *spirits of wine, blue vitriol, tincture of steel, nitric acid*, etc., on the clean surface of the barrel, and then rubbing it well with a *steel scratch-card* until it has a metallic luster. This operation is repeated about a dozen times, until the coating has a deep brown color. The barrel is then washed with boiling water, to dissolve away any of the corroding mixture that may remain, and, when cold, is covered with sperm-oil. When the browning has been worn away in places, it may be entirely removed—first by boiling in lime-water, to remove the varnish or grease, and then soaking in vinegar, which loosens the browning so that it can be wiped away with a rag.

The following method, embodying seven operations,

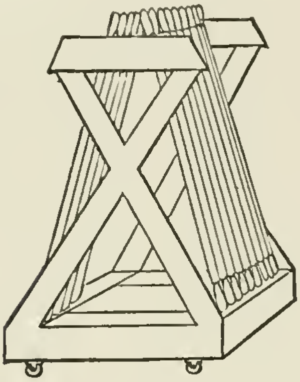


Fig. 1.

is used for browning small-arms at the National Armory:

First Operation.—The first operation with the barrel is to oil the bore with pure sperm, and plug each end to prevent the entrance of either *lime-water*, boiling water, or the browning mixture.

Second Operation.—Place a number of the barrels in a tank of boiling *lime*-water, and allow them to remain thirty minutes, until all grease is removed. After this brush off the lime with a *clean* brush, and avoid touching the barrels with the hand.

Third Operation.—Apply evenly with a clean fine

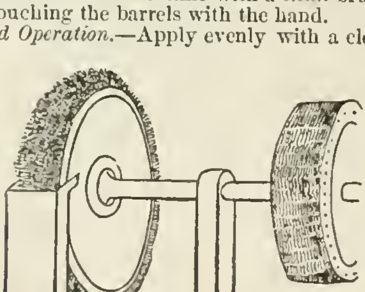

Fig. 2.

sponge a coating of the browning mixture; the barrels are then placed on a rolling or movable frame (Fig. 1). The frame is then rolled into the steam-case, having received its complement of barrels.

Fourth Operation.—Rusting the barrels is accomplished in six or seven hours in the steam-case, at a temperature of 85° and humidity of 70 per cent, determined by the thermometer and psychrometer. By reducing the supply of steam the barrels can remain for a greater length of time (overnight).

Fifth Operation.—Remove the barrels from the steam-case and place them in the hot-water tank (water heated by coils of steam-pipe), where they remain for *fifteen* minutes, when all trace of acid disappears.

Sixth Operation.—An expert operative then passes the barrel obliquely across the surface of a revolving *brush-wheel*, thereby removing all loose particles of oxide (Fig. 2). This wheel is about twelve inches in diameter and four or five inches thick, set on periphery with Russia bristles, and has about eight or nine hundred revolutions per minute.

Seventh Operation.—The operative, after brushing the barrel (which is accomplished in a few moments), in like manner holds it obliquely across the face or surface of the card-wheel (the teeth of which are bent backward) until the surface of the barrel is carded or burnished evenly. The card-wheel (Fig. 2),

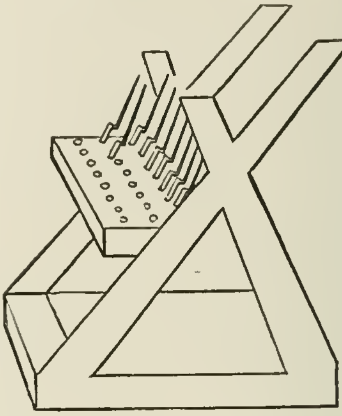

Fig. 3.

revolving at the same rate as the brush-wheel, accomplishes its work in a few moments. After the seventh operation the barrels are ready to receive the *second* coat of browning, when the seven operations before enumerated are repeated. In like manner the *third* and *fourth* applications of the mixture are followed by the several steps before noted.

The browning of bayonets, bayonet-scabbards, bayonet-clasps, and ramrods is accomplished in the same general manner as for barrels (Fig. 3). For convenience a steel spring handle is used to hold the rammer. After the various parts are browned they are well coated with cosmoline or olive-oil.

To Brown a Gun.—Scrape clean; scrub with fresh water, sand, and canvas; allow to dry; wipe off; apply a strong solution of salt and vinegar three or four times a day for two days, or until a good coat of rust is formed; allow to dry, then rub lightly with old canvas; apply a thin coat of the following mixture, rubbing it in well: 4 lbs. beeswax, melted and strained; .50 oz. pure vitrol (white), or 1 oz. pulverized alum; 1 gallon spirits of turpentine. Allow to dry until next day; then put on another thin coat, and when dry rub with a clean cotton cloth. In case of a dull appearance, by reason of having been handled, rub over with a cotton cloth and spirits of turpentine, and then with a dry cloth. See *Bronzing*.

BROWN PIGMENTS.—Substances in which the three primary colors unite in unequal proportions, red being in excess. Brown pigments are chiefly mineral, and are used in the laboratory, sometimes in a raw but usually in a burned state. The most important are bister, asphaltum, umber, terra di sienna, Mars brown, Cassel earth, and brown madder.

BROWN SIGHT.—A valuable improvement in the rear-sight on the U. S. service rifle has been recently proposed by Lieutenant W. C. Brown, U. S. Army. The rear edge of the buckhorn plate is beveled nearly or quite to a sharp edge, and the graduation for wind-allowance being brought down to this edge, the points and fractions thereof are easily read against the outer edge of the leaf. To further facilitate the reading of fractions of a point, a straight line has been drawn on each branch of the leaf, and at such a distance therefrom as to coincide with the outer division when the wind-gauge is at zero. See *Pointing* and *Sight*.

BRUCE STOP.—A stop intended to sustain the Springfield breech-block in the position of loading, when the muzzle of the gun is elevated, or the piece is much shaken, as on horseback at a trot. It consists of a spring and spindle like those used for the ejector, and lying in a counterbore on the opposite side of the receiver. When the block is open, the point of the spindle lies within a shallow cavity in the front surface of the hinge on the breech-block, and is pressed against it by the spring with sufficient force to hold it up, and yet to permit the pressure of the hand properly applied to easily close the piece.

BRUGERE POWDER.—An explosive compound of ammonium picrate and niter. It has been experimented with for use in shell in England, as it acts when strongly confined more violently than gunpowder. See *Explosive Agents* and *Picrates*.

BRUNEL TARGET.—A canvas target used by the Dominion of Canada Rifle Association at Ottawa. The framework of the target is made of iron, about one inch thick, and sharpened like a V in front. The target moves up and down along two iron guide-rods, having a counterbalancing weight attached. When the target is hit, the marker (sheltered by a parapet and trench) draws it down the guide-rods, until it stands before him. He then hangs in the bullet-hole a cardboard disk (provided with a wire hook), painted to indicate its value, lifts the handles, and raises the target to view again. The marker repeats this operation at each hit, taking the disk out of the former hole, patching that hole up, and hanging the disk in the new hole. These disks may be shot through and through several times, and when worn out may be cheaply replaced. See *Target*.

BRUNIA.—A coat of mail worn by the early Franks. It was a short and tight species of *paletot*, more or less closely covered with small pieces of metal sewn upon the fabric of which the piece of armor was composed.

BRUNSWICK BLACK.—A varnish employed for coating over coarsely finished iron-work. It is mainly compounded of lamp-black and turpentine, and when applied with a brush quickly dries, and leaves a shining jet-black surface.

BRUNSWICK GREEN.—A pigment used in the laboratory, and consisting of the hydrated chloride and oxide of copper ($CuCl,3CuO,4HO$). It may be prepared (1) by acting upon metallic copper with common salt and diluted sulphuric acid; (2) by acting upon metallic copper with moistened sal-ammoniac; or (3) by mixing sulphate of copper and common salt into a paste with water. It is found native at Atacama, in Peru, in the form of a green sand, hence the name Atacamite.

BRUNSWICK RIFLE.—This rifle, with back-action hook-lock, was introduced into the English army in the reign of William IV. Its weight with sword-bayonet and scabbard was 11 pounds 5½ ounces; weight of barrel, 3 pounds 14 ounces; length of barrel, 2½ feet; number of grooves, 2, making one turn in the length of the barrel; weight of bullet (which was spherical and belted), 557 grains; diameter, .696 inch; charge of powder, 2⅛ drams. This rifle, from the ball having a belt round it with a patch to prevent its "stripping," was found an inconvenient weapon, in consequence of the delay experienced in placing the belted ball properly in the grooves, without which loading was impossible. The rifle soon fouled, and its shooting beyond 400 yards was wild.

BRUNT.—The troops who sustain the principal shock of the enemy in action are said to bear the *brunt* of the battle.

BRUSHWOOD.—Rough, low, close thickets; under wood, branches of trees cut off. The use it is put to is in making gabions, fascines, and pickets. Brushwood for the above purposes should not exceed 1¼ to 2 inches in diameter at the butt or thick end. Brushwood is cut and tied up in bundles, weighing from 40 to 50 lbs. each.

BUCCANEERS.—A celebrated association of piratical adventurers, who, from the commencement of the second quarter of the sixteenth century to the end of the seventeenth, maintained themselves in the Caribbean Seas, at first by systematic reprisals on the Spaniards, latterly by less justifiable and indiscriminate piracy. The name is derived from the Caribbee *boucan*, a term for preserved meat, smoke-dried in a peculiar manner. From this the French adventurers formed the verb *boucaner* and the noun *boucanier*, which was adopted by the English; while, singularly enough, the French used, in preference, the word *flibustier*, a corruption of our "freebooter." The Buccaneers were also sometimes called "Brethren of the Coast." The arrogant assumption by the Spaniards of a divine right—sanctioned by the Pope's Bull—to the whole New World was not, of course, to be tolerated by the enterprising mariners of England and France; and the enormous cruelties practiced by them upon all foreign interlopers, of which the history of that time is full, naturally led to an association for mutual defense among the adventurers of all other nations, but particularly among the English and French. The fundamental principles of their policy—for they, in course of time, formed distinct communities—were close mutual alliance, and mortal war with all that was Spanish. Their simple code of laws bound them to a common participation in the necessaries of life; locks and bars were proscribed as an insult to the general honor; and every man had his comrade, who stood by him when alive, and succeeded to his property after his death. The principal center of their wild and predatory life was for some time the Island of Tortuga, near St. Domingo. When they were not hunting Spaniards, or being hunted themselves, their chief occupation and means of subsistence was the chase. From the flesh of wild cattle they made their "boucan"; their skins and tallow they sold or bartered to Dutch and other traders. The history of these men embraces, as may be supposed, narratives of cruelty and bloodshed unsurpassed in the annals of crime. It has, however, not a few stories of high and romantic adventure, of chivalrous valor, and brilliant generalship. Among the "Great Captains" whose names figure most prominently in the records of buccaneering, were the Frenchman Montbars, surnamed by the terrible title of "The Exterminator"; and his countrymen, Peter of Dieppe, surnamed "The Great"—as truly, perhaps, as others so distinguished—and L'Olonnas, Michael de Busco, and Bartolomeo de Portuguez, Mansvelt, and Van Horn. Preeminent, however, among them all was the Welshman, Henry Morgan, who organized fleets and armies, took strong fortresses and rich cities, and displayed throughout the bold genius of a born Commander. He it was that led the way for the Buccaneers to the Southern Ocean, by his daring march in 1670 across the Isthmus of Panama to the city of that name, which he took and plundered after a desperate battle. This brilliant but most unscrupulous personage was knighted by Charles II., and became Deputy Governor of Jamaica. A higher subordination of the love of gold to the passion for dominion in him might probably have made him Emperor of the West Indies, some dream of which seems at one time to have occupied his mind. In 1680 and 1689 extensive buccaneering expeditions were made to the Pacific, even as far as the coasts of China, of which the best record is preserved in the lively pages of William Dampier, himself an important partner in these bold adventures. The war between France and Britain, after the accession of William III., dissolved the ancient alliance of the French and English Buccaneers. After the peace of Ryswick, and the accession of the Bourbon Philip V. to the Spanish crown (1701), they finally disappeared, to make way for a race of mere cut-throats and vulgar desperadoes, not yet utterly extinct. The last great event in their history was the capture of Carthagena in 1697, where the booty was enormous.

BUCCELLARII.—An order of soldiery under the Greek Emperors, appointed to guard and distribute the ammunition-bread, though authors are somewhat divided as to their office and quality.

BUCEPHALUS.—The favorite charger of Alexander the Great; probably also the name of a peculiar breed of horses in Thessaly. According to tradition, Alexander in his boyhood was the first to break in the steed Bucephalus, and thus fulfilled the condition stated by an oracle as necessary for gaining the crown of Macedon. The town Bucephalia, on the river Hydaspes, in India, was founded near the grave of Bucephalus, which died during Alexander's Indian Expedition.

BUCK-AND-BALL CARTRIDGE.—A small-arm cartridge containing a round musket-ball and three buckshot, formerly much used in smooth-bore muskets.

BUCKLE.—A metal instrument, consisting of a rim and tongue, used for fastening straps or bands in equipments and harness. In the latter half of the last century the manufacture of buckles was carried on most extensively in Birmingham, there being at one time not less than 4000 people employed in that town and its vicinity, who turned out 2,500,000 pairs of buckles annually, at the average value of 2*s.* 6*d.* per pair.

BUCKLE PROJECTILE.—In this projectile, a cup of lead at the base of the shot is held in place by a thin brass sleeve which is forced into the grooves of the gun.

BUCKLER.—In old armor, a kind of shield worn on the left arm. The bucklers worn by the *hastati*, or spearmen, among the ancient Romans, were about 4 feet long by 2½ in width, made of boards, covered on the inside with linen and sheepskin, and on the outside with iron plate. In the Middle Ages the buckler was round, oval, or square in shape, and was frequently made of wicker-work or of hide, strengthened by metal plates.

BUCKSHOT.—A kind of leaden shot, larger than swan-shot, now used in hunting game, but formerly used in military service. Those employed for making musket-cartridges weighed about 160 or 170 to the pound: 15 (sometimes 12), or a caliber .69 ball and 3 buckshot, were put in a cartridge. Buckshot are usually made by molding or compression.

BUCKSHOT-CARTRIDGE.—A cartridge usually containing 12 buckshot, arranged in four layers. The layers are kept in proper position by passing one half-hitch of the choking-thread between every two layers; the thread is firmly secured by passing two half-hitches around the upper layer. For rifle-arms, the shot-end of the cartridge should be dipped in the composition commonly used for lubricating bullets; with this precaution all leading of the grooves will be avoided. In the United States buckshot-cartridges are principally used in Indian warfare, and especially in night-firing. Until very recently, they were much used in military service, and were adapted to a variety of arms.

In England this cartridge is used with the Snider arms of .577 bore. The cartridge for the muzzle-loader consists of two paper cylinders, one containing 2½ drams of R. F. G. powder, the other containing 12 buckshot, weighing about 220 to the pound. Buckshot-cartridges for the breech-loaders are similar, and are issued to convict-warders. See *Multiball Cartridge* and *Wright Multiball Cartridge*.

BUCKSKIN.—A fanciful name for a heavy-made, strong-twilled woolen fabric for military trouserings, highly milled to about the usual width for such goods—27 inches; and cropped and finished, with the pile or nap so shorn as to show the texture through it.

BUDGE-BARREL.—A small copper-bound barrel having only one head, its mouth being closed by a leathern bag with a cap and draw-string. It is used for supplying the guns of forts and siege-batteries with cartridges from the magazine.

BUFF.—The leather of which belts and certain equipments are usually made. The following is the process pursued in its preparation:

Buff or "losh" leather is manufactured chiefly from the hide of the buffalo. The process of softening, removing the hair, cleansing, etc., is precisely the same as that for common leather (*vide* Leather), until the "pelt" is ready for tanning, when it has to be prepared for a process of oiling. This is done by carefully removing or forcing off the upper grain of the hide, which renders both sides of it as nearly alike as possible. The hides are then subjected to the process of "branning," that is, being steeped in fermented bran from four to twelve hours, according to the atmosphere. They are then wrung out or scraped over, and subjected to the pulling-mill or stocks for two or three hours; afterwards they are spread out and oiled. Cod-oil is the best for this purpose. The oiling is repeated during the first three or four days until each hide has absorbed ¾ of a gallon. For the following three weeks the hides are subjected to alternate soaking and drying, in which great care and attention are required. They are then exposed to a heating process, in hot-houses prepared expressly for the purpose, for two or three days, the heat not exceeding 130° Fahrenheit. Having arrived at this stage, the oil has now to be extracted, which is effected by a solution of potassa, in mills constructed for this purpose. The buff is next carefully cleaned from all alkaline matter by frequent washings, and each hide hung up separately to dry. The facing or surface is completed by rubbing both sides with pumice-stone, and the buff is then in a fit state to be cut up into accouterments.

BUFFALO.—An animal of the ox tribe, very useful as a pack-animal. It is a native of the East Indies, where it has long been domesticated, and whence it was carried to Egypt and the south of Europe. It was introduced into Italy about the close of the sixth century, and is now very generally used as a beast of burden in that country, as it is also in India. It is used in India to a very great extent by the military in field operations. See *Pack-animals*.

BUFF COAT.—A close military outer garment, with short sleeves, and laced tightly over the chest, made of buffalo-skin, or other thick and elastic material, worn by soldiers in the seventeenth century as a defensive covering.

BUFFER.—A contrivance, as applied in the service of artillery, for checking the recoil of heavy guns. The hydraulic buffer consists of a wrought-iron cylinder, closed at one end, the other end fitted with a cap and stuffing-box, through which a piston-rod-passes. The piston fits well into the cylinder, and is perforated with four small holes, the size of which varies with the size of the gun. The cylinder is filled with Rangoon oil or with water, enough air-space being left to act as an elastic buffer, which takes off the violence of the first impact of the piston on the oil. The cylinder is firmly attached to the platform on which the carriage recoils, and the end of the piston-rod to the carriage itself; so that on the discharge of the gun, the carriage drives the piston through the oil or water with great velocity, gradually bringing the gun and carriage to rest in the required distance. See *Hurter* and *Pneumatic Buffer*.

BUFFING AND POLISHING MACHINE.—One having a wheel covered with buff-leather, though not usually made out of cow-hide. The leather holds the polishing material, crocus, rouge, or what not. Buffing has come to mean polishing, from the derived name of the material which is used in applying the polishing material.

BUFFINGTON MAGAZINE-GUN.—This gun belongs to that system in which a fixed chamber is closed by a movable breech-block, sliding and rotating, and operated by a lever from below. The receiver, to which the barrel is attached in the usual way, has a vertical slot entirely through it for the reception of the breech-block, and two grooves, at right angles to each other, on the inner surface of each side. In these grooves the flattened ends of pivots passing through the breech-block slide. The various points of the breech-block, not in the axes of the pivots, thus describe arcs of ellipses when the block is opened or closed. The block is hollowed out to receive the hammer, mainspring, etc. The hammer is slotted to receive one branch of the mainspring which abuts against a pin. The other branch bears against a similar pin through the breech-block. The piece is locked by lugs projecting from pieces screwed to the sides of the receiver, partly across its top and entering grooves on the hammer. The firing-pin is retracted, when the block is unlocked or the hammer cocked, by a slot which receives the head of the pin. The extractor is a bent spring hook secured at its rear to the breech-block by a pin and supported at its front by a pivot. In order to open the block, it is necessary to draw back the hammer to a point a little beyond the full cock, and then control the motion by a lever. Should the hammer be let down while the block is open, it is cocked in the act of closing by the edges of a surface striking on projections on the inner rear surface of the receiver. The magazine is in the tip-stock. It is provided with two cartridge stop-springs. The carrier is made of sheet steel brought to a spring temper, and is secured to the breech-block by a pivot. When the breech-block is closed the carrier-block descends, its spring keeping it in contact with the breech-block, bears down on a stop spring, and slides under the end of the magazine-tube. As it passes under the tube inclined planes raise the ends of a cross-piece riveted to the stop-spring, when a cartridge is forced by the magazine-spring into the carrier. A cut-off enables the piece to be used as a single-loader. As a magazine-gun, three motions are necessary to operate, viz., opened, closed, fired. As a single-loader, four motions are necessary, viz., opened, loaded, closed, fired. This gun carries six cartridges in the magazine and one in the chamber. See *Magazine-gun.*

BUFF JERKIN.—Originally a leathern waistcoat; afterwards one of a buff color, worn as an article of dress by Sergeants and Catchpoles; used also as a dress.

BUFFLETIN.—A stout covering for the body, having a very high stock. It took the place of the cuirass in Germany and in France during the Thirty Years' War.

BUFF-STICK.—A wooden stick covered with buff-leather, used by soldiers in cleaning their equipments.

BUGLE—BUGLE-HORN.—A very old Saxon horn, now used by many infantry regiments. By its soundings their maneuvers are directed, either in advancing, skirmishing, or retreating. The calls to quarters and academic duties, at the United States Military Academy, have for many years been sounded on the bugle.

BUGLER.—One who plays the bugle. In the United States service the buglers are enlisted men, in the Drum Corps or attached to Companies.

BUILT-UP GUNS.—No modern theory of constructing guns can be called new, since guns are in existence that have been either recovered from wrecks, or preserved in other ways, showing every variety of coils, hoops, casting, wire-binding, and so on, as far as the appliances then in use could furnish the quondam inventors with means of carrying their inventions into effect. That in which novelty has been attained is the improvement of processes by which large castings or forgings, accurate turning and boring, can be secured, or by which chemical knowledge can be brought to bear on the manipulation of metals; but no such progress can make a built-up gun, or machine of any sort, stronger than a perfectly homogeneous one, in which the varying strains are closely calculated and properly met by the scientific disposition of the necessary strength. The terms "built-up" and "hooped" are applied to those cannon in which the principal parts are formed separately and then united in a peculiar manner. They are not necessarily composed of more than one kind of metal; some of the most important are made of steel alone; and they may be made by welding or by screwing the parts together, and by shrinking or forcing one part over another. The object of this method of manufacture is to correct the defects of one material by uniting with it opposite qualities of the same or other materials. The defects which follow the working of large masses of iron or steel, such as crystalline structure, false welds, cracks, etc., are avoided by first forming the parts in small masses of good quality and then uniting them separately.

In considering the effect upon a yielding material of any force which may be applied, the rate of application of the force, or the time which elapses from the instant when the force begins to act until it attains its maximum, should not be neglected; for, with equal ultimate pressures per square inch of surface, that force will be most severe upon the gun which attains this pressure in the shortest period of time. The most obvious method of enabling a gun to sustain a greater elastic pressure is simply to thicken its sides, thus increasing the area of the parts to be torn asunder. This rule has been found to work practically with guns of small caliber; but in larger guns it does not work, from the fact that, in cast guns, of whatever metal, the outside helps but very little in restraining the explosive force of the powder, the strain not being communicated to it by the intervening metal. The consequence is that, in large guns, the inside is split while the outside is scarcely strained. This split rapidly increases, and the gun ultimately bursts.

If we take any transverse section of a gun, any unit in length, and suppose the metal to be divided into any number of concentric rings, it will be evident that the greater the distance of any ring from the axis of the gun, the less will it be stretched by the expansion of the bore when the piece is discharged, and consequently the less will it contribute to the general strength of the gun. If the strain upon the bore from the discharge be considered merely as a pressure—statical force—the resistance offered to it by any two rings will be inversely proportional to the square of their circumferences or distances from the axis of the gun. It will, therefore, appear that there is a certain limit beyond which it would be useless to increase the thickness of the metal; viz., when the force exerted on the surface of the bore would be sufficient to rupture the interior portions of the metal before the strain acted to any extent upon the exterior parts. Any arrangement of the parts by which the explosive strain is distributed equally over the entire thickness of the piece necessarily brings a greater amount of resistance into play. In order to obtain the requisite resistance, and with a moderate thickness of metal, it is desirable to equalize, as far as possible, the strain upon every portion of the metal.

There are two general methods of accomplishing this, viz.: first, by giving the exterior portions a certain *initial tension*, gradually decreasing and passing into compression towards the interior, which is done by shrinking heated iron bands or tubes around the parts to be compressed, or by slipping a tube into the bore, which has been slightly enlarged by heat; secondly, by means of the system of *varying elasticity:* this is accomplished by placing that metal which stretches most within its elastic limit around the surface of the bore, so that by its enlargement the explosive strain is transmitted to the other parts. These two methods of equalizing strains without an inordinate increase of thickness are so important that they deserve more than a passing notice. They are called the systems of Initial Tension and Varying Elasticity. Some gun makers use the one, some the other, some a combination of the two, and even in our own hollow-cast guns the idea of initial tension is one of primary importance.

It will be observed that built-up gun-constructions are alone considered as affording a reasonable solution of the problem; that steel tubes in combination with wrought-iron or steel constitute the prominent types; that breech-loading systems, using the interrupted screw or French pattern, are rapidly superseding muzzle-loading guns; and, finally, the more advanced opinions lead strongly to the belief that the true direction in which progress is to be made and light guns secured, combining great strength with high power, resulting from the use of large charges of powder and heavy projectiles, and in bores ranging from 26 to 30 calibers in length, is to introduce a greater degree of subdivision than found in the present systems by the use of steel wires superimposed on steel tubes, which in their turn are jacketed and finished externally by steel bands. See *Armstrong Guns, Blakely Gun, Cannon, Fraser Gun, Initial Tension, Ordnance, Palliser Gun, Parsons Gun, Varying Elasticity*, and *Woolwich Gun*.

BUKORS.—Kettle-drums of the Swedish cavalry. They do not differ materially from the usual kinds.

BULLARD RIFLE.—A repeating rifle recently introduced by a Mr. Bullard, who was for five years master-mechanic at the well-known Smith & Wesson Works. The action of this rifle is positive and not dependent upon springs. It is self-cocking, with a solid breech-block behind the bolt, which must be in place and securely locked before it is possible for the hammer to reach the firing-pin. It is possible to fire this rifle with very great rapidity, from the fact that it works easily and smoothly by reason of its direct leverage on the work to be done, the heaviest work being done with the best leverage, as in extracting the cartridge, which is started when the lever is in position to exert the greatest strain. Cocking the hammer is also done by direct leverage inside the receiver or frame instead of a sliding motion of bolt or firing-pin on and over the top of the hammer, which is very often liable to grind and always makes the arm work hard and unpleasantly. This rifle has been fired twelve shots in five seconds, using the U. S. Government cartridges. The magazine is charged from the under side, and it can be done with equal facility by a right- or left-handed person. And as there are no holes or spring covers on the side, it is not possible to have it clogged by passing through brush or laying it on the ground or in trenches, etc. It is also much easier to load on horseback than any other gun, as there is more choice of position than when the opening is on the side. It can be loaded as a single-loader either top or bottom, leaving the magazine full at all times for an emergency. The drawing shows the working parts of the arm, in position after firing. The breech-block, A, is held firmly in place by the brace, C, which is pivoted and cradled on the hammer-pin and lock-frame. C is brought into place and firmly held by the links, B (only one shown), which are connected by strong pins to the guard-lever, D. It will be seen from the drawing that it is absolutely impossible to get the hammer to strike the firing-pin until the brace, C, is in its proper place. It will also be observed that it is impossible to disarrange the parts, as all are pinned and hinged together, and that there are no sliding surfaces.

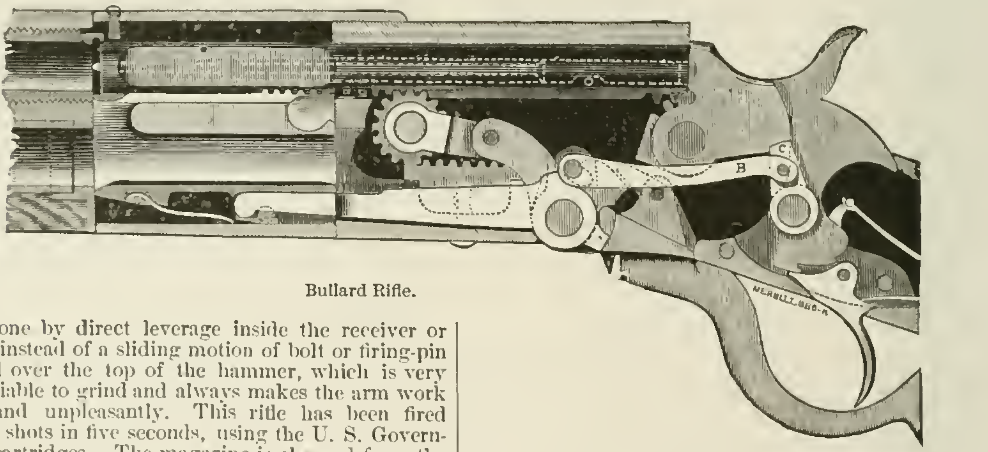
To dismount the gun, take out tang-screw: half-cock hammer and take out lock-frame and hammer-screws; pull out lock-frame down and backwards; disconnect links from brace; take out side-plate screws and remove side plate; remove carrier-lever spring; take out guard-lever bolt; take cut extractor-pin and remove extractor; push back pin before removing the bolt; draw out guard-lever with its connections; take out breech-block bolt; take out breech-block; draw out carrier-lever and take out carrier. The gun is assembled by reversed operations.

To remove the barrel, take out the magazine-plug screw and the two tip-screws, pull out the magazine-tube, and take off the fore-arm. If the bolt has not been previously removed, pull it back so as to prevent the breaking of the extractor while unscrewing the barrel.

To load the gun, carry the guard-lever forward as far as it will go, and then insert the cartridges in the magazine through the opening under the carrier.

To use the gun as a single-loader, carry the lever as far forward as is necessary to extract the spent shell, remove the shell, and insert another cartridge in the chamber of the gun; or, carry the guard-lever as far forward as it will go and insert a cartridge in the magazine through the opening under the carrier.

If the top cover is drawn back, the magazine can be quickly loaded by simply pressing against the under side of the carrier, which will force it up, exposing the entrance to the magazine, and also place the hammer at half-cock. See *Magazine-gun*.



Bullard Rifle.

BULL-DOG.—A refractory material used as a lining for the boshes of puddling or smelting furnaces. It is a decomposed protosilicate of iron.

BULLET.—The leaden projectile discharged from a musket, fowling-piece, pistol, or similar weapon. When the smooth-bore muskets alone were used, the bullets were made by casting. Molten lead was poured into molds; and the molds were dipped in cold water, to hasten the solidification of the lead. The molds were cooled after every few times of using; and the lead was heated only just to the degree for maintaining fluidity. Bullets are now, however, made more expeditiously, and more truly spherical in form, by compressing-machines, one form of which has been invented by Mr. George Napier. The lead is first fashioned into a rod about a yard long by five or six eighths of an inch thick; this rod is passed between rollers to condense it; then between other rollers to press it into a row of nearly globular pieces; then a spherical die gives the proper form to each of these pieces; and, lastly, a treadle-worked punch separates them into bullets. With one of these machines and two dies, nine boys can make 40,000 bullets in a day.

Spherical bullets for the old muskets, carbines, and pistols varied from 14 to 20 to the pound, and from .60 to .68 of an inch in diameter. There is a particular ratio, depending on the specific gravity of lead, by which the number to the pound will give the diameter, or *vice versa*. Such bullets are, however, becoming every year less and less used in the army, being superseded by other forms better suited for rifles. These forms are singularly numerous. Robins' bullet was egg-shaped, with the center of gravity at the larger end; Beaufoy's was ovoid, with a hemispherical cavity at one end; Manton's was a spherical ball put into a wooden cup, with projections on the exterior; Greener's was oval, with a plug of mixed metal driven into a hole barely large enough for it; Norton's, Delvigne's, Minié's, and others are, or were, of various elongated shapes, mostly with some kind of plug, which, driven into the lead by the force of the explosion, causes it to fill up the grooves in the rifling of the barrel. This expanding or dilating action has been claimed by many inventors; but the English Government in 1857 awarded Mr. Greener £1000, as the person who had practically solved the difficulty as far back as 1836. The bullets for the Enfield rifles are now made with extraordinary speed, by machinery of beautiful construction. The machine draws in a coil of leaden rod, unwinds it, cuts it to the required length, stamps out the bullets with steel dies, drops them into boxes, and conveys them away. Each machine, with its four dies, makes 7000 bullets per hour; and four such machines, in an easy day's work, turn out 300,000 bullets. So nearly are the machines automatic that one man can attend them all. Other machines, attended by children, produce an equal number of little boxwood plugs for filling the cavity at the hinder end of the bullet. See *Oblong Bullet*, *Percussion-bullets*, *Projectiles*, *Round Bullet*, and *Shot*.

BULLET-EXTRACTOR.—A pair of pinchers with projecting claws, adapted to imbed themselves in a bullet so as to draw it from its bed and extract it. When closed these form a smooth, blunt surface, like a probe, and are opened against the bullet so as to spread apart the vessels which might oppose the retraction.

BULLET-HOOK.—A hook-ended tool for extracting bullets. An iron bullet-hook was disinterred at Pompeii in 1819 by Dr. Savenko, of St. Petersburg. It was in company with a number of surgical instruments.

BULLET-LADLE.—One for melting lead to run bullets. It is usually a hemispherical ladle with a spout, but in one case the ladle has a hole in the bottom guarded by a spring plug and operated by a trigger on the handle; in another case a part of the ladle is covered, and the lead thus flows out at a guarded opening which keeps back the dross of oxide.

BULLET-MOLD—BULLET-MOULD.—When the smooth-bore muskets alone were used, all bullets were made by casting or molding. Molten lead was poured into molds of the desired shape; and the molds were dipped in cold water, to hasten the solidification of the lead. The molds were cooled after every few times of using; and the lead was heated only just to the degree for maintaining fluidity. Very few bullets are molded at the present time, since they are made more expeditiously, and truer in form, by compression. When molding, use 1 part of tin to 16 of lead, and keep the molds very hot and the handles tight together. It often happens that the handles become too hot for comfort and are not held together properly. The result is a bullet that is not round and one that will not fit the shell. See that the grooves of the bullets are filled with beef-tallow or Japan wax; wipe off all surplus grease before loading. When pressing the bullet into the shell, see that it is forced into the chamber of the reloading tool as far as it will go.

The drawing represents an effective mold. The

Bullet-mold.

melted lead is poured into the mouth at the top, is trimmed just as solidification begins, and the mold is locked by pressing the handles towards each other. After solidification the handles are pressed apart, the mold opens, and the bullet is withdrawn. After the bullet is taken from the mold it is swaged in a die to the proper size and shape.

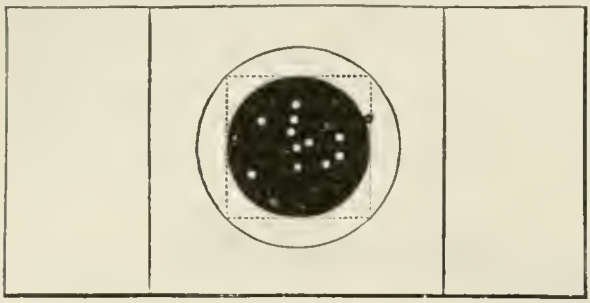
BULLET-PROBE.—A sound for exploring tissue to find the situs of a bullet. It is usually a soft steel wire with a bulbous extremity. Nelaton used a sound with a file-like extremity which might receive traces of the bullet, in cases where there is doubt of the character of the body with which it is brought in collision. He afterwards used a *sonde* with a termination of an olive-shaped body of white unvarnished porcelain, which would receive a black mark by contact with the bullet.

BULLET-SCREW.—A screw at the end of a ramrod to penetrate a bullet and enable the latter to be withdrawn from the piece. See *Ball-screw*.

BULLET-SHELL.—An explosive bullet for small-arms. Jacobs's bullet-shells, used with the rifle of General Jacobs of the East India service, have an inclosed copper tube containing the bursting-charge, which may be of fulminate or common powder, and is exploded by a percussion-cap or globule on striking In experiments made with them at Enfield in 1857, caissons were blown up at distances of 2000 and 2400 yards, and brick walls much damaged at those distances by their explosion.

BULLOCK.—This beast is admirable for slow draught, especially over rough roads, or through forests, or other places where there are no roads. Bullocks stand fire better than any other animals, and used to be employed in India for draught in field-batteries. They must not be hurried; their ordinary pace is from 2 to 2½ miles an hour. If used over hard roads they require shoeing. They need but little care, and thrive on poor food. They attain their prime at six years; the age is known by the annular swelling on the horns, allowing three years for the first ring and one year for each of the others. They are at present used in many parts of India and elsewhere as pack-animals, and carry a load of 200 pounds with comparative ease. See *Draught-animals* and *Pack-animals*.

BULL'S-EYE.—In gunnery and archery, the center of the target. In England the bull's-eye is a black rectangular figure on a white ground which is painted on targets, varying in size according to the distance at which the target is placed, and according to the class of marksmen firing at it. Outside the bull's-eye is a white space bounded by rectangular black lines. The space within these lines and between them and the bull's-eye is called the center. Outside these lines is the remainder of the target. In the United States the smallest circle, always painted black, is called the bull's-eye. The ring embraced between the bull's-eye and the circumference of the next larger circle is called the *center;* and the ring between the second and third circles (regulation target) is called the *inner*, the space outside the larger circle being called the *outer*. In the target represented, the space between the second circle and the vertical lines is the *inner*, and the space outside the vertical lines is the *outer*. See *Targets*.



Bull's-eye.

BULWARK.—The old name for a rampart or bastion. In a ship the bulwarks are the boarding above the level of the upper deck, nailed to the outside of the timber-heads and stanchions. In ordinary vessels they form a parapet, protecting the seamen from the waves, and prevent loose articles from being swept off the deck; in men-of-war they, in addition, serve to protect the men from an enemy's shot. In an inquiry made a few years ago concerning the availability of merchant-steamers as ships of war, it was found that the bulwarks would not afford sufficient protection to the men from musket-shot; but that if hammock-stanchions were fixed all round the bulwarks, and the men's hammocks placed in a netting upheld thereby, a very good protection might be obtained.

BUMFORD GUN.—A celebrated gun cast at South Boston in 1846. It is a 12-inch smooth-bore, having the following particulars:

Total length................	134.00 inches.
Length of bore and chamber.	116.20 "
Diameter over the chamber..	38.20 "
Weight.....................	25,510 lbs.

Before it was hooped the greatest enlargement of the chamber with 20, 25, and 28 pounds of powder and a 150-pound shell, after ninety-three fires, was .005 inch, and the greatest enlargement at the lodgment of the shell .074 inch. The maximum range in ricochet-fire, with 181-pound shell and 28 pounds of powder, was 5800 yards. This gun was hooped in 1862 with wrought-iron rings about 1 inch wide each, making a reinforce 31¾ inches long, 4 inches thick, and 46 inches in total diameter.

BUNG-STOPPERS.—In submarine mining, bung-stoppers are the contrivance for closing the hole in the case through which the charge is inserted, and through which the insulated wires pass from the fuse to the cable leading to the fort. The essential condition to be fulfilled is to have it water-tight and keep the arrangement in proper condition for ignition at any moment required; it should likewise be capable of being unscrewed, so that the fuse may be taken out for examination and replacement if defective.

Various forms of stoppers have been devised, the principal feature of each being a stuffing-box, in which gutta-percha packing is used. When regularly-constructed mines are supplied for service, stoppers will accompany them. For extemporized mines, any device which will hold the insulated wires and at the same time keep the water from the charge will answer. A composition composed of 1 part of tallow, 8 of pitch, and 1 of beeswax will be found good for tightening the joints. It becomes plastic at about 150 F. The addition of a little gutta-percha hardens the composition and renders it less liable to be affected by atmospheric heat.

BUNK.—The term employed by soldiers for a bed, or place for bedding.

BUNTINE.—A thin woolen material, of which flags and signals of stations are made. Also written *Bunting*.

BUOYS.—Buoys are used for temporarily marking the positions of mines, circuit-closers, etc. Small nut-buoys of iron are the best; but when these are not to be had, empty casks, such as beer-kegs, well lashed with rope, are convenient to handle, and answer every purpose. In all cases they must be sufficiently large, or have enough of flotation, to secure the mooring-cable or other object which they are intended to hold.

BURDEN OF PROOF.—In legal procedure, the obligation to establish by evidence certain disputed facts; and, as a general rule, this burden lies on the party asserting the affirmative of the issue to be tried or question in dispute, according to the maxim, *Ei incumbit probatio qui dicit non qui negat;* that is, proof is incumbent on him who asserts, not on him who denies. The principle of the law is that the burden of proof is on the party who would fail if no evidence were adduced on either side. Accordingly, it almost always rests on the plaintiff in an action, or on the party asserting the facts on which the result of the litigation must depend. In one case tried before the late Baron Alderson, that learned Judge laid down that the proper test was, *Which party would be successful if no evidence at all were given?*—the burden of proof, of course, falling on the party not in that position. This test has since been generally adopted and applied; but Mr. Best, in his work on the *Principles of Evidence*, improves on it by the suggestion that in strict accuracy the test ought to be, "Which party would be successful if no evidence at all, *or no more evidence*, as the case may be, were given?"—a consideration on which the discretion and judgment of counsel frequently depend. But although such, in general, is the position of the plaintiff, it sometimes happens that the burden of proof is imposed on the defendant, and in consequence of his having the affirmative of the material issue to be tried.

It is this rule as to the burden of proof that demonstrates the real nature of the plea of *Not Guilty* in a criminal prosecution, and which divests that plea of the objections to it which are frequently heard expressed by overscrupulous sentimentalists; for the meaning of that plea is not necessarily an assertion by the prisoner that he is absolutely guiltless or innocent, but that he wishes to be tried, and that as the burden of proof is on the prosecutor, while he has meanwhile the presumption of innocence in his favor.—Besides the work referred to, see on the subject of this article Starkie on the *Law of Evidence in England*, and Dickson on the same subject in Scotland.

BUREAU OF MILITARY JUSTICE.—In the United States service this Bureau consists of one Judge Advocate General, with the rank, pay, etc., of Brigadier-general. The reports which the Judge Advocate General may make upon cases requiring the action of the President are addressed to the Secretary of War, and forwarded through the General of the Army, for such remarks and recommendations as he may see fit to make. The original proceedings of all General Courts-Martial, Courts of Inquiry, and Military Commissions, after the decision thereon of the reviewing authority, and all proceedings that require the decision of the President under the Articles of War, and copies of all orders confirming, disapproving, or remitting the sentence of Courts-Martial or Military

Commissions, are forwarded direct to and filed in the Bureau of Military Justice. Communications relating to questions of military justice, or proceedings of Military Courts, upon which the opinion of the Judge Advocate General is desired, are forwarded through proper channels to the Adjutant General when such questions cannot be decided by an intermediate authority. Questions of an abstract, general character are not considered. Judge Advocates forward to the Judge Advocate General, at the end of each month, a list of all cases tried and to be tried within their jurisdictions. See *Judge Advocate General.*

BUREAUX OF THE WAR DEPARTMENT.—During the absence of the Chief of any Military Bureau of the War Department, his duties in the Bureau, prescribed by law or regulations, devolve upon the officer of his Department empowered by the President to perform them in his absence. See Military Departments throughout this work under appropriate headings

BURGESS MAGAZINE-GUN.—This gun belongs to that system in which a fixed chamber is closed by a bolt, sliding in line with the axis of the barrel, and operated by a lever from below. The bolt is a single piece, the rear of which serves as a guide to its motion by sliding in grooves on the inner surface of the receiver. The bolt is locked by the interposition of a portion of the breech-bolt lever, between its head and the rear of the receiver. The firing-pin, which is in this portion of the lever, passes through the pivot and prevents it moving either way. The firing-pin is retained in the lever by a screw. The ejector lies in a groove across the front of the bolt, just below the firing-pin hole; its rear terminates in a split spring, which, by friction against the side of an undercut groove in the side of the bolt, retains it in position. The ejector is driven forward against the under side of the head of the cartridge, when the lever is thrown open by its rear striking against a shoulder on the inner rear surface of the receiver. The bottom opening in the receiver is closed by a plate, called the lever-guide; its rear is terminated by a piece the tenon of which enters a corresponding mortise in the plate. An elongated hole in the tenon, through which passes the pin connecting the pieces, permits motion of the smaller part to and from the plate. A spiral spring is comprised between the two pieces. The motion of the lever in opening and closing is a sliding one. The carrier is pivoted on two short screws through the sides of the receiver. It is operated by a hooked projection on the bolt-head, which, sliding under it, supports it until the forward motion of the lever is nearly completed, when, by striking against the surfaces, the carrier is rotated about the pivot-screws, its front descending opposite the mouth of the magazine, which is in the tip-stock. When the lever is closed, the projecting hook, passing out of the recess, slides under the carrier, raising it to a position parallel to the axis of the barrel, when its upward motion is limited by pins projecting from the inner surfaces of the receiver. The hammer is cocked by the backward motion of the bolt when the lever is thrown forward. The piece is fired by a center-lock of the usual pattern. The magazine is loaded through a side cover in the receiver. No wiping-rod is provided, and there is no cut-off to the magazine. As a magazine-gun, three motions are necessary to operate it, viz , opened, closed, fired. As a single-loader, four motions are necessary, viz., opened, loaded, closed, fired. This gun carries ten cartridges in the magazine and one in the chamber. See *Magazine-gun.*

BURGONET.—A helmet that dates from the end of the fifteenth century. It has a rounded crown with a crest, and is distinguished by a shade over the eyes, cheek-pieces, and a neck-guard. Also written *Burganet* and *Burgonette.*

BURGOYNE.—An instrument formed by the combination of a spade, axe, and mantlet. It is intended to form a portion of the equipment of a soldier, and to be used for digging rifle-pits, etc. When used as a mantlet against bullets, the soldier fires through a small hole in the blade. The handle is jointed to facilitate packing.

BURLEY.—A common name for the butt end of a lance.

BURNING.—Joining metals by melting their adjacent edges, or heating the adjacent edges and running into the intermediate space some molten metal of the same kind. The process differs from soldering in this: In burning, a heat is required sufficient to melt the original metal, and a flux is seldom used. In soldering, a lower heat is used and a more fusible metal employed, assisted by a flux. The superior quality of *burning* arises from the fact that the joint will withstand the same heat as the body of the article. Cast-iron is frequently united by burning. It was first practiced by the native smiths of India and China, who occasioned much surprise to their Occidental neighbors by the way in which they mended cast-iron kettles and pots which were supposed to be irretrievably ruined. The first notice of it by Europeans appears to have been by Van Braam, in 1794–95, who was attached to the Dutch Embassy at Pekin, and who afterwards settled in the United States.

BURNISHING.—The process of giving a peculiar luster to a gun-barrel or other part of a rifle by rubbing it with a piece of steel. It is generally forbidden in the service as injurious to the gun.

BURNS AND SCALDS.—These injuries are not unfrequent in the laboratory and field. They are much the same in both cases; therefore the directions for the treatment of burns will be applicable also to scalds. These injuries may be divided into three classes: 1. Burns resulting in simple redness of the skin; 2. Burns resulting in vesication or blistering; 3. Burns resulting in sloughing, or death of the part. The first object, after the accident has occurred, is to relieve the suffering; and cold applied either in the form of ice or water seems in most cases to have almost a specific power in allaying pain and checking the advance of inflammation. In other cases moderate warmth is found more efficacious, and we must be guided mainly by the sensations of the sufferer as to which of these remedies we make use of. In very severe cases opium or chloroform may be employed. But if the injury the body has received be very serious, the patient complains less of pain than of cold; he shivers, is much depressed, and must be well supplied with stimulants, to prevent his dying from the shock. The best local application is the Carron oil, which derives its name from the famous iron-works, where it has been used for many years. It consists of equal parts of olive-oil and lime-water, and should be applied on linen rags or cotton-wool. Blisters may be pricked and the contained serum allowed to trickle away, but on no account is the raised skin to be removed. The dressings should not be changed oftener than cleanliness requires; and as each portion of the old dressing is removed, it must at once be replaced with fresh, so that as little exposure as possible of the burned surface may take place. The main principle of treatment is exclusion of the air from the injured part; and so long as this is effected, it matters but little what remedial agent is employed. Great care must be taken in the treatment of a sore resulting from a burn, that the contraction of the scar does not cause distortion of the neighboring parts.

BURNSIDE CARBINE.—An arm formerly used in the military service. It has a movable chamber which opens by turning on a hinge. A brass cartridge-case is used which packs the joint and cuts off the escape of the gas. The advantages of this arm are its strength, waterproof cartridges, perfectly tight joint, and working machinery. Its disadvantages are the cost, and difficulty of getting the cartridges. When first made, the metallic case of the Burnside cartridge (either of brass or steel) was capped at the larger end with a lead ring. The case was slightly conical, with a small hole at the smaller end. The manner of inserting the cartridge and extracting the shell after firing was similar to that employed at the present time. See *Carbine.*

BURNT UMBER.—A pigment of a russet-brown color. It is semi-transparent, mixes well with other pigments, and dries quickly. It is obtained by burning umber, an ocherous earth containing manganese, and deriving its name from the place where it was first discovered—Umbria, in Italy.

BURQUE.—A kind of cuirass which in ancient times was worn with the brigantine.

BURR.—1. In gunnery, a round iron ring which serves to rivet the end of the bolt, so as to form a round head. 2. Any roughness or unevenness observed in the barrels of guns after manufacture, or on balls which have been cast, or on the edge of tools when ground, or in wood-work when turned, caused by the inequality of the fibers of the material.

BURREL-SHOT.—A medley of shot, stones, chunks of iron, etc., to be projected from a cannon at short range. Frequently called *emergency-shot.*

BURSTING-BAGS.—Bags for the bursting-charges of common shell. In order to prevent the liability to occasional premature bursts when firing filled common shells from M.L.R. guns of 7-inch caliber and upwards, it has been found necessary to inclose the bursting-charge in a serge bag.

BURSTING-CHARGE.—1. A small charge of fine powder, placed in contact with a charge of coarse powder or nitroleum to insure the ignition of the latter. It is usually fired by voltaic means.—2. The charge of powder required for bursting a shell or case-shot; it may be poured in loose, or placed in a *burster-bag.*

BURTON.—A peculiar style of tackle. It has at least two movable blocks or pulleys and two ropes. The weight is suspended to a hook-block in the bight of the running part. This arrangement of cords and pulleys is susceptible of great variation, so as to increase in a twofold, fourfold ratio, or otherwise. Each pulley has but one sheave, and there are as many ropes as movable pulleys.

BURTON MAGAZINE-GUN.—In principle this gun does not differ from the Ward-Burton. The points of difference in construction are as follows: The joint between the body of the bolt and its head is transferred in this gun to the rear, so that the body of the bolt takes the place of the head, while the rear portion serves simply to lock it. As the body of the bolt does not rotate, the sear-bolt slot at right angles to its axis is dispensed with, giving, it is claimed, a stronger bolt. The extractor, though called a lever-extractor, is a spring hook pinned to the bolt near its front. The rear of the extractor is thickened so as to bear against a cam on the firing-pin, which prevents the descent of its rear with the corresponding rise of its front. In withdrawing a shell the spring can only be from the front portion alone. The trigger-spring serves also to hold the carrier in place. The carrier is composed of two principal parts, separated at front by a flat spring. The lower portion, which is pivoted at its rear to the upper, has on its front a sort of finger, which may be made to pass through a slot in the upper portion so as to project partly across the mouth of the magazine, cutting off the escape of cartridges by simply turning a set-screw in rear of the pivot. The motions are the same as in the Ward-Burton. This gun carries eight cartridges in the magazine and one in the chamber. See *Magazine-gun.*

BUSBY.—The head-dress worn by the artillery and hussars in the British army. It consists of a fur hat, with a bag hanging from the top over the right shoulder. The bag, which is made of the same color as the facings of the regiment, appears to be of Hungarian origin, and intended to ward off a sword-cut. In India the artillery whose head-dress in Europe is a busby do not wear it, but are provided with wicker helmets covered with white cloth. The head-dress worn by the fusiliers is called a "busby," and is made of black raccoon-skin for the officers, and of seal-skin for the non-commissioned officers and men.

BUSHEL.—A dry measure for grain, etc. The quarter contains 8 bushels, and the bushel 8 gallons, the gallon measuring 277.274 cubic inches, and holding 10 pounds avoirdupois of distilled water. Hence the imperial bushel contains 80 pounds of water, and measures 2218.2 cubic inches. The old Winchester bushel measured 2150 cubic inches; hence 33 Winchester bushels equals 32 imperial bushels nearly.

The following weights and estimates are often valuable when purchasing supplies in the field: One bushel of wheat weighs 60 pounds; of rye, 58 pounds; of barley, 54 pounds; of oats, 42 pounds; of beans, 62 pounds; of peas and maize, 66 pounds; of potatoes, 60 pounds; of onions, 56 pounds. About 50 pounds of wheat and 30 pounds of oats go to the cubic foot. One cubic yard of well-pressed hay weighs 225 pounds; one cubic yard of straw weighs 145 pounds; one cubic yard of grain will average 20 bushels. The following numbers of bushels will safely go to the acre; wheat, rye, and beans, 25; oats, 45; barley, 37½; peas, 25; maize, 30; potatoes, 250.

BUSHING.—When a pure copper vent is fixed in a gun, the gun is said to be *bushed.* It is done by drilling a hole in the piece where the vent is usually placed, about one inch in diameter, and screwing therein a piece of wrought copper, with a vent of ⅕ of an inch through the center of it. There are two kinds of vent-bushes—a *cone* and a *through* vent. The first is used when the gun is new, and, if practicable, when re-vented; the latter when the cone of the bush is not sufficiently large to remove the wear round the bush.

BUSHING TENTS.—A method resorted to when the soil will not hold well, or in stormy, blowing weather. It is generally necessary under these circumstances to *bush* the main outer ropes of the tent, which is effected by burying to a sufficient depth under the ground a strong bush at each angle of the tent, to which ropes are attached.

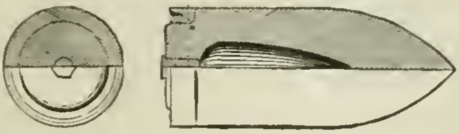
BUSHWHACKERS.—A term much in use in the War of the Rebellion (though well known before) to indicate men who pretended peace or neutrality, but who were ready to make secret attacks whenever opportunity offered. They were numerous in some Western States, where many of them were summarily shot as outlaws.

BUSKINS.—A kind of shoe, or half-boot, adapted to either foot, and formerly part of the Roman dress. They are now worn by some European armies. The ancient tragedians wore buskins (*cothurni*), often with thick soles, to add to their stature. Hence the buskin is often put for tragedy, as the sock (*soccus*, a flat-soled shoe) for comedy. In ancient sculpture, Diana, and hunters in general, as well as men of rank and authority, are represented in buskins often highly ornamented.

BUTIN.—Booty or pillage. At the beginning of the French Monarchy, and for a long time after its establishment, a particular spot was marked out by the Prince or General, to which all persons belonging to the victorious army were directed to bring every species of booty that might have fallen into their hands. This booty was not divided, or appropriated according to the will and pleasure of the Prince or General, but was thrown into different lots, and drawn for in common. The soldiers who distributed these spoils were called Butiniers.

BUTLER PROJECTILE.—This projectile consists of a cast-iron body having a double-lipped expanding ring attached by a screw-thread to its base. Upon discharge, the powder-gases entering the cannelure of the ring expand the outer lip into the grooves communicating rotation to the projectile, and pressing the inner lip tightly against the base of the projectile tends to prevent stripping. The ring may be of brass (75 parts of copper to 25 of tin) or of an alloy of copper, tin, and brass, the brass being fused with the copper.

The *Butler canister* consists of a hollow cylinder made



up of truncated iron wedges inclosed in an envelope of tin. The cylinder is closed at the bottom with a lead cup inclosing a disk of wood, and at the top with a sheet-iron plate, disks of tin being employed on the outside at both ends to facilitate soldering. The interior of the cylinder is filled with the round iron balls. See *Expanding Projectiles* and *Projectiles*.

BUTT.—1. In gunnery, a solid earthen parapet, to fire against in the proving of guns, or in practice. 2. That extremity of a musket which rests against the shoulder when the piece is brought up to the position of firing. The term *butt end* is usually employed in this sense.

BUTTERIS.—A knife with a bent shank, used by farriers to pare the hoofs of horses. It has a blade like a chisel, and is operated by a thrust movement, the handle resting against the shoulder. The term is probably from the French *boutoir;* provincial, *boutaran.* Some old Roman paring-implements of iron are yet extant.

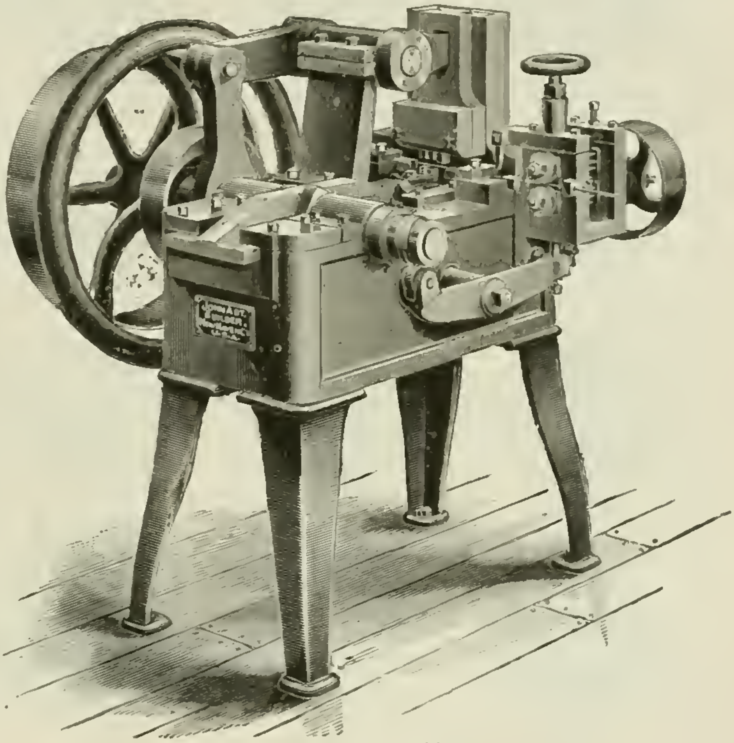
BUTTON.—1. In gunnery, a part of the cascabel, in either a gun or a howitzer, being the hind part of the piece, made round in the form of a ball.

2. A part of the uniform, used both for ornament and for buttoning. In the United States army the button is prescribed as follows:

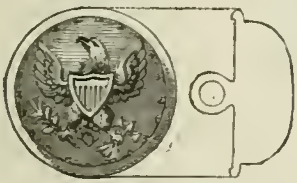
For General Officers, Storekeepers, and Officers of the General Staff.—Gilt, convex, with spread eagle and stars, and plain border; large size, seven eighths of an inch in exterior diameter; small size, one half inch.

For Officers of the Corps of Engineers.—Gilt, nine tenths of an inch in exterior diameter, slightly convex; a raised bright rim, one thirtieth of an inch wide; device, an eagle holding in his beak a scroll, with the word "Essayons," a bastion with embrasures in the distance surrounded by water, with a rising sun—the figures to be of dead gold upon a bright field. Small buttons of the same form and device, and fifty-five hundredths of an inch in exterior diameter.

For Officers of the Ordnance Department.—Gilt, convex, plain border, cross cannon and bombshell, with a circular scroll over and across the cannon, containing the words "Ordnance Corps;" large size,

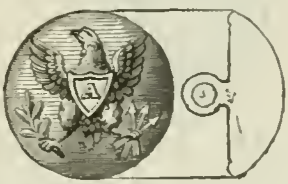


Button-shank Machine.



Staff.

Topographical Engineer.



Artillery.

seven eighths of an inch in exterior diameter; small size, one half inch.

For Officers of Artillery, Infantry, and Cavalry.—Gilt, convex; device, a spread eagle with the letter A, for Artillery—I, for Infantry—C, for Cavalry, on the shield; large size, seven eighths of an inch in exterior diameter; small size, one half inch.

Aides-de-Camp may wear the button of the General Staff, or of their regiment or corps, at their option.

For all Enlisted Men.—Yellow, the same as is used by the Artillery, etc., but omitting the letter in the shield.

The various State buttons, full size, are shown in the drawings above.

The history of button-making is in many ways a curious one. Dating no further back as a trade of any importance than the reign of Elizabeth, it has undergone several extraordinary changes, produced chiefly by the ever-varying fashions in dress, but also by some simple though ingenious inventions, as well as by foreign competition. In Great Britain, Birmingham has always been the principal seat of the button-manufacture. What has been called the "Augustan Age" of button-making in that city included the latter portion of last and the early part of the present century, when even tradesmen wore coats "loaded with innumerable gilt buttons," and when employers on a moderate scale in this manufacture were making incomes of from £2000 to £3000 a year, and their workmen from £2 to £4 per week. Early in the present century Mr. B. Sanders introduced the cloth-covered button, which initiated the change from those made of metal, and by which he rapidly made a fortune. His son in 1825 effected the apparently trivial but really ingenious improvement of making it with a canvas tuft instead of a metal shank, by which both the button-holes and the garment itself were less subject to injury. This kind of button had an enormous sale, and is still much used. A further alteration was made on it by Mr. W. Elliott, who patented in 1837 a mode of covering the button with silk, having a pattern in the center, the demand for which was at one time so great that sixty looms were employed in London in making the special material required for them. Metal buttons, although not relatively so important as formerly, have never ceased to form a prominent section of the trade. They are a numerous class, and include all sorts for uniforms, trouser-buttons, fancy buttons which are gilt, stamped, chased, or enameled, and many cheap varieties in iron and other metals for export. Numerous kinds of composite buttons are also partly composed of metal. Glass buttons form another interesting branch, carried on to a considerable extent in Birmingham, but more largely in Bohemia and Paris; so also do porcelain buttons, which, although an English invention, are now almost exclusively made in France. Vulcanite buttons have been extensively made in the United States. As to other materials, a Birmingham manufacturer says it were easy to write out a long list from which buttons have been made, but very difficult to name one from which they have *not* been made.

Briefly described, the processes in making the military brass buttons are as follows: Circular disks, called "blanks," are first cut out of sheet-brass or other metal by means of fly-presses, usually worked by girls. The fly-press consists of a vertical iron screw with a triple thread, to which screw is attached a horizontal arm, bending downwards at the end to form a handle. A punch attached to the press rises and falls with the motion of this handle, and rapidly cuts out the blanks. When large quantities of one pattern are required, a self-feeding, self-acting machine is used, which cuts out the blanks in rows at one blow, turning them out at the rate of 2000 gross per day. After being annealed, the blanks are next made convex by a blow from a stamp. The shanks are formed of wire by a separate machine shown in the drawing, which cuts off pieces and bends them into loops of the required form. When these are soldered on, the buttons are dressed on a lathe. They are then gilded and burnished; some, however, are only lackered; and some, though gilt, are finished in a dead or frosted style.—"Shell" buttons are those with a convex face, a flat or convex back, and hollow. These are made of two blanks, that forming the face being larger than the back to which the shank is attached. These blanks are pressed into the required shape by dies worked in the fly-press, and then, by another die, the edge of the larger blank is lapped over the smaller, and thus attached without soldering. Military and other buttons having a device in strong relief are stamped by a die placed in a stamping-press.

BUTTRESS.—A counterfort or sustaining wall or pillar, built against and at right angles to the wall to which it forms a revetment. In the classical style there were no buttresses, their place being to a certain extent supplied by pilasters, antæ, etc. The different stages of Gothic architecture are marked by the form of buttresses employed, almost as distinctly as by the form of the arch. The Norman buttress was broad, often semicircular, sometimes dying into the wall at the top, and never projecting from it to any great extent. Early English buttresses project much more boldly, and are considerably narrower, than the Norman. They are frequently broken into stages, which diminish in size as they ascend. In the decorated style, this division into stages is almost invariable, the buttress being often supplied with niches terminating in pinnacles, and very highly ornamented with carving, statues, etc. In the perpendicular style they retain the forms which had been introduced during the decorated period, the ornamentation of course being varied to suit the character of the style. Flying-buttresses—i.e., buttresses in the form of a sloping arch, connecting the upper and central portions of an arched structure with the vertical buttresses of the outer walls—were introduced into England at the period of the early English, though they existed on the Continent previously, where they continued to be used to a greater extent. They were also very common in Scotland. In England they are generally called arch-buttresses.

BYL.—One of the early Norman arms, resembling a war-hatchet. Now obsolete.

BYRNIE.—A name applied to the very ancient English body-armor. Now obsolete.

BYSSA.—An ancient cannon for throwing stones. The byssa was a formidable weapon in its time.

C

CABACLE.—A military coat worn by the modern Grecians. Now obsolete.

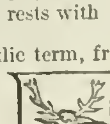
CABAL.—A term employed to denote a small, intriguing, factious party in the State, and also a union of several such, which, for political or personal ends, agree to modify or sacrifice their principles. The word was used to describe an English Ministry in the reign of Charles II., the initials of whose names composed CABAL—viz., Clifford, Ashley, Buckingham, Arlington, and Lauderdale. This was not the origin of the word, however, as some have supposed, but merely the ingenious application of a word previously in use, and which appears to have been derived from the French *cabale*, possessing a very similar signification.

CABAS.—1. A basket made of rushes, used in ancient Languedoc and Roussillon for the purpose of conveying stores and ammunition. 2. A large shield or buckler which served to protect the archers who attacked in intrenchments.

CABASSET.—The common infantry head-piece in the sixteenth century. It was a light *morion*, or iron cap, with a wide brim that was much lowered. It was frequently called *cervelière*, because it only covered the upper part of the head. Also written *Cabacet* and *Capacète*.

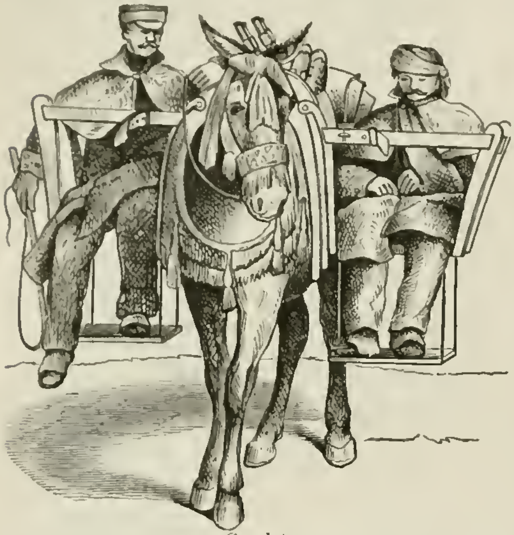
CABINET.—The Heads of Departments who are the immediate advisers or counselors of the Chief Executive. In the United States the Cabinet consists of the Secretaries of State, Treasury, War, Navy, and Interior, the Attorney General, and the Postmaster General. They meet whenever desired by the President, but not publicly. No minutes are kept of their doings, nor are the names of those present recorded. The President presides; and he may at any time require in writing the opinion of any of the members upon matters concerning his Department. But the Cabinet has no responsibility, as that rests with the President alone.

CABOCHED—CABOSSED.—An heraldic term, from the old French word *caboche*, meaning the head. When the head of an animal is borne, without any part of the neck, and exhibited full in face, it is said to be caboched or cabossed. See *Heraldry*.



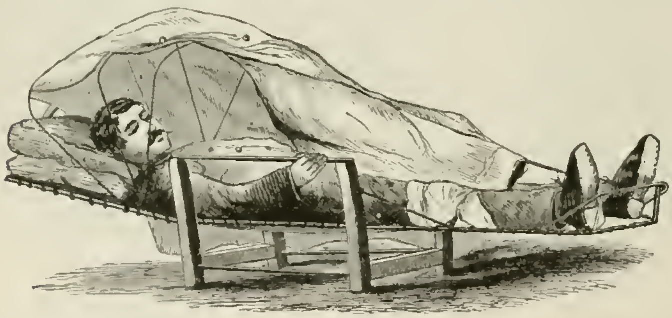
CABULE.—A machine of war, used in early times, but mostly during the twelfth century, to throw stones

CACHE.—A hiding-place, usually a cavity, natural or artificial, in the ground or among rocks, where voyagers, explorers, and troops stow provisions or records, to be found by themselves or others. If containing provisions, the cache needs to be very strong



Cacolet.

to resist the depredations of animals. The name was early used by parties of travelers in the great Western Prairies of the United States. Designing to return on their tracks after crossing the Rocky Mountains, they disburdened themselves of whatever articles could be



Cacolet-litter.

spared, and, to conceal them from the Indians, constructed places of deposit in the wilderness. The making of a cache is a matter of much labor and ingenuity. A hole is dug to a depth of perhaps 6 or 8 feet and several feet broad, and then the articles being interred, the surface is replaced with the utmost possible care. The excavated earth is also carefully removed, so as to leave no trace whatever of the excavation. The situation of the cache, however, is known to the party by some landmark, and returning months afterwards, they probably find its contents undisturbed.

CACOLET.—A folding-chair made to be slung on a pack-saddle, one on each side of an animal. They are used for carrying the sick or wounded in the day of battle. The most approved pattern weighs 56 pounds the pair. The pack weighs the same. Add the weight of two men, say 150 pounds each: total weight to be carried, more than 400 pounds—rather an excessive weight for any but a large-built mule or horse. The drawing shows some of the details of the French and British Crimean *cacolets*. This nature of chair is very tiring for the sick man, and it is, moreover, very difficult to place him in the *cacolet*.

In 1861 the United States Quartermaster's Department purchased a number of *cacolets* of the pattern used in the French army, and employed a French agent to give instruction in their use, and purchased animals specially adapted for their transport. The Quartermaster-general has remarked that these horses and mules were gradually appropriated as draft-animals, and that the *cacolets* were, for the most part, condemned as unserviceable.

A very convenient litter used by the French, under favorable circumstances, but never satisfactorily tested in the United States, was so constructed as to be readily detached from the pack-saddle and unfolded to form a comfortable bed for the patient. This like all other forms of *cacolet* has been considered unsuited to the requirements of field-service in this country. Scarcely a word in favor of them is to be found in any reports of the Medical Directors or Field-surgeons. See *Ambulance*.

CADASTRAL.—A term derived from the French word *cadastre*, a register of lands, or from *cadrer*, to square, and signifying a survey on a large scale, such as has been adopted of late years on the Continent of Europe, and is now used in England in the ordnance maps. The measurement corresponds so nearly to 25 inches to the mile that it is usually spoken of as the 25-inch scale. It has the further advantage of bearing, within a very small fraction, the proportion of one inch to an acre. A cadastral as opposed to a topographical map may be defined to be one on which the subjects represented agree, as to their relative positions and dimensions, with the objects on the face of the country; while a topographical map, drawn on a small scale, exaggerates, for the sake of distinctness, the dimensions of houses, and the breadth of roads and streams, and is, owing to its smaller size, necessarily less correct than a cadastral plan.

CADENCE.—1. A uniform time and pace in marching, indispensable to the correct movements of troops in large bodies. 2. In music, cadence is the finish of a phrase, of which there are three principal species, viz., the whole, the half, and the interrupted cadence. The whole cadence, which finishes on the harmony of the tonic, is also called the perfect cadence, and is always used at the end of a composition, and frequently called the final cadence. In its most perfect use it consists of three chords—the one before the final being always the dominant. The half-cadence, also called the imperfect cadence, isused to mark the termination of an idea or phrase, like the colon and semicolon; showing a considerable division, but at the same time that a continuation is necessary. The harmony of the half-cadence is

Cadences.

the reverse of the whole cadence, as it falls from the tonic to the dominant, and sometimes to the subdominant as in *a*. In the interrupted cadence, the preparation for the ordinary perfect cadence is made; but instead of the harmony of the tonic following the dominant, another harmony quite strange is introduced, so that the ear is deceived. The more particular the preparation for the usual cadence is made, the more strange and unexpected is the interruption, which can be made in so many ways that Reicha, in his *Traité de Haute Composition Musicale*, gives 129 interrupted cadences. Those generally in use are written in *b*.

CADENCY.—The marks by which the shields of the younger members of families are distinguished from those of the elder, and from each other, is an extensive, and, in so far as that term can be applied to Heraldry at all, an important branch of the science. No distinction is usually made by writers on Heraldry, and probably the practice of heralds in general scarcely admits of any being made, between *marks of cadency*, *differences*, *distinctions*, or even *brisures*, though the last term is pretty constantly, and quite appropriately, used to include not only differences in general, but also abatements or bearings by which the arms of the family are broken or diminished. But there is a manifest convenience in the practice which is usually followed in Scotland of appropriating the label, the crescent, the mullet, and the rest of the series of marks, commonly known as marks of cadency, to the purpose of distinguishing the sons from the father, and from each other, during the father's lifetime; and of adopting other distinctions—such as the bordure of various kinds, the chief engrailed, embattled, and the like, as differences between the coats of brothers, after the death of their father, and of the houses descended from them. Another very common mode of differencing the shields of brothers in early times was by changing the tinctures; but this is now regarded as too extensive a change for such a purpose. The method of differencing by means of the ordinary marks of cadency will be understood from the accompanying illustration. Fanciful reasons have been imagined by heralds for assigning these different

Distinction of Houses:

In the First House, the first, second, etc., sons are denoted by 1, the label; 2, the crescent; 3, the mullet; 4, the martlet; 5, the annulet; 6, the fleur-de-lis; 7, the rose (not figured in the cut); 8, the cross moline; 9, the double quatrefoil. In the Second House, or family of the second son, the first son is denoted by (1) the crescent, with the label upon it; the second, by (2) the crescent, with the crescent upon it; and so on. In the Third House, or family of the third son, the first son is denoted by the mullet, with the label upon it; the second, by the mullet, with the crescent upon it; and so on.

marks to the different sons. The differences at present used by the royal family will be found in most of the peerages. The rule with regard to them seems to be that, unlike subjects, they all bear the label of three points argent; but the label of the Prince of Wales is plain, whilst those of the other princes and princesses are charged with crosses, fleurs-de-lis, hearts, or other figures, for the sake of distinction. One of the most frequent reasons for matriculating the arms of the younger branches of families of distinction in the Lord Lyon's Register, is that they may be properly distinguished from those borne by the head of the house. See *Heraldry*.

CADET.—A term applied in a general sense to a junior member of a noble family as distinguished from the eldest; and in France, any officer junior to another is a Cadet in respect to him. In a strict military sense, however, a Cadet is a youth studying for the public service. In England, military cadetship has presented two aspects, according as it is related to the East India Company's or to the Royal service. When the Company possessed political and military authority in India, there were about 5000 English officers in their pay. Those who commanded the Company's own regiments had been professionally educated by the Company. A youth, nominated by the Directors, was examined as to his proficiency in an ordinary English education, and admitted between the ages of 14 and 18 to Addiscombe School or College, near Croydon. If a probation of six months resulted satisfactorily, he entered upon a two years' course of study. If he passed through this ordeal well, he became a Cadet in the Company's service, receiving pay or salary, and being available for service in India, as opportunity might offer. The system of Indian cadetship underwent various modifications by the introduction of competition in the appointments, and by the transference of the Company's powers to the Crown; and ceased in 1861, when the accession of fresh officers to the local Indian armies was stopped. The second aspect of military cadetship in England, adverted to above, is that of the Royal or Queen's Cadets.

Cadets at the United States Military Academy are subject to the Rules and Articles of War. Each Cadet, upon his admission, is required to take the oath of office prescribed by Act of Congress of July 2, 1862, and *before receiving his warrant* shall, in the presence of the Superintendent, or of some officer deputed by him, subscribe to an engagement in the following form:

I, ——— ———, of the State of ———, aged ——— years ——— months, having been selected for appointment as a Cadet in the Military Academy of the United States, do hereby engage, with the consent of my (Parent, or Guardian), in the event of my receiving such appointment, that I will serve in the Army of the United States for eight years, unless sooner discharged by competent authority. And "I, ——— ———, DO SOLEMNLY SWEAR, that I will support the Constitution of the United States, and bear true allegiance to the National Government; that I will maintain and defend the sovereignty of the United States paramount to any and all allegiance, sovereignty, or fealty I may owe to any State, county, or country whatsoever; and that I will at all times obey the legal orders of my superior officers and the rules and articles governing the armies of the United States."

——— ———.

Sworn and subscribed to, at ———, this ——— day of ———, eighteen hundred and ———, before

——— ———.

The punishments to which a Cadet is liable are comprised in the three following classes, viz.: 1st. Privation of recreation, etc.; extra duty (not guard); reprimands; arrests, or confinement to his room or tent, or in the light prison; reduction of officers or non-commissioned officers. 2d. Confinement in dark prison. 3d. Suspension; dismission, with the privilege of resigning; public dismission. The punishments of the first class mentioned may be inflicted by the Superintendent; those of the second class only by virtue of the sentence of a General Court-Martial, except in cases of mutinous conduct, or breach of arrest; and those of the third class only by the Secretary of War.

When a Cadet shall receive a regular degree from the Academic Board, after going through the classes, he is considered as among the candidates for a commission in the Engineers, Ordnance, Artillery, Infantry, or Cavalry, according to the duties he may be judged competent to perform. General Winfield Scott said: "I give it as my fixed opinion that, but for our graduated Cadets, the war between the United States and Mexico might, and probably would, have lasted some four or five years, with, in its first half, more defeats than victories falling to our share; whereas, in less than two campaigns, we conquered a great country and a peace, without the loss of a single battle or skirmish." See *Royal Military Academy, Sandhurst, Staff College*, and *United States Military Academy*.

CADETS' COLLEGE.—A college with this designation was established in 1858 by a remodeling of the Junior Department of the Royal Military College at Sandhurst. Its objects were to give a sound military education to youths intended for the army, and to facilitate the obtaining of commissions when the education was finished. The age of admission was between 16 and 19. The friends of a youth able to pay the sums of money presently to be named applied to the Commander-in-Chief for permission to place the youth on the list of Candidates; this permission was usually granted on production of satisfactory certificates and references. The youth might go up for examination on any half-year. The list of subjects included English composition, Continental languages, mathematics, history, geography, natural sciences, experimental sciences, and drawing. After the examination, the Candidates were reported to the Commander-in-Chief in their order of merit. Those who had the most marks were admitted as Cadets as soon as vacancies occurred in the College. When entered, they studied for two years on a great variety of subjects connected with military science and practice. The friend supplied clothing, books, and instruments. The annual payment for education, board, and lodging varied from £100 per annum down to £20; the highest sum being demanded for "the sons of private gentlemen," while the lowest was deemed sufficient for "the sons of officers of the army or navy who had died in the service, and whose families were proved to be left in pecuniary distress." Twenty of the youths were "Queen's Cadets," sons of officers "who had fallen in action, or had died from the effects of active service, and had left their families in reduced circumstances." These twenty Cadets were admitted and educated gratuitously. This system was abolished in 1870. Sub-lieutenants of cavalry and infantry, styled "Student Officers," who have done duty with a regiment for about 12 months, are now required to attend the College at Sandhurst, and go through a course of study for a year. At the end of it, on passing a satisfactory examination, they are promoted to the rank of Lieutenant, and rejoin their regiments.

CAGE DE LA BASCULE.—A space into which one part of a drawbridge falls, whilst the other rises and conceals the gate.

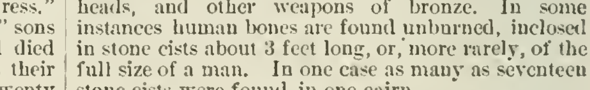
CAIMACAN.—A Turkish officer corresponding with Lieutenant or Lieutenant-governor. The Caimacan of Constantinople is the Lieutenant of the Grand Vizier, whom he represents in processions. Such officers also act as Governors in the principal towns. Also written *Kaimakam*.

CAIRN—CARN.—A Celtic word, signifying a protuberance, a heap, a pile. In that sense it appears in the names of hills and other natural objects in Scotland, Ireland, Wales, Cornwall, and Brittany. It is also applied to artificial heaps of unhewn stones, which, among archæologists, have come to be generally known as "cairns." There are several kinds of cairns. The simplest and most common form seems to be a conical pile of stones of no great size. Next is what may be called the fence or ringed cairns—a heap of stones girdled round by large unhewn stones set upright in the ground. Some cairns have two and a very few have three such concentric girdles; in some instances there are concentric rows of upright stones within the cairn. Many cairns are found in the neighborhood of the circles of unhewn stone pillars which antiquaries used to style "Druidical." In a few instances cairns are found at the end of an avenue of standing stones. Some cairns are fenced round by a narrow ditch and a small earthen rampart. A very few cairns have unhewn flat stones on their tops; a still smaller number are surmounted by an unhewn stone pillar. A few are oblong in shape. Cairns were erected, doubtless, for several purposes. It appears from record that they were often raised to distinguish the marches or boundaries of lands. One cairn, near Balmoral, on the Highland Dee, is said to have been erected as a mustering-place for the men of Strathdee, who took its name, *Cairn-na-cuimhne*, or "Cairn of Remembrance," for their slogan or war-cry. In later times, places where great crimes had been committed were marked by cairns; thus, "Mushet's Cairn," in the Queen's Park, at Edinburgh, shows the spot where a wife was murdered by her husband, under circumstances of peculiar atrocity, in 1720. But that the great purpose of the cairn was sepulchral is shown by the human remains found in so many of them. "*Disjectis et erutis, ossa inveniuntur, et quibusdam honor nominis adhuc manet*," says Robert Gordon of Straloch, writing of Scotch cairns in 1654. "For the cairns or heaps of stones in several parts of Ireland," wrote Thady O'Roddy in 1617, "some of them were heaped as monuments of battles, some made in memory of some eminent persons buried in such a place." A Highland suppliant would have said to his benefactor: *Curri mi cloch er do charne*—"I will add a stone to your cairn." The bones found in cairns are generally calcined or half-burned, and inclosed either in what are called *cists*—small rude coffins of unhewn stones—or in earns of earthenware, which, again, are in many cases protected by stone cists. Along with the bones are often found flint arrow-heads, flint axe-heads, stone hammers, stone rings, glass beads, implements of bone, bones of horses and oxen, spear-heads, and other weapons of bronze. In some instances human bones are found unburned, inclosed in stone cists about 3 feet long, or, more rarely, of the full size of a man. In one case as many as seventeen stone cists were found in one cairn.

CAISSON.—1. A carriage used to transport ammunition; in light field-batteries there is one caisson to each piece, in heavy batteries there are two. The ammunition is contained in three chests—two mounted on the body, and one on the limber. The number of rounds for each chest varies with the caliber of the piece, as follows, viz.:

6-pdr. gun and 3-inch rifle-gun..........	50
12 pdr. gun..........................	32
12-pdr. howitzer......................	39
24-pdr. howitzer......................	23
32-pdr. howitzer......................	15

The whole number of rounds for each piece may be ascertained by multiplying the above numbers by four. The caisson is composed of a *body* and a limber. The body is composed of one *middle* and two *side rails* (1), one *stock* (2), and one *axletree* (3). It carries two ammunition-chests (4, 5), a *spare wheel* (6), which fits upon an iron axle-arm attached to the rear end of the middle rail, one *spare pole* (7), fastened to the under side of the stock, and a *spare handspike*. The spare articles are needed to replace broken parts. The caisson also carries a *felling-axe*, *shovel*, and *pick-axe*, to remove obstructions, repair roads, etc., a *tarpaulin* strapped on to the limber-chest, a *tar-bucket*, and a *watering-bucket*. See *Field-carriages*.



Artillery Caisson.

2. In engineering, a hollow box of iron or wood,

open at the bottom, sunk where piers are to be placed. The largest caisson yet sunk was for the tower of the Brooklyn bridge on the New York side. At the bottom it was 172 feet long and 102 feet wide, with an air-chamber 9½ feet high, the roof 22 feet thick, and the sides carried up 82 feet from the lower edge. It had a cofferdam in the upper part; was built of timber lined with boiler-iron, and bolted together. In its construction there were used of lumber, board measure, 4,200,000 feet, and of iron, including bolts, 620 tons. When completed it weighed 13,271 tons, and there were 30,000 tons of masonry laid within it. There were two double air-locks extending into the air-chamber, in which were steam-pipes to keep an even temperature. Two shafts passed up through well-holes in the masonry, with an elevator in one and two spiral stairways in the other. Below the lowest edge of the caisson extended two water-shafts, each 7⅝ feet in diameter, in which dredges and scoops grappled the stones and soil, raising their loads to cars above, which conveyed the refuse away. At the same time sand and fine dirt were blown out by air-pressure through forty or more pipes in various parts of the structure. The interior was illuminated by gas, and constant communication by telegraph was kept up with the workmen inside. There were four shafts, each 2 feet in diameter, for the introduction of material for the concrete with which the whole interior was finally filled. The caisson was sunk 78 feet below mean tide, a work that required a presssue of 34 pounds per square inch in addition to the normal pressure of air; and to supply this addition, thirteen large compressors were used. The earliest caissons for such purposes were used in England in 1738–40 in laying the foundations of the Westminster bridge over the Thames.

CAKE-POWDER.—Gunpowder which has become lumpy from having imbibed moisture. In this state little permanent good can be done to it by reeling and redrying it, unless it is used at once, as after a time it absorbs more moisture than it did before; powder, therefore, in this state should not be re-stowed. This does not apply to pebble-powder, the grains of which are too large to cake.

CALABAS.—An early light form of musket with a wheel-lock. Bourne mentions it in 1778. Also written *Calabuss*.

CALATRAVA.—An order of knighthood in Spain, instituted at Calatrava. The statutes of the Order, framed by the Chapter-general of the Cistercian monks, were sanctioned by the Bishop of Toledo in 1164, and afterwards by the Pope. At subsequent periods many privileges were added. After the death of the king, their patron, some of the knights were no longer willing to obey the abbot, and they consequently separated themselves from the monks, and elected a Grand-master, Don Garcias de Redon. At a later period they again united themselves to the Cistercians, after they had gained rich possessions from the Moors both in Spain and Portugal. When Castile had fallen into anarchy, and the other kingdoms were exhausting themselves by internal feuds, the war against the unbelievers was almost entirely carried on by the Knights of Calatrava. Their almost uniform success, however, gave rise to rashness; the knights were defeated by Emir Jacob ben Yuseff, nearly all of them perished, and Calatrava was occupied by the Moors. After this disaster the knights transferred their seat to the Castle of Salvatierra, by the name of which they passed for a long time afterwards. A truce of twelve years having been concluded, during which the order was revived, the knights were able, at the battle of Las Navas de Tolosa, in 1212, again to turn the tide in favor of the Christians. They then returned to Calatrava.

CALCANS.—The bucklers of the Turks. These were worn and so called during the Middle Ages.

CALCINATION — CALCINING. — The process of heating or roasting in furnaces or in heaps the various metallic ores. It is resorted to as the first stage in the extraction of the majority of the common metals from their ores, and is essentially a process of oxidation.

CALCIUM.—The metal present in chalk, stucco, and other compounds of lime. It may be obtained by passing a powerful current of voltaic electricity through fused chloride of calcium ($CaCl$), when the metal separates in minute globules. It is a yellowish-white metal, can be rolled into sheets, and hammered into leaves, and is intermediate between lead and gold in hardness. It is represented by the symbol Ca, has the atomic weight or equivalent 30 (new system, 40), and has the density 1.578, or nearly half as heavy again as water. At ordinary temperatures it slowly tarnishes by oxidation; and when placed in contact with water it rapidly decomposes the water (HO), forming lime (CaO), whilst hydrogen escapes. To be retained bright, calcium must be kept under the surface of naphtha. At a red heat it melts and burns with a dazzling white light, accompanied by scintillations.

CALCULUS.—The infinitesimal calculus, otherwise sometimes called the transcendental analysis, is a branch of mathematical science which commands, by one general method, the most difficult problems in gunnery and physics. The merit of the invention of this powerful mathematical instrument has been claimed for Leibnitz, but is undoubtedly due with equal justice to Newton, who laid the foundations for it in that celebrated section of his *Principia* in which he demonstrates the chief theorems regarding the ultimate values or limits of the ratios of variable quantities. The view of one class of writers is that these distinguished men invented the calculus simultaneously and independently; and it is the fact that Leibnitz's system is unfolded from premises differing somewhat from those of Newton. Another class of writers hold that Newton is the real inventor, and that to Leibnitz no more can be conceded than that he was the first who, using the suggestions of Newton's genius, gave a systematic statement to the principle of the transcendental analysis, and invented its appropriate symbolic language. He had the doctrine of limits before him when he wrote, and did little more than unfold more fully the logic of the processes therein suggested, and exhibit them in algebraical forms. The calculus is only applicable where numbers have the continuous character—i.e., where they are or may be conceived as being variable. If two unknown quantities are connected by a single equation only, we clearly have the condition satisfied, as where y and x are connected by the equation

$$(1) \quad y = F(x),$$

where F is a sign denoting some *function* of x, as tan. x, cos. x, x^2, etc. This equality may be satisfied by innumerable values of y and x. One question which the calculus solves is, how does y vary when x varies? To solve it, and at the same time show how the doctrine of limits affects the definition of a differential, suppose x, y, and $x + Dx$, $y + Dy$, to be two pairs of values of the variables which satisfy the above equation; then

$$(2) \quad y = F(x), \quad \text{and (3)} \quad y + Dy = F(x + Dx).$$

From (2) and (3) we have, by subtraction,

$$(4) \quad Dy = F(x + Dx) - F(x);$$

whence we have the ratio

$$\frac{Dy}{Dx} = \frac{F(x + Dx) - F(x)}{Dx}.$$

This ratio will generally change in value as Dx and Dy diminish, till, as they both vanish, which they must do simultaneously, it assumes the form $\frac{0}{0}$. Taking this form, it ceases to have a determinate actual value, and it is necessary to resort to the method of limits to ascertain the value to which it was approaching as Dx and Dy approached zero. Let, then, dx and dy be any quantities whose ratio is equal to the limiting ratio of the increments Dx, Dy, so that

$$\frac{dy}{dx} = \text{limit } \frac{Dy}{Dx}$$

as Dx and Dy approach zero. Then dx and dy are the differentials of x and y. It may be observed that where x and y are connected as above they cannot vary independently of one another. In the case assumed, x has been taken as what is called the *independent* variable, the question being, how does y vary when x varies? If y were made the independent variable, it would be necessary to solve the equation $y = F(x)$, if possible, so as to express x in terms of y. The result would be an equation $x = \varphi(y)$. This being obtained, we should find $\frac{dx}{dy} = \text{limit } \frac{Dx}{Dy}$ as before. It will be seen that on this view differentials are defined merely by their ratio to one another. Their actual magnitude is perfectly arbitrary. This, however, does not render an equation involving differentials indeterminate, since their relative magnitude is definite, and since, from the nature of the definition, a differential cannot appear on one side of an equation without another connected with it appearing on the other.

The idea of a differential being once comprehended, the reader will be able to understand, in a general way, the main divisions of the calculus, which we shall now briefly delineate. So much is clear from what has been stated, that there must be two main divisions—one by which, the primary quantities being known, we may determine their differentials; and another by which, knowing the differentials, we may detect the primary quantities. These divisions constitute the Differential Calculus and Integral Calculus respectively.

1. *The Differential Calculus.*—Recurring to the formula already given, we know

$$\frac{dy}{dx} = \text{limit } \frac{Dy}{Dx} = \text{limit } \frac{F(x + Dx) - F(x)}{Dx}.$$

It is clear that, in the general case,

$$\frac{F(x + Dx) - F(x)}{Dx}$$

at the limit will still be some function of x. Calling it $F'(x)$, we have generally $\frac{dy}{dx} = F'(x)$. $F'(x)$ is called the first differential coefficient of y or $F(x)$. Being a function of x, it may be again differentiated. The result is written

$$\frac{d^2y}{dx^2} = F''(x),$$

$F''(x)$ being the second differential coefficient of y or $F(x)$; and again $F''(x)$ may be a function of x, and so capable of differentiation. Now it is the object of the differential calculus to show how to obtain the various differentials of those few simple functions of quantity which are recognized in analysis, whether they are presented singly or in any form of combination. Such functions are the sum, difference, product, and quotient of variables, and their powers and roots; exponentials, logarithms; and direct and inverse circular functions. The calculus so far is complete as we can differentiate any of those functions or any combination of them—whether the functions be explicit or implicit; and with equal ease we may differentiate them a second or any number of times. This calculus is capable of many interesting applications as to problems of maxima and minima, the tracing of curves, etc., which cannot here be particularly noticed.

2. *The Integral Calculus* deals with the inverse of the former problem. The former was: Given $F(x)$, to find $F'(x)$, $F''(x)$, and so on. The present is in the simplest case—viz., that of an explicit function: Given $\frac{dy}{dx} = F'(x)$, to find $F(x)$. The methods of the integral calculus, instead of being general, are little better than artifices suited to particular cases; no popular view can be given of these. In many cases integration is quite impossible. The explanation of *integration by parts*, by *approximation*, *definite integrals*, and *singular solutions*, is far beyond the scope of the present work. The reader is referred to any of the numerous text-books on the subject. The integral calculus has applications in almost every branch of mathematical and physical science. It is specially of use in determining the lengths of curved lines, the areas of curved surfaces, and the solid contents of regular solids of whatever form. The whole of the lunar and planetary theories may be described as an application of the integral calculus, especially of that branch of it which deals with the integration of differential equations. It is applied, too, in hydrostatics and hydrodynamics, and in the sciences of light, sound, and heat. In short, it is an instrument without which most of the leading triumphs in physical science could never have been achieved.

CALEBASSERIE.—A Belgian method of remelting iron in a sort of cupola furnace, with good results.

CALIBER—CALIBRE.—A technical name for the diameter of the bore of a fire-arm, whether a piece of ordnance or a small-arm. The ordnance from which solid shot are projected are usually denoted by the weight of each shot, as 24-pounder, 68-pounder, etc.; but mortars, and such guns as project shell or hollow shot, are more usually denoted by the caliber, such as 13-inch mortar, 10-inch shell-gun, etc. The caliber of the chief kinds of fire-arms will be noticed under the proper headings; but it may here be observed, generally, that the caliber of ordnance has been greatly increased within the last fifty years, partly by boring up old guns and partly by casting new.

Three important points are to be considered in determining the caliber of small-arms: 1st. The caliber should be as small as possible, to enable the soldier to carry the greatest number of cartridges; with the present caliber, the number of musket-cartridges is limited to 40; the total weight of which is about 3½ lbs. 2d. To diminish the amount of ammunition required to supply the wants of an army, and to prevent the confusion that is liable to arise from a variety of calibers, there should not be more than two for all arms of the same service, viz., one for the musket and one for the pistol. 3d. This point relates to the force and accuracy of the projectile. The introduction of elongated projectiles affords the means of increasing the accuracy and range of fire-arms, without increasing the weight of the projectile, simply by reducing the caliber, which diminishes the surface opposed to the air. Too great reduction of caliber, however, gives a very long and weak projectile; and besides, the effect of a projectile on an animate object depends not only on its penetration, but on the shock communicated by it to the nervous system, or upon the surface of contact. A projectile of very small caliber, having but little inertia, does not expand well into the grooves of the bore by the action of the powder; it is not, therefore, suited to the present method of loading at the muzzle.

The caliber of a piece of ordnance will be determined to a great extent by the purpose for which it is intended. It is necessary in the first place to decide the amount of powder in the charge, and how much expansive action is to be allowed for each pound of powder. The interior capacity of the bore being determined, the question then is to fix the relation between the diameter and length. The capacity increases with the square of the former and with the first power of the latter. The solution of this problem will be largely governed by considerations affecting the projectile. Assuming its weight to be fixed, its length will determine its diameter, so that a long shot implies a small bore. A lengthened projectile has both advantages and disadvantages: It meets with less atmospheric resistance and therefore loses less energy in its flight. It has greater penetration because it has a smaller hole to make. On the other hand, the lengthening of a shot increases its tendency to crush or break on striking. Used as a shell a long projectile contains less powder than a short one of equal weight and larger diameter, and is more liable to break by impact before explosion. Finally, a long projectile requires more rapid rotation to steady it, and this involves a greater expenditure of power in producing rotation. The question of caliber is therefore a very complex one, and it can only be settled by a compromise of conflicting considerations. The tendency, recently, has been toward a reduction in the caliber of guns for armor-piercing, this accompanied, however, by a proportional great increase of power. See *Cannon* and *Ordnance.*

CALIBER-COMPASS.—A form of calipers adapted to measure the sizes of bores. Another kind is used for measuring shot and shell. Also written *Caliper-compass.* See *Calipers* and *Shell-gauge.*

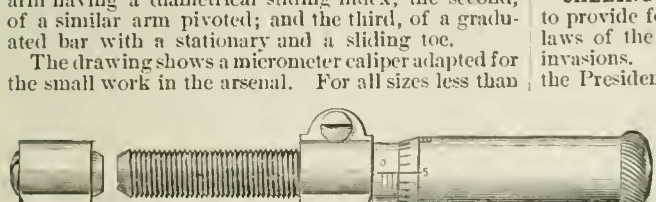
CALIBER-RULE.—A gunner's calipers, having two scales to determine the weight of a ball from its diameter, and conversely. Also written *Calibre-rule.*

CALICO BAGS.—A nature of bag used in England, in and attached to the interior of metal-lined and brass pentagon cases, for the preservation of loose powder in a damp climate when it cannot be preserved in ordinary barrels.

CALIGAE.—A kind of half-boots worn by the Roman soldiers. Such soldiers were sometimes called *Caligati.*

CALIPERS.—An instrument, jointed like a pair of dividers, but with arched legs, and adapted for taking the diameters of convex or concave bodies. It is said to have been invented by an artificer of Nuremberg in 1540. Numerous instruments of this class have been devised for different classes of work. Gunners' calipers are intended for measuring the bore or caliber of guns and projectiles. A scale like a sliding-rule has different sets of numbers engraved on it, to exhibit the corresponding diameters in inches and weights in pounds. The graduation is in accordance with the rule that with balls of the same metal the weights of the balls are as the cubes of their diameters. Calipers for inspecting hollow projectiles comprise those for measuring the thickness of metal at the bottom, at the sides, and at the fuse-hole reinforce. The first consists of a semicircular arm having a diametrical sliding index; the second, of a similar arm pivoted; and the third, of a graduated bar with a stationary and a sliding toe.

The drawing shows a micrometer caliper adapted for the small work in the arsenal. For all sizes less than one inch diameter this caliper will be found a reliable and convenient substitute for the vernier caliper, and will prove invaluable to armorers engaged on small and fine work. The binding and adjusting screws furnish the ready means of compensating for any wear resulting from use. Being small and light, it can be used as a pocket-tool. Although graduated to read to thousandths of an inch, half and quarter thousandths are readily obtained.



Micrometer Caliper.

A calipers designed especially for use in connection with the construction of tubes for 8-inch converted rifles consists of a curved steel plate and two attached measuring-points movable along the same right line. One of these points is fastened to a rod which slides in a socket attached to the steel plate. The rod is designed to occupy one of two positions, according to the size of the diameters to be measured, and is secured in either of these positions by a clamp-screw. At the other end of the curved plate the second measuring-point terminates a graduated limb, which, by means of a vernier and sliding microscope, can be read to .001 inch. This limb is fitted with a clamp and slow-motion screw, and has two sets of graduations, the one above the other; the lower read from about 9 inches to 14 inches, and the upper from about 12 inches to 17 inches. The lower graduations are used when the rod opposite is pushed in and clamped at its inner limit; the upper graduations, when the rod is pulled out and clamped at its outer limit. In making nice measurements, it is indispensable that the plane of the instrument be kept at right angles to the axis of the tube. This is secured by a wooden guide, which is held in rear of the instrument and is slid along the tube from one position to another. The base of the guide has the same curvature as the exterior of the tube, and is held firmly upright by two projecting arms extending in rear from either side, and which rest on the surface of the tube. By keeping the curved plate of the calipers in contact with the face of the guide, its true position is secured. See *Gauge* and *Inspection of Ordnance.*

CALIVER.—A hand gun or arquebuse—supposed by many to be the old name for the matchlock or carabine. It was so called because the bore was of a fixed size, in order that the common stock of bullets might fit every piece in a regiment. It was of greater caliber than the arquebuse, was lighter than the musket, and was fired without a rest.

CALK.—A projection from a shoe or clog which digs into the ice or frozen ground to prevent slipping. The word is also allied to the Anglo-Saxon word *calc*, a shoe; or the Latin *calcar*, a spur. In a horseshoe the calk consists of a downward projection from the heel, made by turning over the iron of the heel and sharpening it. The calk attached to a boot consists of a plate with spurs which project a little below the heel.

CALL.—A military musical term, meaning a signal on the drum, bugle, or trumpet for the assembling of troops, etc.

CALLING FORTH MILITIA.—Congress has power to provide for calling forth the militia to execute the laws of the Union, suppress insurrections, and repel invasions. By Act of Congress, February 28, 1795, the President is authorized to call forth the militia whenever—" 1. The United States shall be invaded or be in his judgment in imminent danger of invasion (from any foreign nation or Indian tribe); and to issue his orders for that purpose to such officer or officers of militia as he may think proper. 2. In case of an insurrection in any State against the government thereof, on application of the Legislature of such State, or of the Executive (when the Legislature cannot be convened). 3. Whenever the laws of the United States shall be opposed, or the execution thereof obstructed in any State, by combinations too powerful to be suppressed by the ordinary course of judicial proceedings, or by the powers vested in the Marshals; but whenever it may be necessary, in the judgment of the President, to *use* the military force hereby directed to be called forth in case of insurrection or obstruction to the laws, the President shall forthwith, by proclamation, command such insurgents to disperse, and retire peaceably to their respective abodes within a limited time." In cases where it is lawful for the President to call forth the militia, it shall be lawful for him to employ for the same purposes such part of the land or naval forces of the United States as shall be judged necessary, *having first observed all the prerequisites of the law in that respect.* See *Militia.*

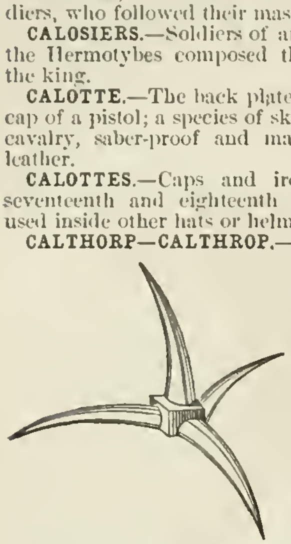
CALONES.—A term applied to menials of the Roman armies; also slaves belonging to the Roman soldiers, who followed their masters to the wars.

CALOSIERS.—Soldiers of ancient Egypt, who with the Hermotybes composed the particular guard of the king.

CALOTTE.—The back plate of a sword-handle; the cap of a pistol; a species of skull-cap worn by French cavalry, saber-proof and made of iron or dressed leather.

CALOTTES.—Caps and iron frameworks of the seventeenth and eighteenth centuries, which were used inside other hats or helmets.

CALTHORP—CALTHROP.—An obstacle in military warfare, consisting of a four-pronged piece of iron, each prong about four inches in length. When it is wished to check the approach of the enemy's cavalry over a plain, or of his besiegers in the ditch of a fortification, calthorps are sometimes thrown down; from their shape, one prong is sure to stand upright, and may work terrible mischief to the enemy's horses or men. Obstacles of other kinds having the same object in view, as small pickets, are sometimes used. Ordinary harrows turned upside down with the teeth upwards and the frames buried; planks with spikes driven into them, placed so as to have the points upwards, etc., may be used when practicable. Also written *Caltrop.* See *Crow's-feet.*



CALTHROP KNIFE.—A weapon about nine inches long, used in Saxony during the Seven Years' War. These knives were screwed on to beams of wood and placed under water in moats. The hole in the blade was intended to put a piece of stick through, so as to form a handle to screw the knife. Sometimes written *Calthorp Knife.*

CALUMET.—The *peace-pipe* of the North American Indians. It is a tobacco-pipe having a stem of reed about two feet and a half long, decorated with locks of women's hair and feathers, and a large bowl of polished marble. It plays an important part in the conclusion of treaties, of which, indeed, it may be described as the ratifier. After a treaty has been signed, the Indians fill the calumet with the best tobacco, and present it to the representatives of the party with whom they have been entering into alliance, themselves smoking out of it afterwards. The presentation of it to strangers is a mark of hospitality, and to refuse it would be considered an act of hostility. When a tribe wishes to go to war, messengers are sent to numerous other tribes asking for warriors for the expedition. The calumet (sacred and public property) goes with the mission. The whole subject is thoroughly discussed in council, and such tribes as grant the request accept the pipe and smoke.

CAM.—In gun-machinery, a curved plate or groove by which motion is communicated and controlled. The moving plate or groove is a *driver;* the rod, bar, or other thing moved is called the *follower.* The follower is held against the driver by its weight, or by a spring or other device. The radii of the driver determine by their length the motion of the follower, and the angles which they make with some one, chosen as a base of calculation, fix the time at which change of motion occurs. For example, it may be desired that the follower shall move upward, and then downward, with a uniform velocity. From the center of the driver any convenient number of radii may be drawn, dividing equally the 360° of angular space. On one of these radii we mark the distance from the center of the driver at which the point of the follower will stand when in its position nearest to that center. Upon the opposite radius, distant 180° from the first, the point is marked which gives the farthest position of the follower; the difference between these radii being divided into as many equal parts as we have made angular spaces in the 180°, we increase the length of each radius in succession, beginning with the shortest, by one of those parts, and we draw a curve connecting the ends of the radii so terminated. Of course the greater the number of parts chosen for the division of the angular space and of the difference of the first and last radii, the more accurately will the curve be drawn. The edge of the driving-plate being cut to this curve, the follower being made to press constantly against it, and the driver being turned with a uniform rotation, the follower will move through its limited space with an equable motion, because the radii of the driver increase by constant amounts, at constant intervals of time. If the curve is reversed, the second part being the symmetrical opposite of the first part, the follower will descend as uniformly as it rose. The cam thus drawn is one of frequent use, and is called the *heart-shaped* cam. To avoid friction the end of the follower often carries a roller which works against the surface of the cam; in this case the cam-surface is found by drawing a line parallel to that above described, at a constant distance equal to the radius of the roller. If we wish the follower to rest at any part of a cycle of motion, the radii for that time will be made equal, and the corresponding cam-surface will be a circular arc; the time will be such a part of that of a complete cycle as the angle between the radii of the ends of this arc is of 360°. The cam-plate has sometimes a groove cut upon its flat side, and the end of the follower runs in the groove. A spiral groove may be cut into the surface of a cylinder as in a screw; if a follower be inserted in this groove it will be driven forward as the cylinder turns; when the groove reaches the end of the cylinder, it may turn back, and cause the follower to return with the same motion, or if the pitch of the groove be made shorter or longer, the return of the follower will be changed accordingly. By a judicious construction and arrangement of cams, almost every variety of motion may be produced with the greatest precision as to time and amount. A cam-form which does not make a complete revolution, but after moving a short distance in one direction oscillates in the opposite direction, is called a *wiper.* A familiar example may be seen in the engine-room of a steamboat, in the rocking arms which raise and let fall the valve-rods. See the various descriptions of gun-machinery and engines throughout this work.

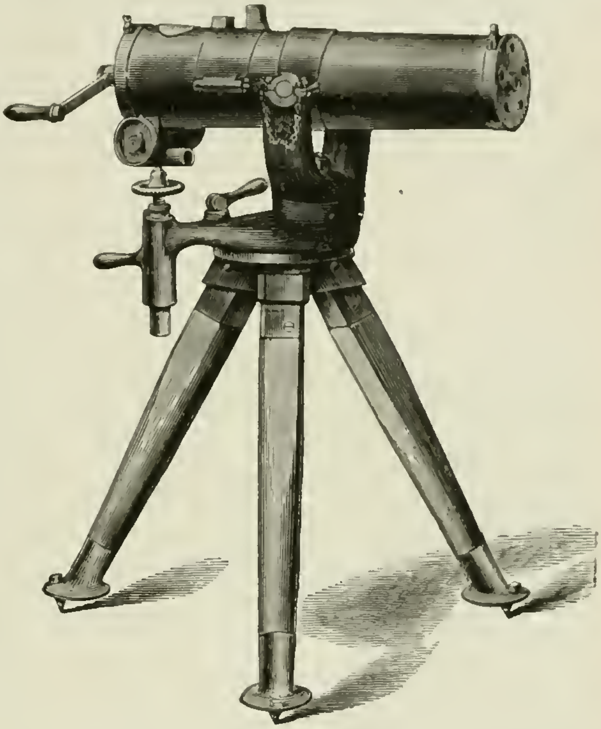
CAMAIL.—A neck-guard of chain, added to the bascinet. The word is either corrupted from *cap-mail* or owes its origin to the camail resembling the lower part of the capuchon, commonly worn by all classes, but which among the higher ranks was made of camel's hair, and therefore termed *camelin* by the French, from whence our word *camlet,* afterwards applied to an inferior stuff made in imitation of it.

CAMBRIDGE ASYLUM.—A charitable institution founded by the father of the present Duke of Cambridge to form a home for one widow of each British regiment. It is not yet completed, and is only capable of receiving, at present, about fifty widows.

CAMEL.—The camel is of great value as a pack-animal, and is admirably adapted for carrying long articles, such as scaling-ladders, pontons, etc. Of the two species, that known as the Arabian camel has only one hump on the back, whilst the Bactrian camel has two. Some confusion has arisen from the occasional employment of the name *dromedary* as a designation of the former species, it being, however, more properly limited to a particular variety of that species, more slender and graceful than the ordinary variety, and of much greater fleetness. Buffon's notion, that the hump is a badge of servitude, and the consequence of harsh treatment throughout many generations, is singularly at variance with what we know of its uses. The hump is a wonderful provision of nature, to adapt the animal to the endurance of long abstinence from food, or subsistence on very scanty supplies, to which it is often subjected in the desert, and without a capacity for which it would be comparatively of little value to man; and the wide deserts across which he journeys and transports his merchandise by its aid would be altogether unpassable. The hump is, in fact, a store of fat, from which the animal draws as the wants of its system require; and the Arab is very careful to see that the hump is in good condition before the commencement of a journey. After it has been much exhausted, three or four months of repose and abundant food are necessary to restore it. The backbone of the camel is as straight as that of other quadrupeds.—Another very interesting adaptation to the desert is to be noticed in the thick sole which protects the feet from the burning sand, and in callosities of similar use on the chest and on the joints of the legs, upon which the camel rests when it lies down to repose, or kneels, as it does for various purposes, and is taught to do that it may be loaded, or that its rider may mount upon its back.—The wedge-shaped cutting-teeth of the lower jaw are also particularly fitted for browsing on shrubby plants, such as the desert produces—the camel's thorn, tamarisk, etc., which form a large part of the food of the camel; the eyes are furnished with long eyelashes, to protect them from the glare and from the drifting sand; whilst the exclusion of the sand from the nostrils is also provided for by a power of closing their oblique openings at will. But most interesting of all is the provision made for the endurance of long drought, by the lining of the inside of the second stomach, or honeycomb-bag, and of a portion of the first stomach or paunch, with great masses of cells, in which water is stored up and long retained. This store of water is well known to the Arabs, who, when sore pressed by thirst, sometimes avail themselves of it by killing some of the camels of the caravan.

The Arabian camel carries twice the load of a mule. The Bactrian camel is sometimes loaded with 1000 or even 1500 lbs. weight, although not generally with so much, The East India Company had at one time a corps of camels, each mounted by two men, armed with musketoons. The use of the camel for the conveyance both of travelers and supplies has won it the name of the *ship of the desert.* A caravan sometimes contains 1000, sometimes even 4000 or 5000 camels. The supply of food carried with the caravan for the use of the camels is very scanty: a few beans, dates, carob-pods, or the like, are all that they receive after a long day's march, when there is no herbage on which they may browse. The pace of the loaded camel is steady and uniform, but slow: it proceeds, however, from day to day, accomplishing journeys of hundreds of miles at a rate of about 2½ miles per hour. Some of the slight dromedaries, however, can carry a rider more than 100 miles in a day. The motion of the camel is peculiar, jolting the rider in a manner extremely disagreeable to those who are unaccustomed to it; both the feet on the same side being successively raised, so that one side is thrown forward and then the other. Camels are particularly handy for fording rivers that are deep but not rapid; and where the bottom of the river is shifting sand, the passage of a number of camels over it renders it hard and firm. The average weight of the camel is about 1170 pounds. See *Pack-animals.*

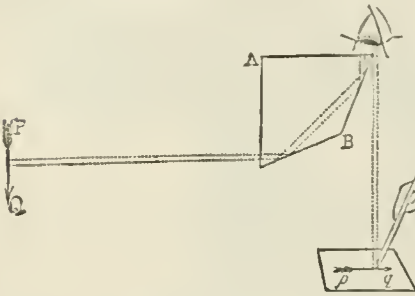
CAMEL-GUN.—When guns, like the Gatling gun, accompany expeditions in which it is impossible to use wheeled vehicles, they are carried on mules, horses, or camels. The guns designed for such use are called "camel-guns," and are lighter and shorter than the field-guns, but fire the musket-cartridge and have the musket range. Each gun with its carriage or tripod is carried on pack-saddles, and fifteen or twenty loaded feed-cases can be carried on the same saddles. The ammunition, with additional feed-cases, should be carried on the animals which march directly in rear of those which carry the gun and tripod. The drawing shows the new-model, musket-caliber, five-barrel Gatling gun, mounted on its tripod and ready for action. Its weight is 100 pounds, and fires 800 shots per minute. It is designed for transportation by mules or camels, or on the shoulders of men for short distances. The Gatling gun and its tripod are very conveniently transported, in the United States, in a packing-box invented by Mr. James Madigan. This box with the old-model Gatling gun is indeed requisite on account of the many projecting parts that would be exposed to the danger of being broken or damaged in timber, or clogged with leaves, twigs, etc., in the brush. The box is adapted to the shape and size of the gun and fixtures, and is so arranged internally that the motion of the pack-animal, when on the march, will not chafe or disarrange any of the parts of the gun or its appurtenances. The box is constructed and adapted for use with a pivoted pack-saddle, the upper arms of which have been arranged for this purpose, so as to bring the weight of the box as low as possible, and to support it firmly. See *Gatling Gun.*



New-model Five-barrel Gatling Gun.

CAMERA LUCIDA.—An optical instrument constructed of various forms, and for various purposes. Dr. Wollaston's instrument, intended to facilitate the perspective delineation of objects, consists of a small quadrilateral prism of glass, of which AB in the drawing is the perpendicular section, held in a brass frame, which is attached to an upright rod, having at its lower end a screw-clamp to fix it to the edge of a table. The prism being at the height of about a foot from the table, has its upper face horizontal. Two of its faces, as in the figure, are at a right angle at A;

the contiguous faces make respectively with them angles of 67½°; so that the remaining obtuse angle at B contains 135°. Rays coming from an object, PQ, and falling nearly perpendicularly on the first surface, enter the prism, and undergo total reflection at the contiguous surface; they then fall at the same angle on the next surface, and are totally reflected again; finally, they emerge nearly perpendicularly to the remaining surface. An eye, as in the figure, then receives the emergent pencil through one part of the pupil, so that an image, *pq*, of the object is seen projected upon a sheet of paper upon the table. The rays from the drawing-pencil passing the edge of the



prism, enter the other part of the pupil; and the pencil and image being seen together upon the paper, a sketch of the latter can be taken. There is, however, a practical difficulty—the image and the drawing-pencil are at distances sensibly different from the eye, and so cannot be seen together distinctly at the same time. To obviate this, a plate of metal, with a small aperture as an eye-hole, is placed at the edge under the eye, so that the rays through the prism, and those from the drawing-pencil, which both pass through the eye-hole, form only very small pencils. By this the difficulty is greatly diminished. It is still, however, difficult to use the instrument satisfactorily; and though many acquire great readiness in its use, others have never been able to attain the same facility. The instrument is remarkable for its small bulk and portability. A good one will pack in a box 8 inches by 2, and ½ inch deep. Besides this form of the instrument, which is the most common, there are others. Its simplest form is merely a piece of smooth glass fixed at an angle of 45° to the horizon. An image from a horizontal object falling on this glass will be perfectly reflected, and that in the vertical, so that the eye looking vertically down will see the image, and, owing to the transparency of the glass, the artist will be able to trace it out upon paper below. In this case, however, the image will be inverted.

The optigraph is an instrument for the same purpose, but of different construction.

CAMERA OBSCURA.—An instrument invented by Baptista Porta in the sixteenth century. It is known in its simplest form as a familiar toy, consisting of a rectangular box, furnished at one end with a lens whose focal length is equal to the length and depth of the box; at the opposite end of which a plane reflector is placed at an angle of 45°, which throws the image of any objects to which the lens may be directed on a piece of ground glass on the top of the box in a non-inverted position, so that they may be viewed or sketched from as in nature. The camera obscura being now an indispensable article in the practice of photography, has received a number of recent improvements, which make it rank as a scientific instrument. The principle, however, involved in the simplest and most refined forms is the same, and may be illustrated and made intelligible by the following experiment: Let a small hole be bored in a window-shutter, and the room be darkened. If, now, the beam of light entering the room by this hole be intercepted by a sheet of white paper, held at a short distance from the hole, an inverted image of objects without will be seen upon the paper. By placing a small convex lens over the hole, this image is rendered much more distinct, or *sharp*, in photographic language. Moreover, it will be found that at a certain distance from the hole the image attains a maximum degree of sharpness; and that if the paper be removed from this point to any position either nearer to the hole or further from it, the image becomes indistinct and confused. At the point of greatest distinctness the image is said to be *focused*. Such being the principle of the camera, it is evident that in practice the instrument may assume many forms, provided always that it consists of a darkened box or chamber having a hole at one end for the insertion of a lens, or combination of lenses, and at the other a screen, generally made of ground glass, on which to receive the image. The body of the instrument may be made of any opaque substance; the tube or tubes are generally formed of brass, and contain one or more lenses; there is the obscured or ground glass, upon which the image is thrown for the purpose of adjusting the focus; and the rack behind, by means of which, and the double sides of the camera, the body of the instrument may be lengthened or shortened till the image on the ground screen is accurately focused. This rack is most frequently placed upon the tubes carrying the lenses. The interior of the whole apparatus is blackened, to prevent reflection of the rays falling on their sides, and to impart greater distinctness to the picture.—The *camera-slide* is a thin, dark box, and is used for conveying a sensitive plate from the operating-room to the camera, and back again after exposure. It consists of a rectangular frame, made to fit exactly into the back of the camera when the focusing-screen is removed. At the back is a hinged door, by means of which the plate is introduced into the slide; and in front is a shutter, which is pulled up when the plate is to be exposed, and shut down after the time requisite for the action of the light upon the plate has expired. It must be constructed so that, when substituted for the focusing-screen, the surface of the prepared plate, which is intended to receive the image, shall correspond exactly in distance from the lens with the ground surface of the focusing-screen. The plate rests upon projections of silver wire in the corners of the slide; and the same slide may be used for plates of different sizes, by introducing into it thin frames of suitable dimensions also furnished with silver-wire corners.

CAMERON HIGHLANDERS.—The designation given to the 79th Regiment of Infantry in the British service, in consequence of the Corps having been raised by Allan Cameron of Erroch in 1793. Originally it consisted of 1000 men, but a second battalion was added in 1804. This gallant regiment, which wears the Highland garb, performed distinguished services in the Peninsula and at Waterloo, and in the chief warlike struggles of more recent times.

CAMERONIAN REGIMENT.—The 26th Regiment of Infantry in the British service, so called from having had its origin in a body of Cameronians during the Revolution of 1688. Taking advantage of their zeal and courage, the Convention which sat at Edinburgh induced a number of them to assist in the Revolution, which it was imagined by some was to re-establish the reign of the Covenants. They were induced to enlist on the understanding that the special object of the Corps was "to recover and establish the work of reformation in Scotland, in opposition to popery, prelacy, and arbitrary power, in all the branches and steps thereof, till the government in Church and State be brought to that luster and integrity which it had in the best of times." Thus was formed the celebrated Cameronian Regiment, with the youthful Lord Angus as Colonel, and William Cleland as Lieutenant-colonel and actual Commander. Under Cleland, not yet in his thirtieth year, the Regiment was sent northwards to quell the insurrection, after the fall of Viscount Dundee. Surrounded by from 4000 to 5000 Highlanders, the Cameronians, only 800 strong, gallantly defended themselves during a whole day in Dunkeld, August 21, 1689. In this terrific struggle the brave Cleland was killed. Considering the issue of the Revolution, they had been entrapped into military service, and their employment on foreign service afterwards greatly scandalized the Cameronian sect. The Regiment has ever done credit to its origin, being distinguished alike for gallantry and for good conduct.

CAMION.—A substantial dray used for transporting heavy ordnance and ordnance stores.

CAMISADO.—1. A shirt formerly worn by soldiers over their uniform, in order to be able to recognize one another in the darkness, in a night-attack. 2. An attack by surprise at night, or at break of day, when the enemy is supposed to be in bed, by soldiers wearing the *camisado*.

CAMOUFLET.—A small mine used to suffocate the enemy's miners without producing an external explosion. It is sometimes formed in the wall or side of a gallery, in order to blow in the earth and to cut off the retreat of the miners. The charge is usually about ten pounds of powder—sufficient to compress the earth all around it without disturbing the surface of the ground.

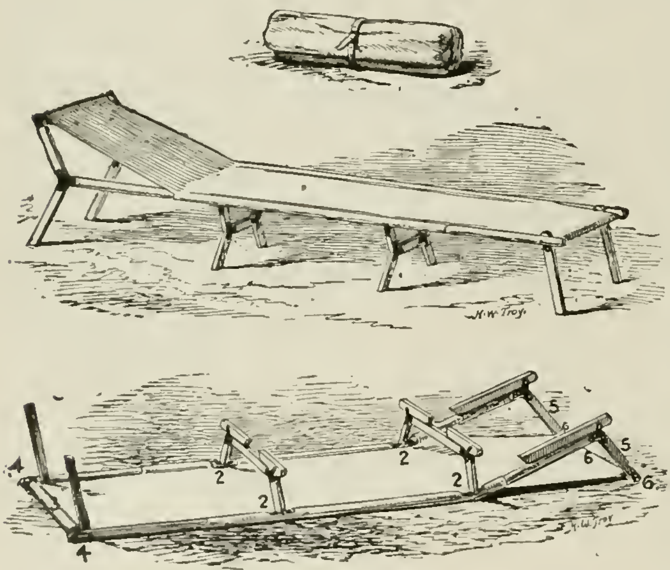
CAMP.—The signification of this word in English is rather that which belonged to the Latin *castrum*, an encampment, or *castra*, a collection of tents, huts, and other structures, for the accommodation and protection of troops, than that which its etymology would more directly indicate. The regular system of encampment ultimately adopted by the Romans was forced upon them by degrees. The most complete account of it is furnished to us by Polybius. When a Roman army was about to encamp, a Tribune and several Centurions were sent on before, to select a suitable site for the purpose. As soon as the locality was determined on, they chose the spot for the Prætorium or General's tent, and marked it with a white flag. Around the Prætorium, as a sort of center or heart to the whole system, the rest of the camp was laid out. It was generally placed on an elevated position, in order that the General might have the rest of the encampment under his eye, and be able to transmit his orders with greater facility. Polybius himself tells us that the best conception which can be formed of a Roman camp of the more permanent kind is by regarding it as a military town, resembling in many respects no doubt that which has recently grown up at Aldershott. The streets were broader than those usually to be found in towns, the wider ones measuring 100 and the narrower 50 feet; and the *Forum*, as its name indicates, was a sort of public market-place. A space of 200 feet was left vacant all round between the tents and the ramparts, partly to afford space for the arrangements of the army, and for stowing away any booty that might be captured, but chiefly to protect the soldiers' huts from incendiary attempts from without. In form the Roman camp was square, except in the case in which it was intended to embrace within its ramparts four legions, or two consular armies, when it became an oblong rectangle. The camp was surrounded by a fosse or trench, which was generally 9 feet deep and 12 broad. On the top of the rampart, which was of earth, there were stakes. The labor of constructing the rampart and the fosse was divided between the allies and the Roman legions, the former making the sides along which they were stationed, and the legions the rest. The task of superintending the construction of the camp amongst the Romans was intrusted to the Tribunes; amongst the allies, to the Prefects. Before the arrival of the troops, the different parts of the camp were so distinctly marked out and measured off that they at once proceeded to their respective stations, as if they had entered a well-known city and were marching to their quarters. The discipline of the camp was of the strictest kind. The Tribunes administered an oath against theft both to freemen and slaves, and two maniples were chosen to keep the *via principalis*, which was a place of general resort, clean and in good repair. The other occupations connected with the camp, too numerous to be mentioned here, were portioned out in like manner; and the superintendence of the whole was intrusted to two Tribunes chosen by lot from each legion, and appointed to serve for two months. The Prefects of the allies possessed a similar authority, which, however, seems to have been limited to their own troops. Every morning at daybreak the Centurions and horsemen presented themselves to the Tribunes, and these, in their turn, received their orders from the Consul. The watchword for the night, marked on a four-cornered piece of wood, was given out with much formality. The night was divided into four watches, each of three hours' length; and there was a curious arrangement for ascertaining that guard was kept with vigilance. The soldiers of the watch companies received from the Tribune a number of small tablets, with certain marks upon them, and these tablets were collected during the night by the horsemen whose duty it was to visit the posts, from such of the guards as they found on duty. Where these inspectors found the guards asleep or absent, they called upon the bystanders to witness the fact, and then passed on to the next. In the morning the inspectors appeared before the Tribunes, and gave up the tablets they had received, when the guards whose tablets were not produced were required to account for them. A regular scale of rewards and punishments was established in the camp. In comparing the encampments of the Romans with those of his own countrymen, Polybius tells us that the Greeks trusted mainly to a judicious selection of their ground, and regarded the natural advantages which they thus secured as supplying in a great measure the place of artificial means of defense. The Greeks, consequently, had no regular form of camp, and no fixed places were assigned to the different divisions of the army. When the practice of drawing up the army according to cohorts, introduced by Marius and Cæsar, was adopted, the internal arrangements of the camp experienced a corresponding change. Latterly even the square form was abandoned, and the camp was made to suit the nature of the ground. It was always held to be of importance, however, that the camp occupied a defensible position; that it could not be overlooked; and that it had a command of water. When stationary camps (*castra stativa*) came into more general use, we hear of several parts which are not mentioned by Polybius; for example, the infirmary (*valetudinarium*), the farriery (*veterinarium*), the forge (*fabrica*), etc.: and as a great variety of troops then came to be employed, they must, of course, have had new stations appointed to them in the camp. Many of the stationary camps ultimately became towns, and to this is ascribed the origin of most of the towns in England the names of which end in *cester* or *chester*. Among the most perfect of those which retained the form of the simple encampment is that at Ardoch in Strathearn, Perthshire, in the grass-covered mounds and ridges of which most of the divisions of the camp have been distinctly traced by antiquaries. It is believed that during the Middle Ages the plan adopted by the Romans in their camps was more or less adhered to, seeing that the weapons employed, which mainly determined the character of the troops, were nearly the same. In Britain, before the arrival of the Romans, and also during the Saxon and Danish periods, the camps, usually circular in form, appear to have been somewhat rude in character, with the cavalry grouped round the standard in the center, and the infantry placed near the front. The principles of castrametation, or camp-formation, underwent much change after the invention of gunpowder, owing to the necessity for defending the camp from artillery. See *Bivouac Cantonments, Castrametation Encampment*, and *Field-service*.

CAMPAIGN.—A connected series of military operations, forming a distinct stage or step in a war. Under the old system of warfare, when armies kept the field only during the summer months, a campaign was understood to include all that was done by an army from the time it took the field till it went again into winter-quarters. Now that winter is no longer allowed to arrest military operations, it is more difficult to say where one campaign ends and another begins. Some writers make a campaign include all the steps taken to accomplish some one immediate object.

CAMPAIGNER.—One who has served in an army through several campaigns; an old soldier or veteran.

CAMP AND GARRISON EQUIPAGE.—All the tents, fittings, utensils, etc., carried with an army, applicable to the domestic rather than to the warlike wants of the soldier. The allowance of camp and garrison equipage to United States troops is prescribed in General Orders from the War Department.

CAMP-BEDSTEAD.—A bedstead made to fold up within a narrow space, so as to be easily transported, and suitable for use in war. The drawing shows such an arrangement, which was patented by Mr. John Boyle, in France and the United States, not long since. It weighs complete about 9½ pounds, and when folded it occupies a space less than 7 inches square by 25 inches in length. After being properly set it is exceedingly strong and durable, and cannot be broken except by violent usage. It can be set anywhere and will remain stationary on a boarded



Boyle Camp-bedstead.

floor or a plowed field. To set it, spread the canvas out face-side down; open the four arms which have iron caps at the ends (the short ones), and insert the ends having the caps into sockets which are used in folding as hinges, the same being about twenty inches distant on each side from the head and foot respectively; put the thinner stick (the one with pins in the end—not screws) through the hem or tabline; insert the pins in the holes, severally, behind the legs at the foot; open the arms which give elevation to the head; run the heavy round stick (the same having a round-headed screw at each end) through the hem. Insert these pins or screws in the slots or grooves; last of all, open the legs, commencing with the center ones; turn the bedstead over right-side up, and it is then ready for using, without mattress, bed, or padding of any description.

CAMP-CHAIR.—A form of folding chair adapted to be carried by a pedestrian, or packed away in the ambulance or wagon when on the march. See *Camp-stool.*

Camp-chair.

CAMP-COLORS.—In the United States army, the camp-colors are the stars and stripes, as described for the garrison-flags, printed upon bunting, 18 by 20 inches, on a pole of ash, 8 feet long and 1¼ inch in diameter; the butt end of the pole is armed with a pointed iron ferrule, screwed on with four wooden screws. See *Colors.*

CAMPESTRE.—A kind of girdle or apron worn by the Roman soldiers around their waists at certain exercises where the rest of their bodies remained naked.

CAMP-FOLLOWERS.—The sutlers and dealers in small wares who follow an army. In India, owing to the peculiar habits and customs of the Hindus, and the large number of servants retained by English officers, the camp-followers are in immense number, comprising the servants, sutlers, cantiniers, hostlers, water-carriers, snake-charmers, dancers, conjurers, and women. In February, 1839, when a Bengal army of 15,000 men left Shikarpoor for Afghanistan, it was accompanied by no fewer than 85,000 camp-followers; the Commander took with him six weeks' food for the whole 100,000. All English Commanders in India find this regulation a very burdensome one. Even in the European armies, however, camp-followers are regarded as necessary; they are under the control of the Commanding Officer, and are subject to the Articles of War—not, however, in cantonments, only in the field. French armies are accompanied by women much more largely than English.

CAMP-GUARD.—A guard consisting of one or two rows of sentinels placed around a camp and relieved at regular intervals. The composition and posts of the camp-guard will depend upon the character of the ground and the degree of danger apprehended.

CAMPHENE.—The name applied to a variety of spirit of turpentine obtained from the *Pinus australis* of the Southern States of America, and rather extensively sold and used in Britain for burning in out-of-door lamps. It is very volatile, and burns very freely, giving off a pure white brilliant light; and when the vapor diffuses itself through air, and is set fire to, it forms a dangerous and violently explosive mixture.

CAMPHOR.—A solid essential oil which is found in many plants, and may be separated from many essential oils. It particularly abounds in certain species of the natural order *Lauraceæ.* Almost all the camphor of commerce is the produce of the camphor-laurel, (*Camphora officinarum,* formerly known as *Laurus camphora*), a native of China, Japan, Formosa, and Cochin-China, and which has been introduced into Java and the West Indies. The camphor-laurel is a tree of considerable height, much branched, with lanceolate, evergreen leaves on short stalks, and small yellowish-white flowers in axillary and terminal panicles. The fruit is in size and appearance not unlike an imperfectly ripened black currant. Every part of the tree, but especially the flower, smells strongly of camphor. The wood is light and durable, not liable to be injured by insects, and much valued for ordnance work. In the extraction of camphor from the camphor-laurel, the wood of the stem and branches

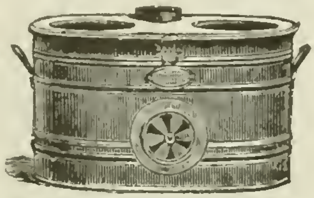
is chopped up into fragments, and introduced into a still with water and heat applied, when the steam generated carries off the camphor in vapor. These vapors rise, and in passing through rice-straw, with which the head of the still is filled, the camphor solidifies, and is deposited round the straw in minute grains or particles, somewhat about the size of raw sugar or coarse sand. These grains of impure camphor are detached, and being introduced into a large globular glass vessel in quantities of about 10 lbs., are reheated, when first the water rises in steam, and is allowed to escape at a small aperture; and thereafter, this aperture being closed, the camphor sublimes and resolidifies in the interior upper part of the flask as a semi-transparent cake, leaving all the impurities



Camp-stove.

behind. The flasks are then cooled and broken by throwing cold water on them, and the camphor taken out and sent into market. The glass globes employed are called by an Italian name, *bomboloes*, the sublimation of camphor having been first practiced in Venice. —Camphor was unknown to the Greeks and Romans, and was first brought to Europe by the Arabs. It is a white tough solid, slightly lighter than water, and floats thereon. It is very sparingly soluble in water, but freely soluble in alcohol, ether, acetic acid, and the essential oils. It fuses at 347°, and boils at 399 , and when set fire to is very inflammable, and burns with a white smoky flame. Thrown upon water, it floats, and may be set fire to when the currents generated alike from the solution in water and the irregular burning of the pieces cause a curious rotatory motion. It has a peculiar hot aromatic taste, and an agreeable characteristic odor. In consequence of its combustible powers it is much used in fire-works.

CAMPIDOCTORES.—Officers to whom was assigned the duty of drilling the Roman soldiery.

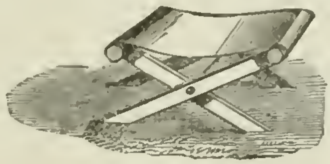
CAMP-KIT.—A box, with its contents, for containing soldiers' cooking and mess utensils, such as the camp-kettles, plates, etc.

CAMP-MILL.—A mill adapted for the use of an army, to grind grain on the march or in camp. It is carried on a wagon or running-gear, and is sometimes driven by the wheels in traveling, sometimes by a sweep operated by horses or men after the wheels are anchored or sunk in the ground. The first portable mill thus adapted to its own carriage appears to have been invented by Pompeo Targone, Engineer to the Marquis Ambrose Spinola, about the end of the sixteenth century.

CAMP OF INSTRUCTION.—An encampment of troops in the field to habituate them to the duties and fatigues of war. They may be either temporary or permanent. Of the latter description are the camps at Aldershott, England, and the Curragh of Kildare, Ireland.

CAMPOOS.—Regiments of Infantry in the service of the Mahratta Confederates.

CAMP-STOOL.—A chair whose frame folds up into a small compass for convenience of packing or carriage. Camp-stools were known in ancient Egypt, and were constructed in a manner similar to ours.



Camp-stool.

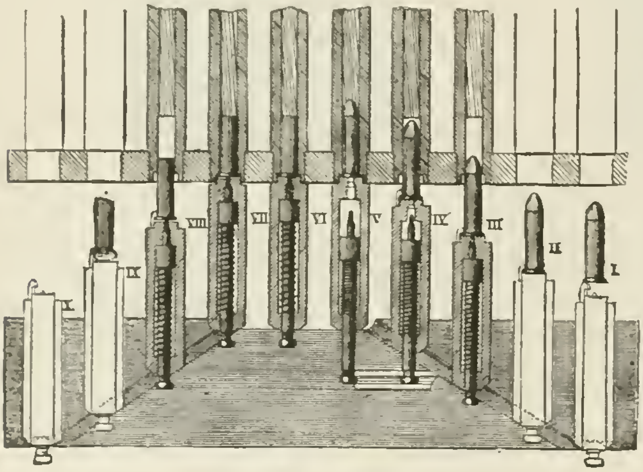
They frequently occur in the paintings, and some have been preserved until our time. One found at Sakkarah is in the Abbott Collection, New York. See *Camp-chair*.

CAMP-STOVE.—A light sheet-iron stove, specially arranged with a view to portability, and adapted for heating a tent or hut, and for cooking purposes. The drawing shows such a stove, capable of cooking for a mess of six or eight persons. When packed for transportation, all the apparatus is inside, and the total weight is 22 pounds. The ware is so constructed that it nests and packs in the oven, which has a capacity sufficient for roasting 20 pounds of beef. The oven packs inside the stove, and leaves sufficient room for packing the plates, knives, forks, spoons, and drinking-cups. This stove boils, bakes, or broils; and when fuel is scarce its excellence is very apparent, as it requires so little. In cold weather it may be placed inside the tent, where it is a great luxury and saves much trouble.

CAMPUS.—In ancient Rome, a vacant space in or near a city, for public combats, etc. There were eight around Rome, of which the Campus Martius (Camp of Mars) was the most important. It was outside the walls, occupying the level space between the Quirinal, Pincian, and Capitoline Hills. In this met the *comitia centuriata* and the *comitia tributa;* and in it was the Public Hall for the use of the Magistrates and Foreign Ambassadors, who were not permitted to enter the city. In later times it became a pleasure-ground, with shaded walks, gardens, baths, theaters, and a race-course. Julius Cæsar built within it the marble halls for the comitia; Agrippa, the baths and the Pantheon; Augustus, his own mausoleum; and Statilius Taurus, the first stone amphitheater. Later emperors crowded this particular campus with public buildings and private residences. Under Aurelian it was taken in as a part of the city. The district in which the old campus was situated is now called Campo Marzo. Another ancient campus was the Sceleratus, the Polluted Field, where vestals who had been untrue to their vows of chastity were buried alive. The drill-grounds around modern colleges often bear the name of *campus*.

CAM-RING.—A portion of the firing mechanism in certain machine-guns. In the Gatling gun, within the cylindrical breech-case attached to the frame, a heavy ring not quite the length of the lock-cylinder is fastened to the case and diaphragm, which nearly fills the space between the inside of the case and the cylinder. Portions of the inside of this ring are so cut away as to leave a truncated, wedge-shaped, annular or spiral *cam* projecting from the inner surface of the ring, having two helicoidal edges inclined to each other, and united by a short, flat plane. Against these edges the rear ends of the locks or breech-plugs continually bear, there being room enough for the locks to lie loosely within the parts of the ring which are cut away. The apex of the wedge-shaped cam points to the barrels. Each lock is held back against the cam by a lug or horn projecting laterally from the end of the lock and entering a groove formed at the base of the cam, in the thin part of the ring.

The drawing shows the *cam-ring* as it would appear if cut open and spread out flat, the lower lines being the development of the edges of the helicoidal cam-surfaces. The ten locks are shown in their relative positions abutting against the cam-surfaces, six of them being shown in section. It will be seen that the points of the firing-pins, or lock-hammers, protrude beyond the front of the locks, while the spindles project from the rear, where they are fashioned into knobs by which the hammers are drawn backward and cocked while passing through the groove in the *rib*. It will be observed that the distance of the apex of the cam from the ends of the barrels is such that the breech-plugs or locks exactly fill the space, so that each plug there forms an abutment which closes the breech of its barrel and abuts against the apex of the cam, which serves to resist the recoil of the plug when the charge is fired.



Cam-ring of Gatling Gun.

The locks are guided in grooves formed in the *lock-cylinder*, and therefore cannot deviate from their alignment with the barrels. The cartridges will, as the carrier-block channels come successively under the hopper, drop into the channels in front of the locks, and be kept in place by the hopper-plate. The revolution of the lock-cylinder carries the locks around with it, and causes them to receive a longitudinal reciprocal motion by their ends sliding along the inclined surfaces of the stationary cam. Each lock, then, one after the other, is pushed forward toward its barrel. As the revolution of the parts keeps the locks in contact with the advancing side of the cam, each lock in succession closes its barrel, and its longitudinal motion ceases, while it passes the flat surface of the cam, and then each slides backward from its barrel when constrained to move along the retreating side of the cam by the corresponding cam-groove; and so on, each lock repeating these movements at each successive revolution of the shaft. The position of the cam relatively to the cartridge-hopper is such that each lock is drawn backward to its full extent when it passes the hopper, so that the cartridges may fall into the carrier in front of the locks. The explosion of each cartridge takes place as its proper lock passes over the flat apex of the cam which resists the recoil. The hammer is cocked by the knob or head at its rear end coming into contact with a flat *rib* located inside of the cam. This rib restrains the hammer from moving forward, while the forward movement of the body of the lock continues; the spiral mainspring is compressed until the revolution carries the hammer-knob beyond the end of the cocking-rib, when the hammer will spring forward and strike with its point the center of the cartridge-head, and explode the charge. The point in the revolution at which the barrels are discharged is below and at one side of the axis. Each breech-plug or lock carries a hooked *extractor* which snaps over and engages the cartridge-flange when the plug is pushed forward, but which, when the plug retreats, withdraws and ejects the empty case. The drawing shows the ten locks, each in a different part of its cycle of action. At I the cartridge has just dropped in front of the lock; at II it has been pushed forward somewhat; at III the point of the cartridge has entered the barrel; at IV it is pushed nearly home, and the head of the hammer is retained by the cocking-rib, the mainspring being partly compressed. At V the lock has reached the flat part of the cam, the cartridge is pushed quite home, and the mainspring has been fully compressed by the retention of the hammer by the cocking-rib, the end of which is just reached by the hammer, which is about being released. At VI the hammer having been released has sprung forward and exploded the cartridge, the end of the lock or breech-plug being firmly braced against the flat surface of the cam. At VII the lock has commenced to retreat, and at VIII it has partially withdrawn the empty cartridge-shell from the barrel. At IX it has completely extracted the shell, which is falling away from the gun. At X the lock is fully drawn back, and is about to pass again into its first position. See *Gatling Gun*.

CANDITEER.—In fortification, a protection for miners, consisting of brushwood, etc.

CANDJIAR.—A kind of crooked Turkish saber Also written *Canjar*.

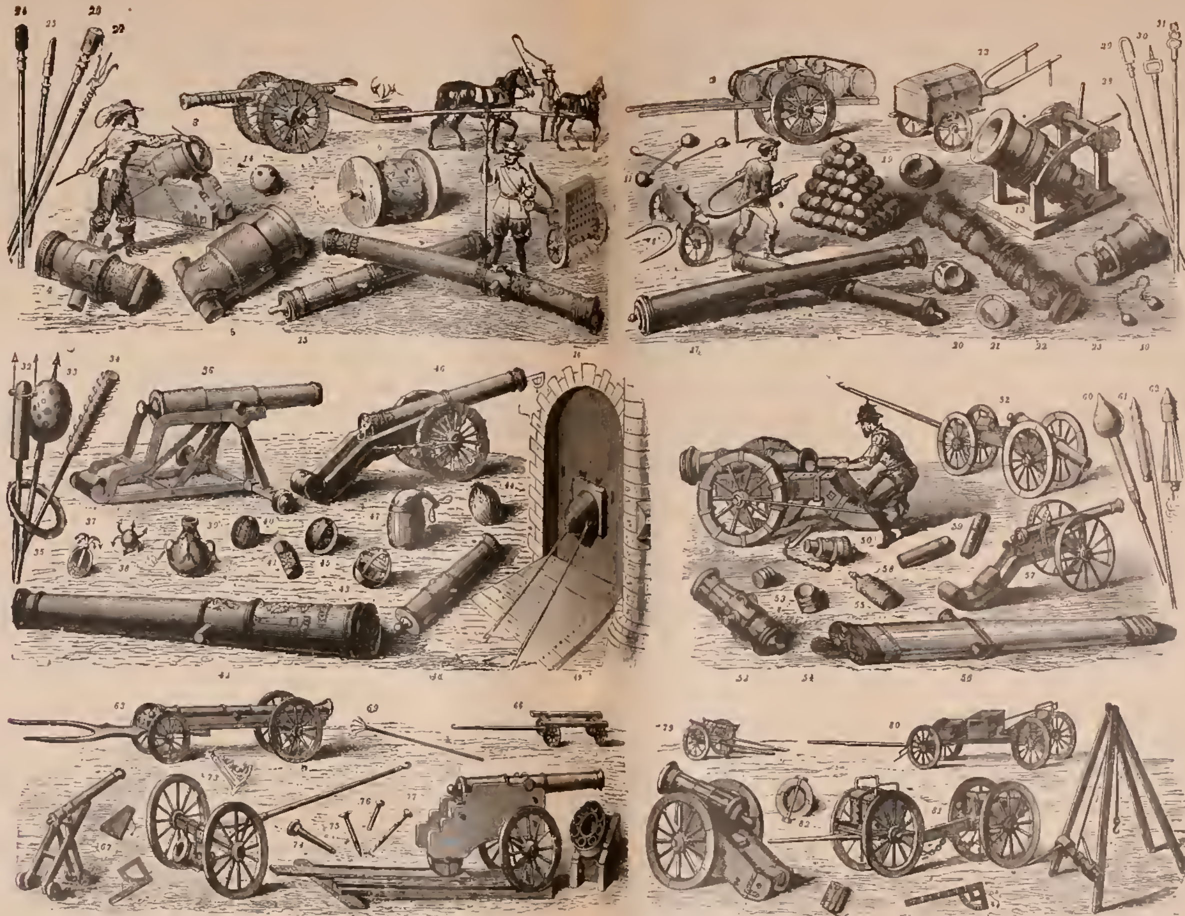
CANDLE-BOMBS. — Pasteboard shells filled with pyrotechnic compositions, which make a brilliant display on explosion. They are used for signaling, and are made up with a powder-charge attached to one side; a strand of quickmatch leads to the charge when placed in the mortar. The mortars used are very light, being simply hollow cylinders of stout paper, sole-leather, or wood. They are made thus light for ease of transportation.

CANDYS.—A loose gown, worn by the Medes and Persians over their other garments. It was made of woolen cloth, which was either purple or of some other brilliant color, and had wide sleeves. In the sculptures at Persepolis nearly all the personages are represented as so attired. A gown of a very similar kind is still worn by Arabians, Turks, and other Orientals.

CANE GUN.—A weapon comprising a gun-barrel with its discharging devices arranged within the shaft of a cane so as to present the appearance of an ordinary walking-stick. See *Air-gun*.

CAN-HOOK.—A device for slinging casks in hoisting. The ends of a piece of rope are reeved through the eyes of two flat hooks and stopped. The tackle is hooked to the middle of the bight.

CANISTER-SHOT.—A canister-shot is a metallic cylinder about one caliber in length, filled with balls and closed at both ends with wooden or metal disks. They are supplied for all guns. For 8-inch canister, and all those of less caliber, the envelope is made of tin, while canister for the larger calibers have an envelope of iron. The bottom of 15-inch canister is made of two thicknesses of 1-inch hard wood, crossing each other, and put together with



CANNON, etc. *Antique:* 1. French six-pound false culverin (1550). 2. French ammunition cart (1560). 3. French twenty-pound mortar. 4. German eighteen-pound mortar, called "Elephant" (1565). 5. German twenty-five-pound mortar (1800). 6. Storming keg (1680). 7. German fire-shield (1620). 8. German chariot of battle (1620). 9. Pile of balls. 10, 11. Chain and stem-shot. 12. Danish cartridge carriage (1720). 13. German twenty-pound mortar, with carriage. 14. Fire bomb. 15. German sectional field-piece (1680). 16. German twenty-pound culverin (1550). 17. French culverin (1550). 18. German falconet (1730). 19. Concentric bomb. 20. Excentric bomb. 21. Explosive fire-bomb. 22. Italian Bombarde (1500). 23. Italian mortar (1500). 24. Sponge. 25. Loading-shovel. 26. Rammer. 27. Fuse. 28. Spike. 29. Swipe. 30. Charge drawer. 31. Ball extractor. 32. Double-barbed spear. 33. Storming spear. 34. Storming club. 35. Storming wreath. 36. Danish iron gun-carriage for forts (1713). 37. Hot-shot, with anchor. 38. Anchor ball. 39. Fire-jug. 40. Fire-ball. 41. Gun-cartridge. 42. Forty-pound cannon of Charles V. 43. Fire-cross. 44. Fire-ball. 45. Explosive-ball. 46. German twelve pound field-piece. 47. Powder-barrel. 48. Prussian twelve-pound field-piece (1812). 49. Petard. 50. German breech-loader (1550). 51. French field-piece (1750). 52. Prussian ten-pound howitzer (1812). 53. Cartridge. 54. Wad. 55. Bag-cartridge. 56. German cannon, with oval lumen (1680). 57. Danish three-pound field-piece, with cast-iron carriage (1713). 58. Ball-cartridge. 59. Shot-cartridge. 60. Prussian petard rocket. 61. Rocket with side-staff. 62. Rocket without staff. 63. Gun-carriage, with heavy ordinance. 64. French mountain-piece (1680). 65. Drag. 66. Block-chassis. 67, 68, 73, 83. Quadrants. 69. Probe. 70. High-chassis, with twenty-four pound cannon. 71. French mortar, with side-chambers (1680). 72. Prussian twenty-five-pound howitzer. 74. Fuses. 75 to 77. Tin-fuses. 78. French brake (1808). 79. Trangree cart. 80. Field-forge. 81. English seven-pound howitzer (1800). 82. Wooden mold for fire-balls. 83. Derrick (1720).

wrought-iron nails clinched. A spindle, with a wrought-iron handle passing through the center of the canister, is riveted on the bottom through a square plate. All other canister have bottom-heads of one thickness of hard wood. Top-heads are all made of white pine. The case is notched, turned over the heads, and tacked down. The balls for all canister are 1.3 inch diameter, and the number used varies with the caliber. To give more solidity to the mass, and prevent the balls from crowding upon each other when the piece is fired, the interstices are closely packed with sawdust. See *Case-shot*, *Projectiles*, *Rifle-canister*, and *Siege and Garrison Ammunition*.

CANKER.—A disease of the foot of the horse, believed by Gerlach, of Berlin, to be truly cancerous, is observed in two different forms: in the acute stage, when the malady is chiefly local; and in the chronic stage, when the constitution suffers, and all local remedies fail to restore a healthy function of the structures of the foot.

Symptoms.—It usually commences by discharge from the heels, or the cleft of the frog of the horse's foot. The horn becomes soft and disintegrated, the vascular structures beneath become inflamed, and the pain which the animal endures is intolerable. It is therefore very lame on one, two, or all feet, according to the number affected. Though there is no constitutional fever, the horse becomes emaciated and unfit for work. During wet weather, and on damp soil, the symptoms increase in severity. The sore structures bleed on the least touch, and considerable fungoid granulations, commonly called *proud flesh*, form rapidly.

Causes.—This disease is occasionally hereditary, and it is most frequently seen in low-bred draught- or coach-horses. Dirt, cold, and wet favor the production of the disease, and there is always a tendency to relapse when once an animal has been affected.

Treatment.—Pare away detached portions of horn, and, in mild cases, sprinkle powdered acetate of copper over the sore; apply over this pledgets of tow, fixed over the foot by strips of iron or wood passed between shoe and foot. In severe cases tar and nitric acid, creosote and turpentine, chloride-of-zinc paste, and other active caustics have to be used for a time with the regular employment of pressure on the diseased surface. The animal requires to be treated constitutionally by periodical purgatives and alteratives. Good food, fresh air, and exercise often aid much in the treatment of the disease.

CANNELURE.—A cut in the lead round the projectile near the base in order to receive a lubricant or any lead that may be drawn down during the passage of the projectile through the bore.

CANNON.—A general name for large pieces of ordnance or artillery, as distinguished from those pieces which can be held in the hand while being fired. No military weapon in use before the invention of gunpowder can fairly come under this designation; they were more generally of the kinds described under BALISTA. At what exact date cannon were first used is not known; but cannon, called "crakys of war," were employed by Edward III. against the Scots in 1327, by the French at the siege of Puy Guillaume in 1338, and by Edward III. at Crecy, and at Calais in 1346. The first cannon or *bombards* were clumsy, wider at the mouth than at the chamber, and made of iron bars hooped together with iron rings. The balls fired from them were first made of stone, afterwards superseded by iron. In the fifteenth century various kinds were known by the names of cannon, bombards, culverins, serpentines, etc. Bombards of great length and power were employed by Louis XI. during his Flemish campaign in 1477, some with stone balls, some with iron. About this time cannon began to be made by casting instead of with hooped bars; and bronze or brass as a material began to be used as well as iron. The cannon of the sixteenth century were generally smaller, but better finished, than those of the fifteenth. The largest cannon made in the seventeenth century, so far as is known, was the Bejapoor cast-iron gun, "Malick é Meidan," or "Lord of the Plain," made either by Aurungzebe or by the Mahrattas; it was 14 feet long, 28 inches bore, and required a ball of 1600 lbs. weight. From the time of the great European wars in that century, cannon have undergone vast improvements, as well as the science and art of artillery necessary for their management.

Cast-iron cannon may generally be divided into five principal parts, viz., *Breech*, *Cylinder*, *Curve*, *Chase*, and *Muzzle*. The *Breech* is the mass of solid metal in rear of the bottom of the bore: the thickness is usually somewhat greater than the greatest thickness of metal in the cylinder. The *Cylinder* is that portion between the base-ring and trunnions, including the seat of charge and the point where the greatest strain is exerted upon the gun. The *Curve* is the portion connecting the cylinder with the chase. It is made somewhat thicker than necessary to resist the pressure of the powder, in order to serve as a proper point of support for the trunnions, and to compensate for certain defects of metal liable to occur in the vicinity of the trunnions of all cast cannon, arising from the crystalline arrangement and unequal cooling of the different parts. The *Chase* is the long, tapering portion of the gun extending from the curve to the muzzle. The principal injury to which the chase is liable in smooth-bore guns arises from the striking or balloting of the projectile against the side of the bore; and the thickness of metal should be sufficient to resist it. The *Muzzle* is the increased thickness of metal which terminates the chase. Inasmuch as the metal situated immediately at the muzzle is supported

only in rear, it has been usually considered necessary to increase its thickness to enable it to resist the action of the projectile at this point; but in the larger guns the *swell of the muzzle* has been omitted. The swell strengthens a part liable to be impaired by an enemy's fire, and affords, also, a good position for a notch or sight.

The *Trunnions*, Fig. 1, are two cylindrical arms attached to the sides of a cannon, for the purpose of supporting it on its carriage. They are placed on opposite sides of the piece, with their axes in the same line and at right angles to its axis. The size of the trunnions depends on the recoil of the piece and the material of which they are made. The resistance which a cylinder opposes to rupture is proportional to the cube of its diameter; on the supposition that the strain is proportional to the weight of the charge, it is usual to make the diameter of the trunnions equal to the diameter of the bore. The position of the trunnions, with reference to the axis of the bore, influences the amount of recoil and the endurance of the carriage. By reference to Fig. 2 it will be seen that if the axis of the trunnions be placed below the

FIG. 2.

axis of the piece, the resultant of the force of the charge, which acts against the bottom of the bore, will act to turn the piece around its trunnion, and cause the breech to press upon the head of the elevating-screw with a force proportioned to the length of the lever-arm, or distance between the axes. The effect will be to throw an additional strain on the carriage by pressing down the rear part of it, and checking the recoil. If the trunnions be placed above the axis of the piece, rotation will take place in the opposite direction, and the effect of the discharge upon the carriage and recoil will be reversed. By placing the two axes in the same plane, the force of the charge will be communicated directly to the trunnions, without increasing or diminishing its effect on the carriage or recoil; this position is given to them in all guns in the United States service. The unequal distribution of the weight of a cannon, with reference to the axis of the trunnions, is called the preponderance. It is the pressure which the breech portion of the gun, when horizontal, exerts on the elevating arrangement. To ascertain the preponderance practically, support the gun at the trunnions as freely as possible, and bring it horizontal by means of a long handspike in the bore. Place a platform-scale under the breech, and fix a block of wood on it, touching the gun underneath at the elevating-point. The handspike being then removed from the bore, the pressure on the block is indicated on the arm of the scale, and is the preponderance of the gun.

In larger guns destined to throw heavy elongated projectiles, where the weight of the charge increases rapidly in comparison with the caliber, the chamber is of the size of the bore, and lately useful results have been obtained by making the chamber of greater diameter than the bore. The necessity for a small chamber being assumed, and its capacity decided upon, the determination of its proper form will be governed by several conditions. 1st. The chamber must be deep enough to receive a cartridge manageable in length. 2d. As the chamber adds materially to the length of the bore, it must evidently be no deeper than the service of the gun renders necessary. 3d. It should contain no angles, on account of the well-known tendency of a split to begin at an angle; hence the bore should terminate in a curve, the hemisphere, semi-ellipsoid, paraboloid, and ogival being those most frequently used. The shape of the chamber generally in use for S. B. guns is conical. The particular kind of chamber represented in the drawing is called a *Gomer Chamber*, after its inventor. Its principal advantages are, distributing the force of the charge over a large portion of the surface of the projectile, thereby rendering it less liable to break if it be hollow, and reducing the windage when the projectile is driven down to its proper place.

The *Vent* is the channel passing through the metal, from the exterior of the breech into the bore, by means of which fire is communicated to the charge. The size of the vent should be as small as possible, in order to diminish the escape of gas and the erosion of the metal, which results from it. In naval ordnance vents are constructed two tenths of an inch in diameter. In bronze pieces the heat of the inflamed gases would be sufficient to melt the tin and rapidly enlarge its diameter. For this reason they are *bouched* by screwing in a perforated piece of pure wrought-copper, called the *vent-piece*. This arrangement allows the vent to be renewed when too much enlarged by continued use. Copper vent-pieces are especially necessary in rifle-guns, in consequence of the prolonged action of the gas arising from the resistance of the projectile. In the largest caliber the interior orifice is lined with *platinum*. The upper portion of the copper is replaced by steel to obtain a harder surface for receiving the blow of the hammer. Some guns have two unbouched vents, situated on opposite sides of the axis of the bore, and inclined at an angle of 70 degrees with that axis. The one on the right side is bored entirely through; the other is simply initiated to give it direction. When the open vent is too much enlarged by wear for further use it is closed with melted zinc, and the other is bored out. Each vent should endure about five hundred service-rounds. In smooth-bore cast guns the vent enters the bore very near the bottom; the vents of heavy built-up guns are usually bored vertically, and in such a position as to strike the cartridge at about four tenths of its length from the bottom of the bore, it having been ascertained by experiment that the ignition of the charge at about this point realizes the greatest projectile force that can be produced by a given charge: but in some of the heaviest rifled guns and in most breech-loading guns the vent is bored in the line of the axis through the breech, and is termed an *axial vent*. Experiment shows that the actual loss of force by the escape of gas through the vent, as compared to that of the entire charge, is inconsiderable, and it may be neglected in practice.

In designing a gun, it is necessary in the first place to endeavor to determine what thickness of metal is required for that part of the gun surrounding the seat of the charge, for it is here where the greatest strain from the explosion of the charge is exerted. No precise rules can be laid down for the regulation of this thickness in various kinds of ordnance, as so much depends upon the physical properties of the material used. The general results of experience, or of experiments carried on for the purpose of establishing this point, can alone furnish us with the requisite data. The amount of metal in a gun must depend upon the charge, the weight and form of the projectile, the material employed, and the method of construction. When a charge of gunpowder is ignited in the bore of a gun, the gas exerts equal pressures in all directions, and therefore, neglecting windage, the pressure in the bottom of the bore is equal to that on the base of the projectile, and the pressures on the top and bottom as well as those on the sides of the bore balance each other. The metal of a gun is subjected to two principal strains: one a *transverse* or *tangential*, which tends to rend the metal lengthwise, or from end to end; and the other a *longitudinal*, tending to fracture the gun across, or to drive out the breech. As the projectile moves towards the muzzle, so will the space in which the gas is confined be increased, and the pressure be decreased; the portion of metal surrounding the space originally occupied by the cartridge, and a little in front of it, is that upon which the *maximum pressure* from the gas is exerted. The maximum pressure will be influenced by the nature of the powder, the resistance offered by the projectile to motion, and by the absence or amount of windage.

Many experiments have been made to determine the gradual decrease of strain upon the metal of a piece of ordnance, from breech to muzzle. The first were accomplished by perforating a gun in several places from the exterior to the bore, at right angles with the bore, and successively screwing a pistol-barrel containing a steel ball into each perforation, and discharging the gun with the pistol-barrel at the different perforations: the relative velocities with which the pistol-ball (received by a pendulum) is forced out at these different positions indicate the force exerted there to burst the gun, and consequently the relative strength of metal necessary in the various parts to resist explosion. The following formula, which is used for calculating the exterior form of cannon of large caliber for the land service, was deduced by Captain Rodman from a series of original experiments on the strength of hollow cylinders, etc.:

$$C = \frac{2pr\sqrt{l}}{S} \times \frac{R\sqrt{L}}{\left((R-r)(2rL+R)(R+r)(R-r)\frac{l^5}{L^5}\right)},$$

in which C is a constant quantity, $r =$ interior radius and $R =$ exterior radius, $p =$ pressure of gas, $l =$ length of bore pressed required to fully develop transverse resistance, $L =$ length of bore corresponding to assumed values of R, $S =$ tensile strength of metal, and $l' =$ length of bore subjected to maximum pressure. The pressure of the gas is supposed to vary inversely as the square root of the length of the bore behind the projectile. The exterior forms thus obtained are entirely made up of curved lines.

For many years cast-iron cannon have been made in Sweden of a form nearly approaching that called for by the actual pressure of the powder at different points of the bore (Fig. 3). In the construction of bronze guns, the thickness of the metal at the neck,

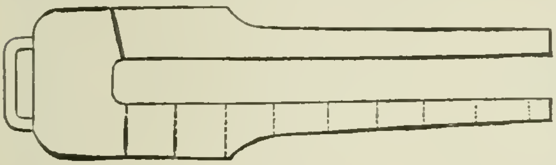

FIG. 3.

or thinnest part, is about equal to $\frac{5}{11}$ of that at the first reinforce, or $\frac{5}{11}E$, given in the empirical formula $E = D\sqrt{\frac{C}{\frac{1}{2}P}}$, in which D represents the diameter of a solid cast-iron shot suited to the bore, C the proof-charge, and P the real weight of the projectile.

The weight of a cannon is determined by the weight of the projectile, the maximum velocity it may be necessary to communicate to it, and the extent of the recoil. The extent of the recoil being limited by the conditions of the service, the weight of the piece may be deduced from the principle that action and reaction are equal and opposite; or that the quantity of motion expended on the inertia of the piece and carriage, and friction, is equal to that expended on the projectile, and the air set in motion by the charge. Let w be the weight of the projectile; v, its maximum velocity; c, the weight of the charge of powder; N, a constant linear quantity, representing the velocity communicated to the piece by a unit of weight of the charge, arising from its action on the air, independent of the projectile (for American powder this has been found by experiment with the gun and ballistic pendulums to be equal to 1600 feet); f, the velocity lost by a unit of mass, from the friction of the carriage on ordinary ground; W, the weight of the piece; V, velocity of recoil; C, the weight of the carriage; R, the pressure of the trail on the ground, arising from the recoil; and g, the force of gravity. From the principle before enunciated, we have

$$\frac{w}{g}v + \frac{c}{g}N = \frac{(W+C)}{g}V + \frac{(W+C+R)}{g}f;$$

or, by reduction,

$$W = \frac{wv + cN - CV - Cf - Rf}{V+f}.$$

For field-guns the velocity of the recoil should not exceed 12 feet. See *Exterior Form of Cannon*, *Firing*, *Injuries to Cannon*, *Ordnance*, and *Pointing*.

CANNONADE.—The act of discharging shot or shells from cannon for the purpose of destroying an army, or battering a town, ship, or fort; usually applied to an attack of some continuance. Also written *Cannonry*.

CANNON-BALL — CANNON-BULLET. — Properly speaking, this term should only be applied to spherical solid projectiles; but it appears to have become generic, extending to elongated bullets for rifled guns, and even to hollow projectiles. Technically, balls are termed "solid shot," or simply "shot," to distinguish them from hollow projectiles. They are now universally made of cast-iron, though stone was formerly employed, and was used in some instances by the Turks as late as 1827. In South America balls of copper were formerly used, this metal being there, at that period, cheaper than iron. Elongated bullets for rifled cannon are now frequently, especially by English writers, termed "bolts." These are often made flat-pointed or angularly pointed, to more readily penetrate iron plating. See *Projectiles*.

CANNON-BASKETS.—The old English phrase for gabions. Not used at present.

CANNON-CLOCK.—A cannon with a burning-glass over the vent, so as to fire the priming when the sun reaches the meridian. Such pieces were placed in the Palais Royal and in the Luxembourg, at Paris.

CANNONEER—CANNONIER—CANONNIER. — An artillery-man or gunner. In 1671, during the administration of Louvois in France, the name of *Canonniers* was given to the first company of the regiment of the king's fusileers; in April, 1693, this regiment was named *Artillerie Royal*, but the first company retained the name of *Canonniers*.

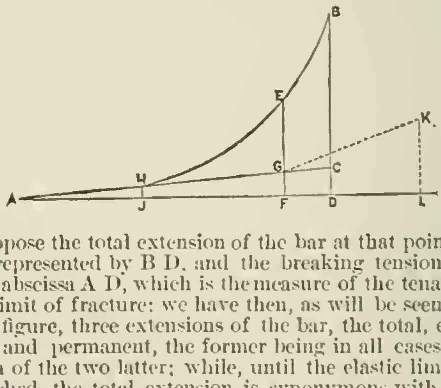
CANNON-FOUNDING.—Since Sir William Armstrong succeeded, by a process first brought under the notice of the British Government in 1854, in making of malleable iron a field-gun of far greater efficiency than any previously in use, cannon-founding has in most European countries gradually ceased. This manufacture, which was formerly an important one, is, however, still carried on in the United States, Sweden, and Russia, all three of which countries produce cast-iron of a very superior quality. Cannon are cast in molds of loam or sand prepared with the help of a pattern. They are usually cast vertically, with an extra mass of metal poured in at the top end of each mold to secure by its pressure greater solidity in its walls, as is often done in the case of a hydraulic cylinder. This superfluous portion is, of course, afterwards removed. Cannon are, or at least were, often cast solid with the same object, and afterwards bored, although it is by no means certain that such are generally sounder or of closer texture than those which are cast hollow. In either case the inner surface of the cannon is accurately finished with a boring-tool to the required caliber, and the outer surface turned. Brass, or rather bronze, cannon were usually cast in loam by means of a clay model on which were often stuck ornamental figures in wax, these being melted out of the mold before casting. In the United States, cast-iron guns are made by Rodman's process; that is, they are cast hollow on a core-barrel which is filled with water.

This is applied so as to cool the metal of the gun in layers, thus modifying the initial strain upon it, and producing the best result that can be obtained from cast-iron for ordnance purposes. Within the last few years guns as large in the bore as 20 inches have been cast by this method at Pittsburg, and one of the same size has been made by it in Russia. The latter weighs 44 tons, throws a spherical ball of 9 cwt., and took 3½ months to finish. Its cost was not more than one fourth that of a built-up gun of steel for the same weight of projectile. Many of the earlier pieces of ordnance, it is curious to observe, were made of hooped bars, in which one can trace the germ of the process by which the Armstrong gun is made. Indeed, it is doubtful if any modern plan of constructing large guns was not tried in olden times, as is seen by an examination of the different kinds of old cannon still preserved. These, however, had to be constructed without the aid of the steam-hammer and other appliances, which render such work comparatively easy nowadays, and were accordingly deficient in strength. The earlier wrought-iron cannon were eventually superseded by those made of cast-iron and bronze, but not entirely for some considerable time after the latter had been in use. The mortar, which was introduced about the commencement of the fourteenth century, appears to have been not only the most ancient form of cannon, but the first European fire-arm as well. From the beginning of the fifteenth century, cannon were cast in bronze, and some of great size are stated to have been used at the siege of Constantinople in 1463. Probably hand-cannon of cast-iron date as far back as bronze guns, and at any rate we know that large and excellent cannon were made of cast-iron in the early part of the sixteenth century, they having been used at Flodden, and England having even then acquired a reputation for this kind of ordnance. Cannon-founding has therefore been practiced for nearly 500 years; and although the art is now to all appearance doomed to decay, no one can predict, in these days of metallurgical wonders, what further change improvements in the manufacture of iron and steel may bring about as respects the making of large fire-arms. In order that the cast guns made on the old system may still be available for some purposes in modern warfare, Colonel Hay Campbell, some years ago, proposed a plan for lining bronze, and Major Palliser another for lining cast-iron cannon with a tube of wrought-iron. Some have been transformed on the Palliser system, which consists in boring a certain thickness off the old gun and forcing a coiled wrought-iron barrel into the interior, and are said to have given very remarkable results as regards endurance. Certain peculiarities in the manufacture of special kinds of ordnance are noticed in the articles relating to them. See *Ordnance*.

CANNON-LOCK.—A contrivance, like the lock of a gun, placed over the vent of a cannon to explode the charge.

CANNON-METALS.—The qualities of metals with which we are more particularly concerned in the construction of ordnance are the physical properties of malleability, ductility, hardness or softness, toughness, elasticity, and tensile strength, while we must also understand what is meant by tenacity and elastic limit as applied to metals. *Malleability* is the property of being permanently extended in all directions without rupture by pressure (as in rolling) or by impact (as in hammering). It is opposed to *brittleness*, which is the tendency to break more or less readily under compression either gradual or sudden. *Ductility* is the property of permanently extending or drawing out, by traction, as in wire-drawing. A metal is said to be *soft* when it yields easily to compression without breaking, and does not return to its original form on the removal of the compressing stress. These terms are, of course, only comparative; thus we have hard leads and soft leads, while any sort of lead whatever is soft as compared with wrought-iron, which latter again is called soft when we compare it with cast-iron. Steel is called *soft* or *low* when the proportion of carbon contained in it is small, and *hard* or *high* when the contrary is the case, because when treated in a similar manner one variety is much harder than the other. It should, however, be remembered that a tolerably soft steel may be made very hard by tempering. It is easy to understand what *toughness* means, but not so easy to define exactly what it is. Dr. Young gives the following explanation of the term as applied to steel: "Steel, whether perfectly hard or of the softest temper, resists flexure with equal force when the deviations from the natural state are small, but at a certain point the steel, if soft, begins to undergo an alteration of form; at another point it breaks if much hardened, but when the hardness is moderate it is capable of a much greater curvature without permanent alteration or fracture, and this quality, which is valuable for the purposes of springs [and also for gun-barrels], is called toughness, and is opposed to rigidity and brittleness on the one side and to ductility on the other." *Elasticity* is the property possessed by a metal of resisting permanent deformation when subjected to a stress, and is measured by the ratio of stress to strain, so that the modulus of elasticity is equal to the cotangent of the angle H A J, in the following figure. The *elastic limit* of a metal is the tension which causes permanent elongation, and in the figure is represented by the abscissa A J. *Tenacity* is the tension required to produce rupture, and is represented by the abscissa A D. *Tensile strength* we shall employ to denote the work done upon the metal to produce rupture by traction. It would be measured in the figure by the area A B D.

In order to understand these several terms more clearly, let us take the figure below, in which the abscissæ represent the tensions, and the ordinates the extensions, of a bar of metal (experimentally determined) corresponding to the tensions. If the bar be subject to a constantly-increasing tension, the extension is at first in a constant ratio to the tension, increasing after a certain point in a varying ratio. This point, represented in the diagram by the extension, H J, and measured by the tension represented by the abscissa A J, is termed the elastic limit. After this point is reached, the extensions increase in a higher ratio for every increment of tension, and the line joining the ordinates becomes a curved line, as shown by H B in the figure. As we continue to increase the tension, we arrive at a point where the bar will fracture.



Suppose the total extension of the bar at that point to be represented by B D, and the breaking tension by the abscissa A D, which is the measure of the tenacity or limit of fracture; we have then, as will be seen by the figure, three extensions of the bar, the total, elastic, and permanent, the former being in all cases the sum of the two latter; while, until the elastic limit is reached, the total extension is synonymous with the elastic extension. The ordinates of the curve (a straight line as far as H) A B represent the total extensions, and the ordinates of the straight line A C the elastic extensions of the bar, while the work required to produce rupture is measured by the area A B D, which thus measures the tensile strength.

Similarly, the work necessary to produce a total extension, E F, is measured by the area A F E. If we move the tension represented by A F, after the bar has been extended by E F, the greatest extension of the bar will not exceed F G; then reimpose it and once more remove the tension, the bar will revert to its former length. Here, of the total work done on the bar represented by the area A F E, that portion corresponding to the area H E G has been absorbed by it and applied to the rearrangement of its molecules, being the measure of the loss sustained in the tensile strength of the bar. Its tenacity may, however, be increased, and we see that its elastic limit is so, for any ductile metal increases (within certain limits) in elastic limit and ultimate strength (as represented by the tenacity), though not in absolute or tensile strength (as shown by the total work required to produce rupture), when subjected to drawing, hammering, or rolling. In fact, a material strained beyond its elastic limit will exhibit the same characteristics as an originally harder metal. To return, however, to the case in the figure. Suppose we now subject the bar, which has been elongated by the permanent extension E G, to a greater tension, then the total extensions may be represented by the same line G K, and we see that the breaking tension, shown by A L, is greater than before. The total work to produce rupture will now be represented by the area A K L, which, however, can never exceed the mechanical work represented by A B D, or, what is the same thing, F G K L cannot exceed B D F E, so that the absolute or tensile strength of the metal is not increased by permanent extension beyond its original elastic limit, although its tenacity and elasticity may be increased by the operation.
